CHAPTER 1 Your Workbench and a Number-Guessing AI **1**
1.1 Why Start with a Guessing Game? 1
1.2 What "AI" Means in This Book 2
1.3 Setting up VS Code and Python on Windows, macOS and Linux 2
1.3.1 Windows 10 and 11 3
1.3.2 macOS 3
1.3.3 Linux 3
1.3.4 Visual Studio Code and the Python extension 4
1.3.5 A project folder and a virtual environment 5
1.3.6 pip and requirements.txt 6
1.3.7 Checking the workbench 7
1.3.8 Jupyter notebooks (optional) 8
1.4 The Idea: Halve What Is Still Possible 8
1.5 The Math, Gently 9
1.6 Building the Guessing AI Step by Step 11
1.7 Running It 13
1.8 Measuring Three Strategies 14
1.9 Testing It Automatically 16
1.10 Improving It 18
1.11 Common Mistakes, and How to Avoid Them 18
1.12 Chapter Summary 19
1.13 Exercises 19
1.14 Solutions to the Exercises 20
References 21

CHAPTER 2 A Smart Expense Categorizer for Bank and E-Wallet Statements **22**
2.1 Where Does the Money Go? 22
2.2 The Idea in Plain Words 23
2.3 The Math, Gently 23
2.3.1 From a description to words 23
2.3.2 Naive Bayes 24
2.3.3 Knowing when to ask 25
2.3.4 Measuring the categorizer 25
2.3.5 Forecasting the month 26
2.4 The Algorithm as Pseudocode 26
2.5 Building It Step by Step 26
2.5.1 The data 27
2.5.2 Importing statements 28
2.5.3 Keyword rules 29
2.5.4 The learned model 29
2.5.5 Summary and budget alerts 30
2.5.6 The application 31
2.6 Running It 33

2.7 Measuring It 35
2.8 Testing It 38
2.9 Improving It 40
2.10 Using It for Real 40
2.11 Common Mistakes, and How to Avoid Them 41
2.12 Chapter Summary 41
2.13 Exercises 42
2.14 Solutions to the Exercises 42
References 43

CHAPTER 3 A Warehouse Picking-Route Optimizer: BFS, DFS and A* 44
3.1 Every Step Costs Money 44
3.2 The Idea in Plain Words 45
3.3 The Math, Gently 45
3.3.1 Squares, steps and distances 45
3.3.2 Breadth-first search 45
3.3.3 Depth-first search 46
3.3.4 A* and the Manhattan distance 46
3.3.5 The length of a route 47
3.3.6 Nearest neighbor and 2-opt 47
3.3.7 Batching 47
3.4 The Algorithms as Pseudocode 48
3.5 Building It Step by Step 48
3.5.1 The data 48
3.5.2 The grid and the three searches 49
3.5.3 Routes and batches 53
3.5.4 The application 55
3.6 Running It 57
3.7 Measuring It 58
3.8 Testing It 62
3.9 Improving It 64
3.10 Using It for Real 64
3.11 Common Mistakes, and How to Avoid Them 65
3.12 Chapter Summary 65
3.13 Exercises 66
3.14 Solutions to the Exercises 66
References 68

CHAPTER 4 A Meal Planner on a Budget and a Nutrition Target 69
4.1 Good Food on a Small Budget 69
4.2 The Idea in Plain Words 69
4.3 The Math, Gently 70
4.3.1 The cost of what we can eat 70
4.3.2 The linear program 70
4.3.3 A small linear program by hand 71
4.3.4 The greedy rule 72
4.3.5 Shadow prices 72
4.3.6 When the budget is too small 72
4.3.7 Whole portions 73
4.4 The Algorithm as Pseudocode 73
4.5 Building It Step by Step 73
4.5.1 The data: TKPI nutrients and market prices 73
4.5.2 The model 74
4.5.3 The application 78
4.6 Running It 79

4.7 Measuring It 82
4.8 Testing It 83
4.9 Improving It 85
4.10 Using It for Real 85
4.11 Common Mistakes, and How to Avoid Them 86
4.12 Chapter Summary 86
4.13 Exercises 86
4.14 Solutions to the Exercises 87
References 88

CHAPTER 5 A Timetable Scheduler for a School or a Clinic: Constraint Satisfaction 89
5.1 The Week Nobody Wants to Plan 89
5.2 The Idea in Plain Words 89
5.3 The Math, Gently 90
5.3.1 The timetable as a CSP 90
5.3.2 How big is the search space? 91
5.3.3 Backtracking, MRV and forward checking 91
5.3.4 A small example by hand 91
5.3.5 Soft constraints and local search 92
5.4 The Algorithms as Pseudocode 92
5.5 Building It Step by Step 93
5.5.1 The data 93
5.5.2 The CSP and the search 94
5.5.3 Soft constraints and local search 97
5.5.4 The application 99
5.6 Running It 100
5.7 Measuring It 101
5.8 Testing It 102
5.9 Improving It 104
5.10 Using It for Real 104
5.11 Common Mistakes, and How to Avoid Them 105
5.12 Chapter Summary 105
5.13 Exercises 105
5.14 Solutions to the Exercises 106
References 107

CHAPTER 6 A Customer-Service Chatbot for a Small Business: Intents, Rules and a Human in the Loop 108
6.1 Answering the Same Question for the Hundredth Time 108
6.2 The Idea in Plain Words 109
6.3 The Math, Gently 109
6.3.1 From text to numbers: character n-grams 109
6.3.2 TF-IDF weights 110
6.3.3 Logistic regression: from scores to probabilities 110
6.3.4 Rules first, then the classifier, then a person 110
6.3.5 Which language? 111
6.3.6 What to count 111
6.4 The Algorithm as Pseudocode 111
6.5 Building It Step by Step 112
6.5.1 The data 112
6.5.2 Understanding a message 112
6.5.3 The dialog 115
6.5.4 The application 119
6.6 Running It 120
6.7 Measuring It 121

6.8 Testing It 123
6.9 Improving It 125
6.10 Using It for Real 125
6.11 Common Mistakes, and How to Avoid Them 126
6.12 Chapter Summary 126
6.13 Exercises 126
6.14 Solutions to the Exercises 127
References 128

CHAPTER 7 A Rule-Based Expert System: The Laundry-Stain Advisor 129
7.1 Knowledge Behind the Counter 129
7.2 The Idea in Plain Words 130
7.3 The Math, Gently 131
7.3.1 Rules and certainty factors 131
7.3.2 A worked example 132
7.3.3 Forward and backward chaining compared 132
7.3.4 Forward chaining by hand 133
7.3.5 Certainty factors are not probabilities 133
7.4 The Algorithm as Pseudocode 133
7.5 Building the Advisor Step by Step 134
7.5.1 The knowledge base 134
7.5.2 The inference engine 137
7.5.3 The consultation 140
7.6 Running It 141
7.7 Evaluating the Knowledge Base 143
7.8 Testing It 145
7.9 Improving It 146
7.10 Common Mistakes, and How to Avoid Them 146
7.11 Chapter Summary 147
7.12 Exercises 147
7.13 Solutions to the Exercises 148
References 149

CHAPTER 8 A Route Planner for Surabaya: Dijkstra and A* on a City Graph 150
8.1 Every Delivery Is a Search Problem 150
8.2 The Idea in Plain Words 151
8.3 The Math, Gently 152
8.3.1 Distances on the Earth 152
8.3.2 Road lengths and travel times 152
8.3.3 Relaxation and Dijkstra's algorithm 152
8.3.4 A* with a straight-line heuristic 153
8.3.5 Why the heuristic never overestimates, and why rounding matters 154
8.3.6 How much work does it take? 154
8.3.7 Relaxation by hand 154
8.4 The Algorithm as Pseudocode 155
8.5 Building the Planner Step by Step 155
8.5.1 The map as data 155
8.5.2 The graph 157
8.5.3 Dijkstra and A* 158
8.5.4 The application 159
8.6 Running It 160
8.7 Testing It 163
8.8 Improving It 164
8.9 Common Mistakes, and How to Avoid Them 165
8.10 Chapter Summary 165

8.11 Exercises ... 166
8.12 Solutions to the Exercises ... 166
References ... 167

CHAPTER 9 A Genetic Algorithm Scheduler ... 168
9.1 A Busy Saturday at Rungkut ... 168
9.2 The Idea in Plain Words ... 168
9.3 The Math, Gently ... 169
9.3.1 From an order to a schedule ... 169
9.3.2 Weighted tardiness ... 169
9.3.3 How many orders are there? ... 170
9.3.4 Selection pressure ... 170
9.3.5 The cost of the search ... 170
9.3.6 Why does crossover help? ... 170
9.4 The Algorithm as Pseudocode ... 171
9.5 Building the Scheduler Step by Step ... 172
9.5.1 The jobs ... 172
9.5.2 Decoding and cost ... 173
9.5.3 The genetic algorithm ... 174
9.5.4 The application ... 175
9.6 Running It ... 176
9.7 Testing It ... 179
9.8 Improving It ... 180
9.9 Common Mistakes, and How to Avoid Them ... 181
9.10 Chapter Summary ... 181
9.11 Exercises ... 182
9.12 Solutions to the Exercises ... 182
References ... 183

CHAPTER 10 A Fuzzy-Logic Controller for a Fan ... 184
10.1 Hot, Humid and a Little Bit Vague ... 184
10.2 The Idea in Plain Words ... 185
10.3 The Math, Gently ... 185
10.3.1 From crisp sets to fuzzy sets ... 185
10.3.2 Fuzzy AND, OR and NOT ... 186
10.3.3 Rules, clipping, aggregation and the centroid ... 186
10.3.4 A worked example: 32 °C and 75 % humidity ... 187
10.3.5 Why the crisp controller jumps, in numbers ... 188
10.4 The Algorithm as Pseudocode ... 188
10.5 Building the Controller Step by Step ... 188
10.5.1 The engine ... 188
10.5.2 The fan ... 190
10.6 Running It ... 192
10.7 Fuzzy Versus Crisp ... 194
10.8 Testing It ... 195
10.9 Improving It ... 196
10.10 Common Mistakes, and How to Avoid Them ... 197
10.11 Chapter Summary ... 197
10.12 Exercises ... 198
10.13 Solutions to the Exercises ... 198
References ... 199

CHAPTER 11 House-Price Predictor: Linear Regression from Scratch and with scikit-learn ... 200
11.1 Why a House-Price Predictor? ... 200

11.2 The Idea in Plain Words 201
11.3 The Mathematics, Gently 202
11.3.1 A line through the points 202
11.3.2 Measuring how wrong a line is 202
11.3.3 The best line, exactly 203
11.3.4 Many features at once 204
11.3.5 Walking downhill: gradient descent 204
11.3.6 The normal equation 205
11.3.7 How good is good? 206
11.4 Building It Step by Step 206
11.4.1 The project folder 206
11.4.2 The data 207
11.4.3 One feature, by hand 208
11.4.4 The from-scratch library 208
11.4.5 The same model in scikit-learn 211
11.4.6 The app 212
11.5 Running It 213
11.6 Improving It 214
11.7 Common Mistakes, and How to Avoid Them 217
11.8 Chapter Summary 218
11.9 Exercises 218
11.10 Solutions to the Exercises 219
References 220

CHAPTER 12 Spam Filter: Logistic Regression 222
12.1 Why a Spam Filter? 222
12.2 The Idea in Plain Words 222
12.3 The Mathematics, Gently 223
12.3.1 From a message to a vector 223
12.3.2 A score and a probability 223
12.3.3 Punishing a wrong probability: log-loss 224
12.3.4 The gradient, and why it is so simple 225
12.3.5 Judging a classifier 226
12.4 Building It Step by Step 227
12.4.1 The data 227
12.4.2 From text to numbers 227
12.4.3 Logistic regression from scratch 228
12.4.4 The same filter in scikit-learn 231
12.4.5 The app 232
12.5 Running It 233
12.6 Improving It 234
12.7 Common Mistakes, and How to Avoid Them 236
12.8 Chapter Summary 237
12.9 Exercises 237
12.10 Solutions to the Exercises 237
References 239

CHAPTER 13 Iris Flower Classifier: k-Nearest Neighbors 240
13.1 Why an Iris Classifier? 240
13.2 The Idea in Plain Words 240
13.3 The Mathematics, Gently 242
13.3.1 Distance between two flowers 242
13.3.2 The vote 242
13.3.3 Units matter: standardization 243
13.3.4 How much work is a prediction? 243

13.3.5 Choosing k honestly: cross-validation 243
13.4 Building It Step by Step 244
13.4.1 A first look at the data 244
13.4.2 k-NN from scratch 244
13.4.3 Choosing k with scikit-learn 246
13.4.4 The app 248
13.5 Running It 248
13.6 Improving It 249
13.6.1 From flowers to laundry customers 251
13.7 Common Mistakes, and How to Avoid Them 251
13.8 Chapter Summary 252
13.9 Exercises 252
13.10 Solutions to the Exercises 253
References 254

CHAPTER 14 Loan Approval Advisor: An Explainable Decision Tree 255
14.1 Why a Loan Advisor? 255
14.2 The Idea in Plain Words 255
14.3 The Mathematics, Gently 256
14.3.1 How mixed is a pile? Gini impurity and entropy 256
14.3.2 How good is a question? Weighted impurity and gain 257
14.3.3 Growing the tree, and stopping 258
14.3.4 The feature a loan officer uses 258
14.4 Building It Step by Step 258
14.4.1 The data 258
14.4.2 A tree from scratch 259
14.4.3 The app 262
14.5 Running It 263
14.6 Improving It 264
14.6.1 Give the tree the right question 264
14.6.2 How deep should it grow? 267
14.7 Common Mistakes, and How to Avoid Them 269
14.8 Chapter Summary 269
14.9 Exercises 269
14.10 Solutions to the Exercises 270
References 271

CHAPTER 15 Sentiment Analyzer: Naive Bayes in Indonesian and English 273
15.1 Why a Sentiment Analyzer? 273
15.2 The Idea in Plain Words 273
15.3 The Mathematics, Gently 274
15.3.1 Bayes' theorem 274
15.3.2 The naive step 275
15.3.3 Estimating word probabilities by counting 275
15.3.4 Working in logarithms 276
15.3.5 Which words matter 276
15.4 Building It Step by Step 276
15.4.1 The data 276
15.4.2 Naive Bayes from scratch 277
15.4.3 The same model in scikit-learn 280
15.4.4 The app 281
15.5 Running It 282
15.6 Improving It 284
15.6.1 Negation 284
15.6.2 More data 284

15.6.3 Knowing the limits 285
15.7 Common Mistakes, and How to Avoid Them 286
15.8 Chapter Summary 286
15.9 Exercises 287
15.10 Solutions to the Exercises 287
References 289

CHAPTER 16 Customer Segmentation: k-Means on Laundry Data 290
16.1 Why Customer Segmentation? 290
16.2 The Idea in Plain Words 291
16.3 The Mathematics, Gently 291
16.3.1 Points, centers and distances 291
16.3.2 What k-means minimizes 291
16.3.3 The two steps 292
16.3.4 A better start: k-means++ 292
16.3.5 Preparing the features 293
16.3.6 How many clusters? Elbow and silhouette 293
16.4 Building It Step by Step 293
16.4.1 From bills to RFM 293
16.4.2 k-means from scratch 294
16.4.3 How many segments? 296
16.4.4 The app 297
16.5 Running It 298
16.6 Improving It 300
16.7 Common Mistakes, and How to Avoid Them 301
16.8 Chapter Summary 302
16.9 Exercises 302
16.10 Solutions to the Exercises 302
References 304

CHAPTER 17 Data Explorer with Principal Component Analysis 305
17.1 Why a Data Explorer? 305
17.2 The Idea in Plain Words 306
17.3 The Mathematics, Gently 306
17.3.1 Centering and the covariance matrix 306
17.3.2 The variance along a direction 307
17.3.3 The best direction is an eigenvector 307
17.3.4 How much to keep: explained variance 308
17.3.5 Projecting and reconstructing 308
17.3.6 The same thing by SVD 308
17.4 Building It Step by Step 309
17.4.1 PCA from scratch 309
17.4.2 Reading the components 311
17.4.3 The explorer app 312
17.5 Running It 313
17.6 Improving It 314
17.6.1 PCA for images: compression 314
17.6.2 Beyond linear PCA 315
17.6.3 A checklist for exploring a new table 316
17.7 Common Mistakes, and How to Avoid Them 317
17.8 Chapter Summary 317
17.9 Exercises 317
17.10 Solutions to the Exercises 318
References 319

CHAPTER 18 Handwritten Digit Recognizer: Support Vector Machines 320
18.1 Why a Digit Recognizer? 320
18.2 The Idea in Plain Words 321
18.3 The Mathematics, Gently 322
18.3.1 A line, and the distance to it 322
18.3.2 The widest margin 322
18.3.3 Soft margins and the hinge loss 322
18.3.4 Training by stochastic sub-gradients: Pegasos 323
18.3.5 From two classes to ten 324
18.3.6 Kernels 324
18.4 Building It Step by Step 324
18.4.1 A linear SVM from scratch 324
18.4.2 Kernels and tuning with scikit-learn 326
18.4.3 The app 328
18.5 Running It 329
18.6 Improving It 331
18.7 Common Mistakes, and How to Avoid Them 333
18.8 Chapter Summary 333
18.9 Exercises 334
18.10 Solutions to the Exercises 334
References 335

CHAPTER 19 Churn Predictor: Random Forests and Gradient Boosting 337
19.1 Why a Churn Predictor? 337
19.2 The Idea in Plain Words 338
19.3 The Mathematics, Gently 338
19.3.1 Turning a log into examples: snapshots 338
19.3.2 Bootstrap samples 339
19.3.3 Why averaging helps 339
19.3.4 Gradient boosting 339
19.3.5 Judging a ranking: AUC 340
19.4 Building It Step by Step 340
19.4.1 Snapshots 340
19.4.2 Forests and boosting around single trees 342
19.4.3 scikit-learn's ensembles, and an honest baseline 345
19.4.4 The app 347
19.5 Running It 348
19.6 Improving It 349
19.6.1 Watch the split 349
19.6.2 Better features 349
19.6.3 Tuning, and knowing when to stop 349
19.7 Common Mistakes, and How to Avoid Them 350
19.8 Chapter Summary 351
19.9 Exercises 351
19.10 Solutions to the Exercises 351
References 353

CHAPTER 20 Model Evaluation Dashboard: Metrics, ROC and Cross-Validation 354
20.1 Why an Evaluation Dashboard? 354
20.2 The Idea in Plain Words 354
20.3 The Mathematics, Gently 355
20.3.1 The confusion matrix and its metrics 355
20.3.2 The ROC curve and its area 356
20.3.3 Cross-validation 357
20.3.4 Comparing two models fairly 358

20.4 Building It Step by Step ... 358
20.4.1 Metrics from scratch ... 358
20.4.2 Six models, one protocol ... 361
20.4.3 The dashboard ... 362
20.5 Running It ... 365
20.6 Improving It ... 367
20.6.1 Compare models in pairs ... 367
20.6.2 Do not choose and report on the same numbers ... 367
20.6.3 More than accuracy on the page ... 367
20.7 Common Mistakes, and How to Avoid Them ... 368
20.8 Chapter Summary ... 369
20.9 Exercises ... 369
20.10 Solutions to the Exercises ... 369
References ... 371

CHAPTER 21 Tokenizer and Word Counter ... 372
21.1 Why Count Words? ... 372
21.2 The Idea in Plain Words ... 373
21.3 The Mathematics, Gently ... 373
21.3.1 Tokens, types, and their ratio ... 373
21.3.2 Zipf's law ... 374
21.3.3 Fitting a straight line ... 374
21.3.4 Heaps' law ... 375
21.4 Building the Tokenizer ... 375
21.4.1 Regular expressions in one page ... 375
21.4.2 One alternative per kind of token ... 375
21.4.3 Running the tokenizer ... 378
21.4.4 Splitting sentences ... 379
21.5 Building the Word Counter ... 380
21.5.1 Stop words ... 380
21.5.2 The counter ... 380
21.5.3 Running the counter ... 381
21.6 Zipf and Heaps on Our Corpus ... 383
21.7 Improving It: Indonesian Clitics and Beyond ... 385
21.7.1 The trouble with *-nya* ... 385
21.7.2 From words to subwords ... 386
21.7.3 Other improvements worth making ... 386
21.8 Testing the Tokenizer ... 387
21.9 Common Mistakes, and How to Avoid Them ... 388
21.10 Chapter Summary ... 388
21.11 Exercises ... 389
21.12 Solutions to the Exercises ... 389
References ... 391

CHAPTER 22 Spell Checker ... 392
22.1 Why a Spell Checker? ... 392
22.2 The Idea in Plain Words ... 392
22.3 The Mathematics, Gently ... 393
22.3.1 Edit distance ... 393
22.3.2 The table ... 393
22.3.3 How many candidates? ... 394
22.3.4 Choosing among candidates ... 394
22.4 Building the Edit-Distance Module ... 395
22.5 Building the Corrector ... 398
22.6 Improving It: A Keyboard-Aware Noisy Channel ... 401

22.7 Measuring It ... 403
22.8 Testing Honestly ... 404
22.9 Speed and Scale ... 406
22.10 Testing the Code ... 406
22.11 Common Mistakes, and How to Avoid Them ... 407
22.12 Chapter Summary ... 408
22.13 Exercises ... 408
22.14 Solutions to the Exercises ... 409
References ... 411

CHAPTER 23 Keyword Extractor (TF-IDF) ... 412
23.1 Why Extract Keywords? ... 412
23.2 The Idea in Plain Words ... 412
23.3 The Mathematics, Gently ... 413
23.3.1 Term frequency ... 413
23.3.2 Document frequency and its inverse ... 413
23.3.3 TF-IDF and normalization ... 414
23.3.4 A worked example ... 415
23.3.5 Measuring keyword quality ... 415
23.4 Building the Keyword Extractor ... 415
23.5 Running It ... 418
23.6 Improving It ... 420
23.6.1 Phrases ... 420
23.6.2 The lead sentence ... 420
23.7 Measuring It ... 421
23.7.1 Agreement with scikit-learn ... 422
23.8 Testing ... 423
23.9 Keywords for Profitina Laundry's Inbox ... 423
23.10 Where TF-IDF Stops ... 424
23.11 Common Mistakes, and How to Avoid Them ... 424
23.12 Chapter Summary ... 424
23.13 Exercises ... 425
23.14 Solutions to the Exercises ... 425
References ... 427

CHAPTER 24 Extractive Summarizer ... 428
24.1 Why Summarize? ... 428
24.2 The Idea in Plain Words ... 428
24.3 The Mathematics, Gently ... 429
24.3.1 Sentence vectors and similarity ... 429
24.3.2 Position ... 429
24.3.3 Word frequency ... 429
24.3.4 Centroid ... 430
24.3.5 TextRank ... 430
24.3.6 Maximal marginal relevance ... 430
24.3.7 ROUGE ... 431
24.4 The Data ... 431
24.5 Building the Summarizer ... 431
24.6 Running It ... 435
24.7 Measuring It ... 437
24.7.1 When position is not a clue ... 439
24.8 Improving It ... 440
24.8.1 Less repetition ... 440
24.8.2 Other improvements worth trying ... 440
24.9 A Morning Digest for Profitina Laundry ... 440

24.10 Testing 441
24.11 Common Mistakes, and How to Avoid Them 442
24.12 Chapter Summary 443
24.13 Exercises 443
24.14 Solutions to the Exercises 443
References 445

CHAPTER 25 News Topic Classifier 446
25.1 Why Classify Topics? 446
25.2 The Idea in Plain Words 446
25.3 The Mathematics, Gently 447
25.3.1 Bayes' rule for documents 447
25.3.2 The naive assumption 447
25.3.3 Estimating the probabilities 447
25.3.4 Working in logarithms 448
25.3.5 A worked example 448
25.3.6 Measuring a classifier 448
25.4 Building the Classifier 449
25.5 Running It 453
25.5.1 Explaining decisions 454
25.5.2 What the model learned 456
25.6 One Model, Two Languages 456
25.7 How Good Is Good? Comparing Models Honestly 457
25.7.1 More data 459
25.8 Testing 460
25.9 A Classifier for Profitina Laundry's Messages 461
25.10 Common Mistakes, and How to Avoid Them 461
25.11 Chapter Summary 461
25.12 Exercises 462
25.13 Solutions to the Exercises 462
References 464

CHAPTER 26 Language Detector 466
26.1 Why Detect Languages? 466
26.2 The Idea in Plain Words 466
26.3 The Mathematics, Gently 467
26.3.1 Character n-grams 467
26.3.2 The rank-profile method 467
26.3.3 Naive Bayes over n-grams 468
26.3.4 How sure is the decision? 468
26.3.5 A worked example 468
26.4 The Data 468
26.5 Building the Detectors 469
26.6 Running It 472
26.7 Improving It 475
26.7.1 Marker words for close languages 475
26.7.2 An honest second test 475
26.7.3 Knowing when not to answer 476
26.7.4 Inside one decision 476
26.8 Testing 477
26.9 Detectors in the Real World 478
26.10 Language Detection at Profitina Laundry 478
26.11 Common Mistakes, and How to Avoid Them 478
26.12 Chapter Summary 479
26.13 Exercises 479

26.14 Solutions to the Exercises ... 480
References ... 481

CHAPTER 27 Smart-Reply Suggestions for Business Chats ... 482
27.1 Who Uses Smart Replies Today ... 482
27.2 The Idea in Plain Words ... 482
27.3 The Mathematics, Gently ... 483
27.3.1 Choosing a reply with Bayes' rule ... 483
27.3.2 The message as a chain of words ... 484
27.3.3 Estimating by counting, with interpolation ... 484
27.3.4 The shop's own habits ... 485
27.3.5 Measuring with hit@k ... 485
27.3.6 Replies that mean the same thing ... 486
27.4 Building It Step by Step ... 486
27.4.1 Writing the corpus ... 486
27.4.2 The model ... 488
27.4.3 The application ... 491
27.4.4 Tests ... 492
27.5 Running It ... 494
27.6 Measuring It ... 495
27.7 Improving It ... 497
27.7.1 Letting replies share: clusters ... 497
27.7.2 Following the seller's fingers ... 499
27.7.3 What else would help ... 499
27.8 Common Mistakes, and How to Avoid Them ... 500
27.9 Using It for Real ... 500
27.10 Chapter Summary ... 501
27.11 Exercises ... 501
27.12 Solutions to the Exercises ... 502
References ... 503

CHAPTER 28 Named-Entity Finder ... 505
28.1 Why Find Entities? ... 505
28.2 The Idea in Plain Words ... 505
28.3 The Mathematics, Gently ... 506
28.3.1 BIO tags ... 506
28.3.2 The perceptron tagger ... 506
28.3.3 Learning the weights ... 507
28.3.4 Measuring entities, not tokens ... 507
28.4 The Data ... 507
28.5 Building the Rule-Based Finder ... 508
28.6 Building the Statistical Tagger ... 511
28.7 Measuring It ... 514
28.8 Improving It: A Name List from the Laundry's Own Records ... 516
28.9 What Is Special About Indonesian Names ... 519
28.9.1 Annotating your own data ... 520
28.10 Testing ... 520
28.11 Common Mistakes, and How to Avoid Them ... 521
28.12 Chapter Summary ... 522
28.13 Exercises ... 522
28.14 Solutions to the Exercises ... 522
References ... 524

CHAPTER 29 FAQ Answer Bot (BM25) ... 525
29.1 Why an FAQ Bot? ... 525

29.2 The Idea in Plain Words ... 525
29.3 The Mathematics, Gently ... 526
29.3.1 The BM25 score ... 526
29.3.2 Saturation ... 526
29.3.3 Length normalization ... 527
29.3.4 A worked example ... 527
29.3.5 Measuring a retrieval system ... 527
29.3.6 When not to answer ... 528
29.4 The Data ... 528
29.5 Building the Ranker and the Bot ... 528
29.5.1 One query, traced ... 532
29.6 Measuring It ... 532
29.6.1 Choosing the threshold ... 535
29.7 Improving It ... 536
29.8 Serving the Bot on the Web ... 536
29.9 Testing ... 538
29.10 Common Mistakes, and How to Avoid Them ... 539
29.11 Chapter Summary ... 539
29.12 Exercises ... 539
29.13 Solutions to the Exercises ... 540
References ... 542

CHAPTER 30 Plagiarism Checker ... 543

30.1 Why Check for Copying? ... 543
30.2 The Idea in Plain Words ... 543
30.3 The Mathematics, Gently ... 544
30.3.1 Shingles and Jaccard similarity ... 544
30.3.2 MinHash ... 544
30.3.3 A family of hash functions ... 545
30.3.4 Locality-sensitive hashing ... 545
30.4 The Data ... 546
30.5 Building the Checker ... 546
30.6 Running It ... 548
30.7 Scaling Up with LSH ... 550
30.8 Improving It and Knowing Its Limits ... 552
30.8.1 Choosing k, measured ... 553
30.9 Testing ... 553
30.10 Common Mistakes, and How to Avoid Them ... 554
30.11 Chapter Summary ... 555
30.12 Exercises ... 555
30.13 Solutions to the Exercises ... 555
References ... 557

CHAPTER 31 Perceptron from Scratch ... 558

31.1 Why Start with One Neuron? ... 558
31.2 The Idea in Plain Words ... 558
31.3 The Mathematics, Gently ... 560
31.3.1 The weighted sum ... 560
31.3.2 The step function ... 560
31.3.3 The decision boundary is a straight line ... 560
31.3.4 The learning rule ... 561
31.3.5 Working an epoch by hand ... 561
31.3.6 A promise that it will stop ... 562
31.3.7 Scaling the inputs ... 562
31.4 Building It Step by Step ... 562

31.4.1 The perceptron class 562
31.4.2 First test: logic gates 564
31.4.3 The application: a flower sorter 564
31.4.4 Tests 566
31.5 Running It 566
31.5.1 Why XOR is impossible 567
31.5.2 Sorting flowers 567
31.6 Improving It: When No Line Is Perfect 568
31.7 Common Mistakes, and How to Avoid Them 571
31.8 Chapter Summary 572
31.9 Exercises 572
31.10 Solutions to the Exercises 572
References 574

CHAPTER 32 Multilayer Network in NumPy 575
32.1 Why Stack Neurons? 575
32.2 The Idea in Plain Words 576
32.3 The Mathematics, Gently 577
32.3.1 The forward pass 577
32.3.2 The loss 578
32.3.3 Gradient descent 578
32.3.4 The chain rule 578
32.3.5 Backpropagation, step by step 579
32.3.6 A worked example with real numbers 580
32.3.7 Checking a gradient numerically 580
32.3.8 Momentum 580
32.4 Building It Step by Step 581
32.4.1 The network 581
32.4.2 Solving XOR 583
32.4.3 Checking the gradients 583
32.4.4 The application: a two-moons classifier 584
32.4.5 Tests 584
32.5 Running It 585
32.6 Improving It 587
32.7 Common Mistakes, and How to Avoid Them 589
32.8 Chapter Summary 589
32.9 Exercises 589
32.10 Solutions to the Exercises 590
References 592

CHAPTER 33 Digit Recognizer in PyTorch 594
33.1 Why Recognize Digits? 594
33.2 The Idea in Plain Words 595
33.3 The Mathematics, Gently 595
33.3.1 Tensors and linear layers 595
33.3.2 The loss from raw scores 596
33.3.3 Automatic differentiation 596
33.3.4 Optimizers 596
33.3.5 Accuracy, validation and early stopping 597
33.3.6 Dropout 597
33.4 Building It Step by Step 597
33.4.1 Autograd, checked against Chapter 32 598
33.4.2 The data 598
33.4.3 The model and the training loop 599
33.4.4 Training and saving 601

33.4.5 The application 602
33.4.6 Tests 602
33.5 Running It 603
33.6 Improving It 606
33.7 Common Mistakes, and How to Avoid Them 607
33.8 Chapter Summary 607
33.9 Exercises 608
33.10 Solutions to the Exercises 608
References 610

CHAPTER 34 Autoencoder That Compresses and Denoises 611
34.1 Why Learn to Copy? 611
34.2 The Idea in Plain Words 612
34.3 The Mathematics, Gently 612
34.3.1 Encoder, code and decoder 612
34.3.2 The reconstruction loss 613
34.3.3 How much is saved 613
34.3.4 The denoising objective 614
34.3.5 The linear cousin: PCA 614
34.4 Building It Step by Step 614
34.4.1 The model 614
34.4.2 Training both models 616
34.4.3 The application 617
34.4.4 Tests 618
34.5 Running It 619
34.6 Improving It 621
34.7 Common Mistakes, and How to Avoid Them 623
34.8 Chapter Summary 623
34.9 Exercises 623
34.10 Solutions to the Exercises 624
References 626

CHAPTER 35 Convolutional Network for Images 627
35.1 Why Convolutions? 627
35.2 The Idea in Plain Words 628
35.3 The Mathematics, Gently 629
35.3.1 One convolution 629
35.3.2 Many channels in, many maps out 629
35.3.3 Output size and padding 629
35.3.4 Counting parameters 630
35.3.5 Max pooling 630
35.3.6 Shifting along 630
35.4 Building It Step by Step 630
35.4.1 A convolution by hand 630
35.4.2 The models and the data 631
35.4.3 Training and the shift test 634
35.4.4 The application 634
35.4.5 Tests 635
35.5 Running It 636
35.6 Improving It: Data Augmentation 637
35.7 Common Mistakes, and How to Avoid Them 638
35.8 Chapter Summary 639
35.9 Exercises 639
35.10 Solutions to the Exercises 640
References 641

CHAPTER 36 Next-Word Prediction for a Phone Keyboard 642
36.1 Who Uses Next-Word Prediction Today 642
36.2 The Idea in Plain Words 642
36.3 The Mathematics, Gently 643
36.3.1 Characters as vectors 643
36.3.2 The recurrence 643
36.3.3 Why plain RNNs forget, and the GRU 644
36.3.4 Training by predicting the next character 644
36.3.5 From characters to a word 644
36.3.6 The n-gram keyboard 645
36.3.7 Temperature 645
36.3.8 Measuring a keyboard 645
36.4 Building It Step by Step 645
36.4.1 One person's messages 646
36.4.2 The data split and the n-gram keyboard 647
36.4.3 The character GRU and its keyboard 648
36.4.4 Training 652
36.4.5 The application 653
36.4.6 Tests 655
36.5 Running It 656
36.6 Measuring It 657
36.7 Improving It 660
36.7.1 Two models are better than one 660
36.7.2 Eight bits are enough 662
36.7.3 What else would help 662
36.8 Common Mistakes, and How to Avoid Them 663
36.9 Using It for Real 663
36.10 Chapter Summary 664
36.11 Exercises 664
36.12 Solutions to the Exercises 665
References 667

CHAPTER 37 Word Embeddings Trained from Scratch 668
37.1 Why Words Need Vectors 668
37.2 The Idea in Plain Words 669
37.3 The Mathematics, Gently 669
37.3.1 From index to vector 669
37.3.2 The skip-gram model 670
37.3.3 Negative sampling 670
37.3.4 Which negatives? 670
37.3.5 Measuring similarity 670
37.3.6 The counting alternative 671
37.3.7 Analogies 671
37.4 Building It Step by Step 671
37.4.1 The corpus 671
37.4.2 The model 673
37.4.3 Training and inspecting 675
37.4.4 The application 675
37.4.5 Tests 676
37.5 Running It 676
37.6 Improving It 679
37.7 Common Mistakes, and How to Avoid Them 681
37.8 Chapter Summary 681
37.9 Exercises 682
37.10 Solutions to the Exercises 682

CHAPTER 40 Privacy-Preserving Synthetic Data with a GAN ... 719

40.1 Who Uses Synthetic Data Today ... 719
40.2 The Idea in Plain Words ... 719
40.3 The Mathematics, Gently ... 720

40.3.1 The contest 720
40.3.2 The Wasserstein critic and the gradient penalty 720
40.3.3 Turning a bill into numbers, and back 721
40.3.4 Measuring utility 721
40.3.5 Measuring privacy risk 722
40.4 Building It Step by Step 722
40.4.1 From the database to one table 723
40.4.2 The GAN 724
40.4.3 Training 727
40.4.4 The measures 728
40.4.5 Tests 730
40.5 Measuring Utility and Privacy 732
40.6 Improving It 734
40.7 Releasing a Synthetic Table 736
40.8 Common Mistakes, and How to Avoid Them 738
40.9 Using It for Real 738
40.10 Chapter Summary 739
40.11 Exercises 739
40.12 Solutions to the Exercises 739
References 741

CHAPTER 41 Image Filters (Convolution by Hand) 742
41.1 Why Filters Matter 742
41.2 A Picture Is a Grid of Numbers 743
41.3 The Idea: A Sliding Window of Weights 743
41.4 The Math, Gently 744
41.4.1 Convolution in one formula 744
41.4.2 The box blur 745
41.4.3 The Gaussian blur 745
41.4.4 Sharpening as “add back what the blur removed” 746
41.4.5 Edge kernels, whose weights sum to zero 746
41.4.6 Borders, padding, and the size of the output 747
41.4.7 Measuring quality: MSE and PSNR 747
41.5 Building the App 748
41.5.1 Pictures without downloads 748
41.5.2 The kernels 749
41.5.3 Convolution, slowly and then fast 751
41.5.4 The app 752
41.6 Running It 755
41.7 Improving It 757
41.7.1 Tests that pin the behavior down 757
41.7.2 Separable kernels: fewer multiplications 757
41.7.3 Other directions 758
41.8 Common Mistakes, and How to Avoid Them 758
41.9 Chapter Summary 759
41.10 Exercises 759
41.11 Solutions to the Exercises 759
References 762

CHAPTER 42 Edge and Corner Detector 763
42.1 Why Edges and Corners Matter 763
42.2 The Idea in Plain Words 764
42.3 The Math, Gently 764
42.3.1 The image gradient 764
42.3.2 Sobel: a derivative that has been smoothed 765

42.3.3 Canny: thin, connected edges 765
42.3.4 Harris: what happens if I move the window? 766
42.4 Building the App 767
42.4.1 A scene with known answers 767
42.4.2 Shared filters 768
42.4.3 The edge detector 769
42.4.4 The corner detector 771
42.4.5 The app 772
42.5 Running It 774
42.6 Improving It 776
42.6.1 Tests 776
42.6.2 Choosing the parameters 777
42.6.3 Beyond this chapter 777
42.7 Common Mistakes, and How to Avoid Them 778
42.8 Chapter Summary 778
42.9 Exercises 779
42.10 Solutions to the Exercises 779
References 781

CHAPTER 43 Color Palette Extractor (k-means) 782
43.1 Why a Palette Is Useful 782
43.2 The Idea in Plain Words 782
43.3 The Math, Gently 784
43.3.1 Pixels as points, distance as difference 784
43.3.2 What k-means minimizes 784
43.3.3 A good start: k-means++ 785
43.3.4 How many colors: the elbow 785
43.3.5 Colors as people see them: CIELAB 785
43.4 Building the App 786
43.4.1 Color conversions 786
43.4.2 k-means from scratch 788
43.4.3 Palettes and recoloring 789
43.4.4 The app 790
43.5 Running It 791
43.6 Improving It 794
43.6.1 Tests 794
43.6.2 Restarts, speed and better color differences 795
43.7 Common Mistakes, and How to Avoid Them 795
43.8 Chapter Summary 795
43.9 Exercises 796
43.10 Solutions to the Exercises 796

CHAPTER 44 Product-Defect Inspection on a Production Line 800
44.1 Who Uses Visual Inspection Today 800
44.2 The Idea in Plain Words 800
44.3 The Mathematics, Gently 801
44.3.1 A picture as numbers 801
44.3.2 A convolutional layer, with batch normalization 801
44.3.3 From scores to probabilities, and the loss 802
44.3.4 One number for the reject gate 803
44.3.5 The cost of a miss 803
44.4 Building It Step by Step 803
44.4.1 Drawing good and defective lids 803
44.4.2 The network and its training 806

44.4.3 Training two inspectors 808
44.4.4 Tests 809
44.5 Choosing the Threshold 810
44.6 Improving It 813
44.7 Running a Shift 815
44.8 Common Mistakes, and How to Avoid Them 817
44.9 Using It for Real 817
44.10 Chapter Summary 818
44.11 Exercises 818
44.12 Solutions to the Exercises 818

CHAPTER 45 Simple OCR for Printed Digits 822
45.1 Why Read Digits? 822
45.2 The Idea in Plain Words 823
45.3 The Math, Gently 824
45.3.1 Ink and paper 824
45.3.2 Projections cut the line 824
45.3.3 Recognition by template correlation 825
45.3.4 Recognition by nearest neighbors 826
45.3.5 Measuring a reader: edit distance and CER 826
45.4 Building the App 827
45.4.1 Rendering digits from bundled fonts 827
45.4.2 Segmentation 828
45.4.3 The recognizers and the line reader 829
45.4.4 The app 831
45.5 Running It 834
45.6 Improving It 836
45.6.1 Tests 836
45.6.2 Toward a real reader 836
45.7 Common Mistakes, and How to Avoid Them 837
45.8 Chapter Summary 837
45.9 Exercises 838
45.10 Solutions to the Exercises 838
References 840

CHAPTER 46 Object Counter (Connected Components) 842
46.1 Why Count Objects? 842
46.2 The Idea in Plain Words 843
46.3 The Math, Gently 844
46.3.1 Foreground by color distance 844
46.3.2 Connectivity and components 844
46.3.3 The two-pass algorithm and union-find 844
46.3.4 Measuring the objects 845
46.3.5 The distance transform and its peaks 846
46.4 Building the App 846
46.4.1 A tray of buttons 846
46.4.2 Labeling, twice 848
46.4.3 Counting 849
46.4.4 The app 851
46.5 Running It 852
46.6 Improving It 854
46.6.1 Tests 854
46.6.2 When peaks are not enough 855
46.7 Common Mistakes, and How to Avoid Them 855

46.8 Chapter Summary ... 855
46.9 Exercises ... 856
46.10 Solutions to the Exercises ... 856

List of Figures

Figure 1.1 The parts of Visual Studio Code used in this book: (1) Activity Bar, (2) Explorer, (3) editor, (4) Run button, (5) integrated terminal, (6) Status Bar with the selected interpreter. 5
Figure 1.2 A project folder with its virtual environment: `.venv` holds a private `python`, `pip` and the packages installed for this project only. 6
Figure 1.3 Every possible game of the halving guesser on the numbers 1 to 15: the first guess is 8 and each answer, lower (l) or higher (h), moves one level down. 10
Figure 1.4 The real game above: the numbers still possible before each guess (bars) and the guess itself (triangles); the secret 71 is found on the fifth guess. 13
Figure 1.5 How many guesses each of the 100 secrets needed, for random guessing and for halving (real run of `guess_lab.py`); the halving counts double level by level up to the last level. 16
Figure 2.1 The categorizer: keyword rules decide first, a naive Bayes model learned from your labels decides the rest when it is confident enough, and everything else is left for you to label. 23
Figure 2.2 The budget check on 20 September 2026: spending so far (solid), the month-end forecast (hatched) and the monthly limit (grey frame); amber marks a warning. 35
Figure 2.3 The effect of the confidence threshold on the 222 test transactions: below 0.7 seven are categorized wrongly, from 0.7 on none are, at the price of more questions. 38
Figure 3.1 Order SO-025 walked in the order it was typed (left) and along the planned route (right); circles are the stops in visiting order, D is the packing table. 58
Figure 3.2 The squares each search expanded (light teal) on the way from the depot (navy) to a bay in the far corner (amber): BFS floods almost the whole hall, DFS wanders and returns a 49-step path, A* heads for the goal. 61
Figure 3.3 Total walking for the 40 orders when each trolley trip carries one to six orders; the program's default of four is highlighted. 62
Figure 4.1 The two-food problem of Equation (4.4): plans in the shaded region meet both targets; the cheapest one is the corner where both constraints are exactly met. 71
Figure 4.2 The cheapest plan that meets every target: where the money goes (left) and each nutrient as a percentage of its minimum (right); energy and fiber are exactly met, the others come for free. 81
Figure 4.3 The cheapest plan meeting every target as the daily fiber target changes; the AKG target for a woman aged 19 to 29 is 32 g, and above about 37 g no plan exists with these foods and limits. 83
Figure 5.1 The improved timetables of the four classes; each color is a subject, and the grey cells are the Friday periods that do not exist. 100
Figure 5.2 Assignments needed by the four search settings on the two schools, on a logarithmic scale; "gave up" marks runs stopped at the limit of 20,000. 102
Figure 5.3 The three soft penalties of the first valid timetable and after local search. 102
Figure 6.1 How the chatbot handles a message: detect the language, apply the rules, classify the intent, then answer, fill the form, or hand the conversation to a person. 109
Figure 6.2 Answers, wrong answers and follow-up questions on the 44 test messages as the confidence threshold rises; from 0.30 on no wrong answer gets through. 123
Figure 7.1 The structure of the knowledge base: five observations, asked of the user, lead to two intermediate conclusions (the stain and the care the fabric needs), which lead to methods and warnings. 130
Figure 7.2 MYCIN's combination of two positive certainty factors: whatever the first value, a second piece of evidence only moves the total toward 1, never past it; the marked point is the turmeric example of Section 7.6. 132
Figure 7.3 The reasoning of the coffee consultation: the user's answers (teal), the conclusions drawn from them (amber) with their certainty, and the rules, with their certainty factors, on the arrows. 142

Figure 8.1 The road graph of this chapter: 26 places (laundry outlets in amber) and 36 roads, with the shortest (amber) and fastest (teal) routes from Profitina Laundry Keputih to Profitina Laundry Wiyung found by the planner. 151
Figure 8.2 The places settled (teal) while searching for the shortest route from ITS to Juanda: Dijkstra's algorithm settles almost the whole map, A* only the four places on the route. 162
Figure 9.1 Order crossover on eight jobs: the slice 1, 4, 8 is copied from parent 1, and the remaining jobs 5, 2, 6, 3, 7 are filled in the order in which they appear in parent 2. 172
Figure 9.2 The best and average cost in each generation of the run above, compared with the EDD rule and with random search given the same number of evaluations. 177
Figure 9.3 The genetic algorithm's schedule for the two stations (job numbers without the letter B); late jobs are red, and the ticks above the bars mark the due times. 178
Figure 10.1 The membership functions of the fan controller; the dashed lines mark the worked example of Section 10.3.4, 32 °C and 75 % humidity, with the degrees read off each curve. 186
Figure 10.2 Mamdani inference for 32 °C and 75 % humidity: the output words medium, high and max clipped at their rule strengths (shaded), their maximum (dark outline), and its centroid, 72.6 %. 187
Figure 10.3 Fan speed over temperature and humidity: the fuzzy controller changes gradually, the crisp controller in three abrupt steps. 195
Figure 11.1 The 300 houses of `data/houses.csv`: building area against price, the least-squares line through them, and five residuals (the vertical gaps between a house and the line). 201
Figure 11.2 The cost $J(w, b)$ of Equation (11.2) over all lines, as contour rings (darker is lower), with a gradient-descent path (one dot every 60 steps) sliding down to the minimum marked by the star. 203
Figure 11.3 Training MSE per epoch of gradient descent on the four scaled features, for three learning rates: 0.01 creeps, 0.1 converges in about 30 epochs, 0.4 diverges. 205
Figure 11.4 Predicted against actual price for the 60 test houses, using the improved model with `dist_km` squared. 214
Figure 11.5 Residuals of the four-feature model against distance to the center. The band means (squares) form a smile: the true distance effect is curved. 216
Figure 12.1 The spam filter from message to verdict: tokens, a 0/1 vector over the vocabulary, a linear score, the sigmoid, and a threshold. 223
Figure 12.2 The sigmoid of Equation (12.2). Scores above zero give probabilities above one half; with the usual threshold of 0.5, the shaded half of the axis is classified as spam. 224
Figure 12.3 The log-loss penalty $-\ln p$ for the probability p that the model gave to the true class: small for confident right answers, unbounded for confident wrong ones. 225
Figure 12.4 The ten most negative and ten most positive word weights learned by `logreg.py`; red words push toward spam, teal words toward a genuine message. 231
Figure 12.5 Fraction of spam caught (recall) and fraction of genuine messages flagged, against the decision threshold, for the character n-gram model on the 54 test messages. 235
Figure 13.1 Petal length and width of the 150 iris flowers. The star is the new flower (6.3,2.8,4.9,1.6); the circles mark its seven nearest neighbors, measured with all four features. 241
Figure 13.2 Accuracy against k on the training folds and under 5-fold cross-validation, for standardized features. The dashed line marks the chosen $k = 7$. 247
Figure 13.3 Decision regions of k-NN on petal length and width, for $k = 1$ (left) and $k = 15$ (right). Small k follows every individual flower; larger k smooths the border. 249
Figure 14.1 Gini impurity (Equation (14.1)) and entropy (Equation (14.2), halved to share the scale) as functions of the share p of approved cases. Both are zero for pure piles and largest for an even mix. 257
Figure 14.2 Installment against income for the applicants with a good credit history. The policy boundary is a diagonal, which single-feature questions can only approximate with a staircase. 265
Figure 14.3 The depth-3 tree grown by `tree.py` on the training applications with the DSR feature. Yellow leaves approve; each leaf shows its number of past cases and their approval share. 267
Figure 14.4 Training and test accuracy of trees with the DSR feature, by maximum depth. Beyond depth 4 the tree fits the training set better and the test set worse. 268
Figure 15.1 Ten-fold cross-validated accuracy of multinomial naive Bayes against the smoothing strength α on the 240 reviews. 281

Figure 15.2 Log-ratios $r(w)$ of Equation (15.8) for the ten most negative and ten most positive words that occur at least three times in the 240 reviews, with negation marked. 283
Figure 15.3 Learning curves of naive Bayes on the review data: 5-fold cross-validated accuracy against the number of training reviews, for plain words and with negation marked. Shaded bands show one standard deviation across folds. 285
Figure 16.1 Lloyd's iterations on two features (recency and spend, as z-scores of logarithms): each center starts at a k-means++ choice and moves to the mean of its members until nothing changes. 296
Figure 16.2 Choosing k: inertia (left) falls ever more slowly as k grows, with its clearest bend at $k = 4$; the average silhouette (right) is highest at $k = 4$. 297
Figure 16.3 The 253 customers by days since their last visit and total spend (log scale), colored by segment, with the size of each segment in the legend. 299
Figure 17.1 A cloud of 120 points and its two principal components. The first points along the direction of greatest spread; the second is at right angles to it. Arrow lengths are proportional to the spread along each direction. 306
Figure 17.2 Scree plot of the standardized wine data: the share of variance of each of the 13 components (bars) and the cumulative share (line). The dashed line marks 80 percent, reached with five components. 310
Figure 17.3 The 178 wines on their first two principal components, colored by grape cultivar. PCA never saw the cultivar labels. 311
Figure 17.4 Loadings of the thirteen standardized wine measurements on the first two principal components. Bars of the same color pull a wine's score in the same direction. 311
Figure 17.5 Four handwritten digits and their reconstructions from $k = 2,5,10,20$ and 64 principal components of the raw pixel values. 315
Figure 18.1 Thirty training images of the digits data set, 8×8 pixels each, with their labels. 320
Figure 18.2 A linear SVM on two groups of points: the decision boundary (solid), the edges of the margin (dashed) and the support vectors (circled) that alone determine it. 321
Figure 18.3 The hinge loss $\max(0,1 - yf)$ against the functional margin yf, with the 0-1 loss that simply counts mistakes. Points beyond margin 1 cost nothing. 323
Figure 18.4 Five-fold cross-validated accuracy of the RBF SVM for each combination of C and γ on the training images. 328
Figure 18.5 The eight misclassified test images, labeled "true → predicted". 328
Figure 19.1 A snapshot: features come only from the history before the cutoff; the label asks whether the customer ordered in the following 60 days. 338
Figure 19.2 Test AUC of the from-scratch random forest and gradient boosting as the number of trees or rounds grows, against a single tree. The forest levels off; boosting peaks and then overfits. 344
Figure 19.3 The two ensemble ideas: a random forest averages independent trees grown on bootstrap samples; gradient boosting adds small trees in sequence, each fitted to the errors left by the ones before. 345
Figure 19.4 Permutation importance of the eight features for the random forest: the drop in test AUC when each column is shuffled, averaged over ten shuffles, with its standard deviation. 347
Figure 20.1 The confusion matrix for a two-class problem: rows are the actual classes, columns the predicted ones. 355
Figure 20.2 Five-fold cross-validation: in each round a different fold is held out for validation and the model is trained on the other four. Every example is validated exactly once. 357
Figure 20.3 The evaluation dashboard in a browser: cross-validated metrics of six models, their ROC curves and fold-by-fold accuracies, and the confusion matrix and threshold sweep of logistic regression. 366
Figure 20.4 ROC curves of the six models from out-of-fold scores (left) and the top-left corner enlarged (right), with the pooled AUC in the legend. 366
Figure 21.1 The demonstration text cut into tokens. Each box is one token, colored by the kind of the alternative that matched it. 379
Figure 21.2 Left: rank against frequency on logarithmic axes, with the fitted least-squares lines. Right: the number of distinct types as more tokens are read, with the fitted Heaps exponent. 385

Figure 22.1 The Levenshtein table for turning the typo *sepda* into *sepeda*. The shaded cells are the path found by walking back from the bottom-right corner; the one horizontal step is the insertion of *e*. 398
Figure 22.2 Accuracy of the two correctors on the three typo sets. The vertical axis starts at 85% so that the differences are visible. 406
Figure 23.1 The inverse document frequency as a function of document frequency for $N = 48$ documents, plain and smoothed. The dots mark words of the Indonesian corpus. 414
Figure 23.2 The top eight words of item id25 by raw count (left) and by TF-IDF weight (right). The inverse document frequency pushes general words such as *memakai* and *dan* down. 419
Figure 24.1 The sentence graph of the article id-pasar. Lines join similar sentences, circle size shows the TextRank score, and the three highlighted sentences form the summary. Sentence 5 is almost isolated. 436
Figure 24.2 Mean ROUGE-1 F1 of each method on the four articles as written and with their sentences shuffled. Only the lead baseline depends on sentence order. 439
Figure 25.1 Confusion matrix of naive Bayes under 4-fold cross-validation on the 96 news items. Rows are true topics and columns predicted topics; the diagonal holds the correct answers. 454
Figure 25.2 Learning curve of naive Bayes: cross-validated accuracy against the number of training items per fold, averaged over ten random draws. The dashed line is the accuracy of guessing. 460
Figure 26.1 The ten most frequent character trigrams in the training text of each language; the open box marks a word boundary. Indonesian and Malay share almost the same list. 474
Figure 26.2 Accuracy of the three detectors on the 48 test sentences when only the first characters of each sentence are given. The dotted line is the accuracy of guessing among four languages. 474
Figure 27.1 How a message becomes three suggestions: the message is split into words, every whitelisted reply of the shop is scored by how well it explains the message and how often the shop sends it, and the best three are shown. 483
Figure 27.2 Hit@1 and hit@3 on 480 test messages for six suggesters, from always showing the most frequent replies to the per-reply bigram models with a shop prior and reply clusters. 496
Figure 27.3 Hit@3 for the catering shop's test messages as the number of its own training pairs grows (averages of three random subsets), without and with reply clusters. The other shops' data is always complete. 499
Figure 28.1 A training sentence with its BIO tags. Every entity starts with a B- tag and continues with I- tags of the same type; all other tokens are O. 506
Figure 28.2 Entity-level F1 of the four taggers on the ordinary test set and on the hard test set written after the rules were fixed. 516
Figure 29.1 Left: the term-frequency part of BM25 saturates at $k1 + 1$, unlike raw term frequency. Right: for a term that occurs twice, longer documents get less credit, and more so for larger b. 527
Figure 29.2 Right answers, wrong answers and handovers to staff on the 40 test questions as the threshold on the best BM25 score rises. The dashed line is the threshold chosen on the development questions. 535
Figure 30.1 Jaccard similarity of 3-word shingles for every pair of the eight essays. Only the near-verbatim copies stand out; the paraphrase and the translation look unrelated. 550
Figure 30.2 Left: the error of the MinHash estimate falls as the square root of the number of hash functions, as predicted. Right: the probability that a pair becomes an LSH candidate as a function of its Jaccard similarity, for three choices of bands and rows. 552
Figure 31.1 A perceptron with three inputs. Each input is multiplied by its weight, the products and the bias are added into z, and the step function turns z into the answer y. 559
Figure 31.2 The lines learned for AND, OR and NAND, each passing through or beside the corner points so that the circles (answer 1) lie on the firing side. For XOR the circles sit on one diagonal and the squares on the other, and no single straight line can separate them. 567
Figure 31.3 Left: mistakes per epoch while learning AND and XOR, from the run of **Listing 31.2**. Right: training accuracy after each epoch of the plain perceptron on overlapping flowers, from the run of **Listing 31.5**; the dotted line marks the best epoch. 567
Figure 31.4 Left: setosa and versicolor after scaling, with the boundary learned by `flower_sorter.py`. Right: versicolor and virginica overlap; the dashed line is where the plain perceptron happened to stop, the solid line the best weights it met on the way (the pocket). 568

Figure 32.1 A 2-3-2 network. Every input is connected to every hidden unit through the weights $W1$ and biases **b**1, and every hidden unit to every output through $W2$ and **b**2. Predictions flow forward; the error flows backward. 576
Figure 32.2 Left: the step function of Chapter 31 and three smooth activation functions (ReLU is shrunk by 4 to fit). Right: their slopes. The slope of tanh is largest at 0 and fades away on both sides; the step has slope 0 everywhere except at the jump, which is why it cannot be trained by gradients. 577
Figure 32.3 Left: the decision regions of the trained 2-3-2 network for XOR; triangles are class 1, circles class 0. Right: the training loss per epoch (logarithmic axis) from the run of **Listing 32.2**. 586
Figure 32.4 The two moons with the decision regions of logistic regression (left) and of the 2-16-2 network trained by **Listing 32.4** (right). The titles give the test accuracy. 587
Figure 32.5 Training loss per epoch on the moons for full-batch gradient descent, mini-batches of 16, and mini-batches with momentum 0.9, from the run of **Listing 32.6**. 588
Figure 33.1 Three examples of each digit from the scikit-learn digits data set. Each image is only 8×8 pixels with 17 gray levels. 594
Figure 33.2 The five steps that `fit` performs for every mini-batch. Step 4 is where autograd replaces the hand-written backward pass of Chapter 32. 601
Figure 33.3 Training loss (left axis) and validation accuracy (right axis) after each of the 30 epochs of **Listing 33.4**. 604
Figure 33.4 The confusion matrix of the trained model on the 360 test images. Diagonal cells (teal) are correct answers; off-diagonal cells (red) are mistakes. 604
Figure 33.5 The twelve test images the model misreads, each with the true digit, the model's answer and the probability it gave that answer. 605
Figure 34.1 An autoencoder is an hourglass. The encoder f squeezes 64 pixels into an 8-number code **z**; the decoder g rebuilds 64 pixels from the code. The digit on the right is the real reconstruction of the digit on the left. 612
Figure 34.2 Eight test digits: the original, the plain autoencoder's reconstruction from 8 numbers, the same digit with noise of standard deviation 0.3, and the denoising autoencoder's output for the noisy input. 620
Figure 34.3 The 360 test digits described by two numbers each. Left: the first two principal components. Right: the code of an autoencoder with $k = 2$. Circled numbers mark the median position of each digit. Labels were not used by either method. 621
Figure 34.4 Test reconstruction error for codes of 2 to 32 numbers, from the run of **Listing 34.5**. The autoencoder wins for small codes; PCA wins at 32. 622
Figure 35.1 A convolution. The 3×3 window (amber) of the input is multiplied cell by cell with the kernel and added up, giving one output number; moving the window gives the whole 3×3 output. This kernel responds to a rise in darkness from left to right. 628
Figure 35.2 The network of this chapter. Two rounds of 3×3 convolution and 2×2 max pooling turn the 8×8 image into 16 maps of 2×2; these 64 numbers feed a linear layer with 10 outputs. 628
Figure 35.3 Top: the eight 3×3 kernels learned by the first convolution layer (teal positive, red negative). Bottom: the feature maps they produce for the test digit on the left, after ReLU; dark means strong response. 636
Figure 35.4 Test accuracy on ordinary digits (navy) and on digits moved by up to one pixel (amber) for the four models of **Listing 35.6**. 638
Figure 36.1 The trained character GRU reading "aku o": each character updates the hidden state $\mathbf{h}t$ of 128 numbers, whose most probable next character is shown in amber. To suggest words, every lexicon word that begins with the typed prefix "o" is scored by the log-probability of its remaining characters followed by an end character. 643
Figure 36.2 Loss per character during training: one random training batch every 250 steps, and the whole development text. The weights with the lowest development loss are kept. 653
Figure 36.3 Top-3 next-word accuracy against the time per suggestion on a laptop CPU (logarithmic axis) for the three keyboards; the dotted line marks the 20 ms response time users expect. 660
Figure 37.1 The skip-gram game. For the center word *es* and a window of two words on each side, the four surrounding words become its context, giving four training pairs. 669

Figure 37.2 Cosine similarity (Equation (37.5)) between the learned vectors of six drinks and six animals. Blocks along the diagonal are sub-groups: hot and cold drinks, pets and farm animals. 677
Figure 37.3 The embeddings of the 42 content words projected onto their first two principal components. Each label names the words of one sub-group. 678
Figure 38.1 The worked example. Left: the scores of Equation (38.1) and the softmax weights of Equation (38.2). Right: the values of **Table 38.1**, sized by weight, and the output of Equation (38.3), their weighted average. 687
Figure 38.2 The attention weights of the three trained models for the input 20250917. Rows are output positions, columns input positions (with their digits); darker means more attention. 694
Figure 38.3 Attention weights of the trained lookup model for one example. The query letter *j* attends to the record whose key is *j* (amber) and retrieves its value, 9. 696
Figure 38.4 Left: the average largest attention weight among six random keys, with raw and scaled scores, as the dimension grows; the dotted line is the uniform $1/6$. Right: training loss of the lookup model with $d = 256$, with and without scaling (running mean over 20 steps, logarithmic axis). 697
Figure 39.1 The tiny Transformer. Characters become token-plus-position vectors, pass through two identical blocks of causal self-attention and feed-forward layers, each wrapped in a layer norm and a residual connection (red lines), and end as probabilities for the next character. 703
Figure 39.2 Training and validation loss every 100 steps during the run of **Listing 39.2**; the checkpoint with the lowest validation loss (step 700) is kept. 712
Figure 39.3 The attention weights of the eight heads for the input *bu wulan mencuci kemeja* (spaces shown as underscores). Rows are the positions that look, columns the positions looked at; head 4 of layer 1 looks at the previous character. 713
Figure 40.1 A GAN for tables. The generator turns random noise into synthetic rows; the critic scores real and synthetic rows; the generator is trained through the critic's score (dashed) to make its rows score like real ones. 720
Figure 40.2 Units against amount for the wash-dry-fold service (Rp8,000 per kilo, amber line) in the held-out real bills, in the GAN's synthetic bills and in the table of independent columns. 734
Figure 40.3 Utility (the $R2$ of a model trained on the release and tested on real held-out bills) against risk (the AUC of the membership attack) for the five releases. The ideal is the top left: useful, and no better than guessing for the attacker. 734
Figure 41.1 One step of a convolution: the 3×3 window of the image is multiplied cell by cell with the (flipped) kernel and the nine products are added to give one output pixel, here 71.25. 744
Figure 41.2 The 5×5 box kernel gives every cell the weight $1/25 = 0.040$; the 5×5 Gaussian with $\sigma = 1$ gives the center 0.162 and the corners 0.003. Both sum to one. 746
Figure 41.3 The test card, the same card with Gaussian noise of $\sigma = 25$, and the noisy card cleaned by a 3×3 box and a 5×5 Gaussian, with their PSNR against the clean card. 756
Figure 41.4 The `china.jpg` photograph bundled with scikit-learn after each kernel of the library; the edge kernels are shown with 128 added so that zero response is gray. 756
Figure 42.1 The Harris score $R = \lambda 1 \lambda 2 - 0.05(\lambda 1 + \lambda 2)2$ over the plane of the two eigenvalues: positive (corner) where both are large, negative (edge) where one is much larger than the other, small (flat) near the origin. 767
Figure 42.2 The test scene, its horizontal and vertical Sobel responses (amber positive, teal negative), and the gradient magnitude. 775
Figure 42.3 The stages of Canny on the scene with noise $\sigma = 10$: gradient magnitude, non-maximum suppression, a single threshold for comparison, and the hysteresis result that Canny returns. 775
Figure 42.4 Harris on the scene with noise $\sigma = 30$: teal circles mark the 17 true corners, amber squares the detections. Left, derivatives of the raw picture; right, the picture smoothed with $\sigma = 1.5$ first. 776
Figure 42.5 Canny edges ($\sigma = 2$) and Harris corners (smoothing 1.5, threshold 0.01 of the maximum, one corner per 15×15 neighborhood) on the photograph bundled with scikit-learn. 776
Figure 43.1 A sample of 4,000 pixels of `china.jpg` drawn as points in the RGB cube, each in its own color; the six large circles are the palette colors that k-means finds. 783
Figure 43.2 k-means on three groups of points in the plane: the starting centers (red crosses), the centers after one and two rounds of assign-and-update, and the converged centers. 783

Figure 43.3 Six-color palettes: `china.jpg` clustered in RGB and in CIELAB, and `flower.jpg` in RGB. Each strip is divided in proportion to the share of the picture that each color covers. 792
Figure 43.4 The elbow curve for `china.jpg`: inertia per pixel (logarithmic scale) against the number of palette colors k. 793
Figure 43.5 `china.jpg` redrawn with only 2, 4, 8 and 16 palette colors, with the PSNR of each against the original. 793
Figure 44.1 The architecture of `InspectNet`: three convolution blocks, each halving the picture and widening the stack of channels, and two fully connected layers that produce four class scores. 802
Figure 44.2 Eight generated 48×48 pictures of each class: good lids, scratches, dents and misprints (a shifted logo, wrong colors or a missing part). 806
Figure 44.3 The cost per 1,000 lids of Equation (44.7) as the threshold on $P(\text{defect})$ moves, for the validation and the test pictures (logarithmic scale). Low thresholds pay for false alarms, high thresholds for missed defects. 813
Figure 44.4 The confusion matrix of the weighted inspector on the 2,020 test pictures: rows are the true classes, columns the most probable class; the shade is the share of the row. 813
Figure 45.1 The ten fonts bundled with matplotlib that the app uses: six for training (top) and four unseen fonts for testing (bottom, in red). 823
Figure 45.2 Segmentation of a printed line: the picture, the number of ink pixels in each column, the character boxes found from the runs of inked columns, and each character centered and scaled to 16×16. 825
Figure 45.3 The ten templates: each is the pixel-by-pixel average of the 142 training glyphs of one digit, rendered in six fonts, two sizes, three tilts, with and without blur and noise. 826
Figure 45.4 A line printed in `cmtt10` with noise of standard deviation 40, its ink mask without blur (specks fill the gaps), and its ink mask after a Gaussian blur with $\sigma = 1$ (clean characters and clean gaps). 835
Figure 45.5 Character error rate of three readers under five conditions on four unseen fonts; bars above 60% are cut, with their values written above them. 835
Figure 46.1 A generated tray of 20 separated buttons, its foreground mask (the holes stay white), and the 20 connected components found by labeling, each drawn in its own color with its number. 843
Figure 46.2 The 4-neighbors of a pixel share a side with it; the 8-neighbors also include the four pixels that share only a corner. 843
Figure 46.3 The two-pass method with 4-neighbors on a small grid: pass 1 gives provisional labels and records the equivalences $2 = 1$ and $4 = 3$; pass 2 merges them into two objects. 845
Figure 46.4 Tray 1 with touching buttons: the picture, its 11 connected components (chains of buttons share a color), the distance transform of the hole-filled mask, and the 20 distance peaks marked on the picture. 853
Figure 47.1 One query (a 9) and its five most similar gallery digits, with their labels and cosine similarities: pixel search on the original query, pixel search on the query shifted by one pixel down and right, and search with the CNN trained with shifts on the same shifted query. 860
Figure 47.2 Cosine similarity depends only on the angle θ between two vectors: **a** and **c** point in the same direction and have cosine 1, whatever their lengths. 861
Figure 47.3 Precision at 5 of four embeddings on queries that are not shifted, shifted by one pixel down, and shifted by one pixel down and right. 870
Figure 47.4 The gallery digits projected to two dimensions with PCA, from their pixel vectors (left) and from their CNN embeddings (right); each class has its own color and its label at its median position. 871
Figure 48.1 The seven generated product photos (top) and their cutouts by the backdrop model with cleaning (bottom, transparency shown as a checkerboard), with the IoU against the true outline 878
Figure 48.2 The gray-level histogram of the yellow shirt photo: the shirt (amber) forms a narrow hill, the unevenly lit backdrop (gray) a wide one; Otsu's threshold (red) falls inside the backdrop, and the fixed threshold at 128 (dashed) misses everything. 887
Figure 48.3 The backdrop model on the light gray bottle: the photo, the backdrop fitted to the border by least squares, the color difference between them, and the cleaned mask. 887

Figure 48.4 On a photograph whose background is a blurred garden rather than a backdrop, Otsu (middle) and the backdrop model (right) both find most of the main flower but not all of it. 889
Figure 49.1 Three training digits (a 2, a 3 and a 5) and one random draw of each transformation; the horizontal flip in the last column changes what a digit looks like, the others do not. 894
Figure 49.2 Ten test digits as they come (top) and the same digits after a random small shift, rotation and zoom (bottom): the moved test set. 894
Figure 49.3 Mixup of a 3 ($\lambda = 1$) and an 8 ($\lambda = 0$): the blended picture at $\lambda = 0.8$ is labeled "80% three, 20% eight". 896
Figure 49.4 Mean accuracy over three seeds on the clean and the moved test sets for every augmentation recipe, trained on 100 digits. 903
Figure 50.1 The plan of the chapter: pretrain a network on printed letters, then copy its feature layers into a network with a new head for handwritten digits. 910
Figure 50.2 The source task (printed letters in different fonts, weights and tilts) and the target task in its hardest setting: one labeled handwritten digit per class. 910
Figure 50.3 Mean accuracy over three seeds for six methods and three label budgets, on clean test digits (left) and moved test digits (right); solid lines are trained with random moves. 921
Figure 50.4 Accuracy on the moved test digits during training with ten labels per class and random moves: from scratch (100 epochs) and two-stage fine-tuning from the letter network (30 epochs for the head, then 100 for every layer). 921
Figure 51.1 The content-based recommender from file to list. Each film becomes a bag of words and then a TF-IDF vector of length 1; a person becomes a taste vector in the same space, and cosine scores rank the unseen films. 929
Figure 51.2 Cosine similarity between twelve films of the catalog, computed by `content_model.py`. Films with shared genres and rare shared words form blocks along the diagonal. 939
Figure 51.3 All 48 films projected onto their first two principal directions. The plain top five (red rings) crowd into one cluster; the MMR top five (amber dots) spread over two regions. 940
Figure 52.1 The ratings matrix of the simulated film club: 60 members, 48 films, 1,096 ratings. Colored cells hold one to five stars; grey cells are films the member has not rated. Filling the grey cells is the recommender's job. 948
Figure 52.2 Two ways to fill the same empty cell. User-based filtering borrows the opinions of similar members; item-based filtering borrows Ani's own opinions of similar films. 948
Figure 52.3 Error on 233 held-out ratings (lower is better). Both kinds of collaborative filtering beat the two baselines; item-based filtering with ten neighbors is best. 956
Figure 53.1 The idea of matrix factorization. The ratings matrix, most of it empty, is approximated by the product of a tall matrix P (one row of k numbers per member) and a wide matrix $Q\top$ (one column of k numbers per film). The highlighted row and column produce one predicted rating. 968
Figure 53.2 Training (dashed) and test (solid) error of ten-factor models over 60 epochs. With weak regularization (red) the training error keeps falling but the test error turns upward after about 40 epochs; with $\lambda = 0.1$ (teal) the test error keeps improving slowly. 975
Figure 53.3 All 48 films placed by their two learned factors, colored afterwards by genre. Family films gather on the right, comedies on the left, mysteries at the bottom and dramas at the top, although the model never saw a genre. 977
Figure 54.1 Semantic search. An encoder, trained on a log of customer messages, turns every article into a vector once; at question time it turns the question into a vector of the same kind, and the articles with the highest cosine are returned. 986
Figure 54.2 Search quality on 24 unseen customer questions. Every method that learned from the chat log beats keyword search; the hybrid of the dense encoder and keywords has the best mean reciprocal rank. 998
Figure 55.1 The two-stage product search engine. BM25F retrieves up to 20 candidates by text; filters remove products the customer excluded; six features describe each candidate; a scorer whose weights were learned from judged queries orders them. 1007
Figure 55.2 The BM25 term-frequency fraction of Equation (55.3) with $k1 = 1.2$ and $b = 0.75$. Extra occurrences help less and less, approaching $k1 + 1$; longer products need more occurrences for the same credit. The dashed line is an unsaturated count for comparison. 1008

Figure 55.3 Feature weights learned by pairwise logistic regression from all 28 judged queries. Features are on comparable scales except BM25, whose values reach about 14. 1016
Figure 56.1 The search space for **Table 56.1** with minimum support 2 of 8 orders. Teal sets are frequent; red sets were counted and found rare; dashed sets were never counted, because one of their subsets is already rare. 1026
Figure 56.2 Itemsets per size on the shop's orders (logarithmic scale): all possible sets, the candidates Apriori actually counted, and the frequent ones. 1033
Figure 56.3 Every rule from the frequent itemsets of the shop's orders, by support and confidence, colored by lift. The dashed line marks the confidence threshold 0.3. 1034
Figure 57.1 The same twelve songs in three orders, drawn on a two-dimensional map of the catalog (the amber dot is the first song). The map is a projection, so the drawn lengths only approximate the true distances in the titles. 1053
Figure 57.2 The Saturday-morning energy arc: target energy (dashed) and the energy of each song chosen by beam search, labeled with its genre. 1054
Figure 57.3 The Saturday-morning playlist as a path through the catalog map, numbered in playing order and colored by genre. 1055
Figure 58.1 The bandit loop. For each visit the policy sees the context, chooses one section, observes only whether that section was clicked, and updates itself before the next visit. 1063
Figure 58.2 Cumulative regret over 20,000 visits, averaged over five seeds. Context-free policies settle on one section and keep losing clicks at a steady rate; LinUCB's regret flattens as it personalizes. 1071
Figure 58.3 Thompson sampling's Beta beliefs about four sections' click rates after 300 and after 20,000 visits; n is the number of times each section was shown. 1071
Figure 59.1 The duplicate-question detector. A new question is paired with every existing FAQ question; six features describe each pair; logistic regression turns them into a probability, and the best match above 0.5 is shown to the customer. 1080
Figure 59.2 The 145 test pairs by character TF-IDF cosine and concept overlap (with a little jitter so overlapping points stay visible). Concept overlap separates most duplicates from non-duplicates; character similarity hardly does. 1089
Figure 59.3 ROC curves of the two detectors on the 145 test pairs. The dashed diagonal is chance. 1090
Figure 60.1 A trie of four queries with their counts, drawn compressed (each edge carries the letters until the next branch). Every node stores the two most frequent queries below it, so a suggestion is a lookup, not a search. 1098
Figure 60.2 Autocomplete quality on 641 later searches by the number of characters typed: the share of searches whose query is among the five suggestions, and the mean reciprocal rank. 1107
Figure 61.1 Weights that simple exponential smoothing gives to past weeks. A larger α trusts the latest week more and forgets faster. 1117
Figure 61.2 Weekly sales of the three outlets with the SES level, the four-week moving average, and the forecasts for the eight hidden test weeks (grey band). Holt's trend forecast extrapolates the July rise and misses badly. 1123
Figure 61.3 One-step SSE of simple exponential smoothing on the 43 training weeks for every α from 0.01 to 0.99. The minimum is at $\alpha = 0.31$. 1123
Figure 62.1 Orders per day at the three outlets from October 2025 to September 2026, with a seven-day average, national holidays (red dots) and the four closure days (amber band). 1138
Figure 62.2 The eight hidden test weeks: actual orders, the seasonal naive forecast and the Poisson regression. The regression predicts the two holiday dips in August. 1139
Figure 62.3 Multiplicative effects learned by the Poisson regression on the whole year, relative to a Monday. The closure factor (×0.009) is left out of the drawing. 1139
Figure 63.1 The simulated series (top) and its first difference (bottom). The level wanders; the difference moves around a constant mean, the dashed line. 1151
Figure 63.2 Sample ACF and PACF of the differenced series. Bars outside the grey band (teal) are larger than white noise would usually produce. The PACF cuts off after lag 2. 1158
Figure 63.3 Twenty-step forecast of the fitted ARIMA(2,1,1) with its 95% interval, compared with the twenty hidden values. 1159
Figure 64.1 Random cuts isolate an ordinary point only after many steps (left) but an odd point after a few (right). The shaded box is the last region, which contains the red point alone. 1167

Figure 64.2 Hours from arrival to finished for every live bill, by service, on a log scale. Red points have a robust z-score above 3.5 in absolute value; the dark bars are the medians. 1173
Figure 64.3 Planted anomalies caught by each detector, by kind. No single detector catches every kind; the layered detector of Section 64.8 combines their strengths. 1175
Figure 65.1 One healthy cycle: water temperature (top) and motor current (bottom) with the expected values from the program (dashed). The five phases are marked at the top. 1187
Figure 65.2 One planted fault of each kind in the temperature sensor. Grey: the planted period; dashed: the expected value; red: samples where at least one check fired. 1192
Figure 66.1 Average electricity use for every hour of the week over the year. The shop is closed from 21:00 to 07:00; weekends are busier. 1202
Figure 66.2 Extra energy, compared with the usual for that hour and type of day, against outdoor temperature. Only open hours respond to heat. Temperatures with fewer than 30 hours are not plotted. 1203
Figure 66.3 One test week: actual hourly use, the linear regression and the same hour a week earlier. The hourly jumps come from how many machines happen to run and cannot be predicted a day ahead. 1207
Figure 67.1 One week at the Rungkut outlet. Top: every order as a bar from arrival to finished. Bottom: the number of orders in the shop, $L(t)$; its average is the area under the curve divided by the length of the week. 1216
Figure 67.2 Hours from arrival to finished for wash-dry-fold orders, with the median and the 90% quantile. 1216
Figure 67.3 Average wait at the front counter against the arrival rate, for one and two clerks, each serving 12 customers per hour. Waiting explodes as the load approaches capacity. 1223
Figure 68.1 Sixty simulated paths of the fictional asset (grey) with the median and the 25–75% and 5–95% bands of 20,000 paths. The dashed line is the starting price. 1232
Figure 68.2 Distribution of the price after one year over 20,000 paths, with the median, the mean and the 5% and 95% percentiles. 1233
Figure 68.3 Root mean squared error of the estimated mean price against the number of simulated prices, for plain and antithetic sampling, on logarithmic axes. Both follow the slope $-1/2$; the antithetic line is about 3.4 times lower. 1236
Figure 69.1 The request stream around the three planted events (grey bands), with the alarms of each detector marked as triangles above the data. 1247
Figure 69.2 Daily orders with their seven-day average and the CUSUM alarms: teal for a pace that rose above the weekday baseline, red for a pace that fell below it. 1250
Figure 69.3 Minutes between false alarms against the delay in detecting a shift from 20 to 23 requests per minute, for CUSUM thresholds h from 2 to 12. 1253
Figure 70.1 Rolling-origin evaluation: at each origin the method is trained on all data up to that day and scored on the next 14 days; then the origin moves forward a week. 1258
Figure 70.2 MASE by forecast horizon for the five methods, over 34 weekly origins. The zig-zag repeats every seven days because every origin falls on the same weekday. 1265
Figure 71.1 Beliefs about the three conversion rates after one simulated month of Thompson sampling, Beta(1 + bookings, 1 + misses). More visitors make a narrower curve. 1283
Figure 71.2 Cumulative regret of the four rules, averaged over 100 simulated months of 10,000 visitors. The dotted line marks the end of the fixed test phase. 1284
Figure 72.1 The optimal policy (arrows) and optimal values $V\star(s)$ (shading and small numbers) computed by value iteration on the slippery floor. Grey cells are shelves, blue cells are wet floor, and G is the washer. 1301
Figure 72.2 Return per episode during training (moving average of 100 episodes) for Q-learning and SARSA, both exploring with $\epsilon = 0.1$. 1302
Figure 73.1 The CartPole system: a cart on a track of half-width 2.4, a pole at angle θ from vertical, and a push of fixed size to the left or right at every step. 1310
Figure 73.2 Steps balanced in each training episode of REINFORCE (dots) and the average of the last 20 episodes (line). Training stops when the average reaches 475. 1317
Figure 73.3 Pole angle over one episode from the same starting state: the lean rule overcorrects and falls after 36 steps; the learned policy stays within a few degrees for 500 steps. 1317

Figure 74.1 The room model: heat leaks in from outside through the walls, the sun and the occupants add heat, the air conditioner removes it, and the PLN meter counts the electricity the AC draws. 1326
Figure 74.2 One test day from noon to noon. Top: outdoor temperature (dashed), the comfort band and the room under three controllers; the grey area is when someone is home. Bottom: the AC level each controller chose. 1338
Figure 74.3 Mean reward per simulated day during training (thousands of rupiah, logarithmic scale). The policy network sees 32 days per iteration, the table 16. 1339
Figure 74.4 Energy against discomfort per day for Q-learning agents trained with four prices w of one degree-hour, and for the two everyday controllers. 1341
Figure 75.1 The pricing agent proposes, the guardrails decide what may be posted, customers respond, and every decision is logged for the owner to review. 1348
Figure 75.2 Left: expected cups per weekday against price. Right: expected gross profit per week, with the six menu prices as dots; the shaded band is what the guardrails allow. 1360
Figure 75.3 Expected cumulative regret over 52 weeks, averaged over 20 simulated years, for the fixed price and the two learners. 1360
Figure 75.4 The guarded agent on rainy days, normal days and paydays (averages of 400 simulated days each). Left: the posted price in each block. Right: loaves left at the start of each block. 1361
Figure 76.1 Left: the number of days on which the three outlets used each number of bags, October 2025 to September 2026 (mean 12.25, marked). Right: bags used per week over the same year. 1382
Figure 76.2 The optimal expected cost per day, $(1-\gamma)V(x,q)$, against the bags on the shelf, with no order open and with 50 or 100 bags on order. Red dots mark the stock levels at which the optimal rule orders. 1383
Figure 76.3 Exact expected cost per day of every (s,S) rule with $S = 100$ and $S = 150$, starting from 60 bags; the best rule is marked. 1384
Figure 76.4 Bags on the shelf each evening of the real year under the rule "order 150 when empty" (top) and the optimal rule (43,150) (bottom); red dots mark the days the shelf ran out. 1385
Figure 77.1 The nearest-neighbor route (left, 66.6 km) and the route found by simulated annealing plus 2-opt (right, 65.1 km) through the same 30 customers. The amber square is the depot. 1400
Figure 77.2 The replanned day: the grey part has already been driven, the three stars are the new calls, and the dark line is the rest of the route after cheapest insertion and 2-opt (67.2 km in total). 1403
Figure 78.1 The simulated market of 1,500 trading days, with the hidden regime shaded. The dashed line separates the training days (0–999) from the test days (1000–1499) used in Section 78.5. 1412
Figure 78.2 Left: paper portfolios of the four rule-based strategies on the simulated market (starting at 10 million). Right: total returns of 200 coin flippers on the same market; the vertical line is buy and hold. 1417
Figure 79.1 Space–time diagram of the ring road (200 cells, 40 cars, $p = 0.3$): each row is one second, each colored dot a car colored by its speed. Jams (red) form without any obstacle and move backwards. 1431
Figure 79.2 Left: the fundamental diagram (flow against density) for three dawdling probabilities. Right: the number of cars waiting at the junction during one hour of uneven traffic (800 and 250 cars per hour) under the fixed timer and the adaptive controller. 1432
Figure 80.1 A STRIPS action: it can be applied only when all its preconditions hold; it then makes the facts of its add list true and those of its delete list false. 1439
Figure 80.2 Number of states expanded by four planners for one, two and three bags (logarithmic scale). The additive heuristic reduces the search by up to three orders of magnitude. 1446
Figure 81.1 One client, two possible servers: the `OLLAMA_HOST` setting sends the same HTTP requests either to tinystub (this book, offline) or to a real Ollama server. 1455
Figure 81.2 The stub's six most likely next words after "a model" at three temperatures, computed with Equation (81.6) from the real model. 1477
Figure 82.1 Prompt tokens sent at each turn of the same ten-turn conversation under four memory policies (server counts from tinystub). 1495
Figure 83.1 Left: accuracy of six prompts on the twelve test reviews. Right: variety of ten answers to one prompt as temperature rises (all from tinystub). 1509

Figure 84.1 The two phases of retrieval-augmented generation: indexing the notes once, and answering each question from the retrieved chunks. 1516
Figure 84.2 Cosine similarity of one question to every chunk of the notes; the three highest (teal) are sent to the model (tinystub embeddings). 1526
Figure 85.1 Map-reduce summarization: each part of a long document is summarized on its own, and the partial summaries are summarized again. 1532
Figure 86.1 Ten order messages asked for JSON in three ways: without a format, in JSON mode and with a JSON Schema (tinystub). 1560
Figure 87.1 The agent loop: the model either answers or asks for tools; every call is validated before it runs, and errors are sent back to the model as results. 1566
Figure 88.1 Findings for the sample file by rule and severity (tinystub's rule-based review). 1592
Figure 89.1 Pass rate per category at two temperatures, with 95% Wilson intervals; 5 runs per case (tinystub). 1605
Figure 90.1 Guard layers around the model: rate limit, injection detector and redaction on the way in; canary check and redaction on the way out. Any layer can turn the request into a refusal. 1612
Figure 90.2 Attack suite results: attacks that leaked a secret or personal data, and benign prompts wrongly blocked, for the raw and the guarded assistant (tinystub). 1621
Figure 91.1 The path of one request through the service. The model file is read once, at startup (dashed arrow); invalid input is stopped by validation and never reaches the model. 1629
Figure 91.2 The self-hosted documentation page of our running service: (1) the example request body, (2) the Execute button, (3) the equivalent curl command, (4) the JSON answer, (5) the timing header added by our middleware. 1641
Figure 91.3 Wash-and-fold test orders (July to September 2026) sorted by predicted median: most true turnaround times (dots) fall below the p90 promise (dashed); a few very late orders lie far above it. 1643
Figure 91.4 Latency of 200 sequential /predict requests on one CPU core: median 17.0 ms, 95th percentile 27.9 ms. 1645
Figure 92.1 The two round trips of the page. (A) A classic form submission returns a whole new HTML page rendered from the template. (B) The live estimate sends a small JSON request and updates one element in place. 1654
Figure 92.2 The running page after an estimate: (1) the language switch, (2) the form with the submitted values kept, (3) the typical ready time, (4) the latest ready time, (5) the live estimate updated by JavaScript. 1665
Figure 92.3 The server-side check at work: with the browser's limit removed, a weight of 500 still reaches the server, which refuses it with a message in the page's language. 1665
Figure 93.1 Every interaction reruns the whole script. The two cached functions do their slow work only on the first run; later runs get the stored table and the same model object, and only the cheap computations are repeated. 1674
Figure 93.2 The running dashboard for July to September 2026: (1) the filters in the sidebar, (2) the headline numbers with their change against the previous quarter, (3) daily orders with the 7-day moving average, (4) the table per outlet, (5) revenue by service, (6) the "what if?" estimate from the model. 1683
Figure 94.1 From a browser drawing to the 64 numbers the model reads: invert so that ink is bright, crop to the ink, center it in a square with a margin, and shrink to 8 by 8 with values from 0 to 16. 1691
Figure 94.2 The digit tab after clicking the first example: (1) the drawing tools (image, brush, eraser), (2) the canvas holding the drawing, (3) the model's top three answers with their probabilities, (4) the clickable examples. 1698
Figure 94.3 The laundry ETA tab: drop-downs, a number box, radio buttons and a slider feed the model; the answer appears in the text box. 1699
Figure 95.1 From source folder to installed command: the build turns the folder into a wheel (a zip file with a standard layout), and installing the wheel puts the code on Python's path and the `laundry-eta` command on the system's `PATH`. 1706
Figure 95.2 Time of `laundry-eta batch` against the number of orders (dots), the fitted line $T(n) = a + b\,n$ (dashed), and the time estimated for the vectorized version (diamond). 1719

Figure 96.1 The four layers of the test suite. Lower layers are fast and give exact answers; upper layers train or query the model and judge its behavior statistically. 1727
Figure 96.2 Typical estimate against weight for wash-and-fold at Rungkut on Thursday at 9:00. The v1 model (red) jumps below 3 kg, where no training data exist (shaded: the range seen in training); the v2 model (teal) is flat. Dots: median turnaround per weight over all outlets and days. 1735
Figure 97.1 What one tracked run records. Parameters and metrics also go into the shared `index.csv`; the fingerprints of data and code make any later change detectable. 1743
Figure 97.2 Validation MAE of the sixteen grid runs, as eight pairs that differ only in the weight feature. Without it (teal) the error is lower in every pair. 1751
Figure 98.1 The monitoring loop. Every prediction is logged; outcomes arrive later; a regular monitor compares recent data with the training data and recent errors with past ones, raises alerts, and a person decides what to do. 1761
Figure 98.2 Monthly MAE (top) and p90 coverage (bottom) of the model trained on October to December 2025 and never retrained (red), and of a model retrained on the first day of every month (teal). The shaded month contains the Nyepi and Idul Fitri holidays. 1768
Figure 99.1 Personal data protection in Indonesia, 2022 to 2027, as of September 2026: the law, the end of its transition, the implementing regulation and the still-missing supervisory agency. 1777
Figure 99.2 Privacy by design, step by step: from the raw customer table to what an analysis or a report actually needs. 1777
Figure 99.3 Selection rate (left) and true positive rate (right) for customers born in Surabaya and elsewhere, under four voucher policies. 1786
Figure 100.1 The assistant's architecture. An intent router sends each question to one tool; the tool's short sentences become FACTS; a local language model words them into an answer, or, if no model replies, the facts are returned plainly with a note. 1795
Figure 100.2 Daily orders at all three outlets in August and September 2026 (bars), their 7-day moving average (line), and the forecast for October 1 to 7 (amber). 1802
Figure 100.3 The running assistant after four questions. Under each answer: the intent, the number of facts, and the model that worded them. The times in the first answer are relative to the moment the question was asked. 1810

List of Tables

Table 1.1 The tools of the workbench and the versions used throughout the book. 2
Table 1.2 Activating the virtual environment on each operating system. 6
Table 2.1 Counts from the 206 labeled transactions of April to June, for the word QRIS and four categories. 25
Table 2.2 The thirteen categories of the sample household, with typical descriptions. 27
Table 4.1 The thirteen foods: price as bought, edible share and nutrients per 100 g edible part (TKPI 2017), portion size and the most portions per day. 74
Table 7.1 Forward and backward chaining over the same knowledge base. 132
Table 8.1 The order in which Dijkstra's algorithm settles places from ITS toward Juanda, with the A* estimate for the places A* considers; Dijkstra settles 21 places, A* only those with the smallest f: ITS, Keputih, Rungkut and Juanda. 153
Table 9.1 The settings of the genetic algorithm, as defaults of `genetic_algorithm`. 171
Table 9.2 The processing-time model used to turn orders into jobs. 172
Table 10.1 The fan's rule base; each cell is one rule "IF temperature is (row) AND humidity is (column) THEN speed is (cell)", and the row "cool" is a single rule with no humidity condition. 192
Table 11.1 The files of the house-price project. 207
Table 21.1 The seven kinds of token, in the order in which the tokenizer tries them. 376
Table 27.1 The bigram probabilities of Equation (27.3) for the message "udah jadi belum" under two laundry replies, with the real training counts. 485

Table 27.2 The four shops of the corpus: message–reply pairs, how many are in English, how many different replies each shop sends, and its most frequent reply. 488
Table 30.1 Jaccard similarity of `kebaya_asli` with four other essays for shingles of k words. 553
Table 31.1 The first two epochs of learning AND with $\eta = 0.1$, starting from zero weights; the columns Sum, Answer and Error hold z, y and $y - y$. Each row applies Equation (31.1), Equation (31.2) and Equation (31.4) once. 561
Table 38.1 Hand-made keys and values for the four words of the worked example. 687
Table 45.1 The edit-distance table for the truth `487` (rows) and the output `4817` (columns); the bottom-right cell is the distance, one insertion. 827
Table 51.1 The six fields of `films.csv` and the role each plays in the recommender. 932
Table 52.1 A tiny ratings matrix; the question mark is the rating we want to predict. 949
Table 56.1 Eight small orders. A is detergent, B softener, C stain spray, D an iron. 1025
Table 62.1 The three kinds of special day in `calendar_2025_2026.csv`. 1134
Table 64.1 Columns derived for every bill before detection. 1168
Table 65.1 The five planted fault types and the check aimed at each. 1188
Table 67.1 Median and 90% quantile of the hours from arrival to finished, per service, over all 2,909 finished orders. 1221
Table 74.1 The four controllers on the same 30 simulated days, with the PLN tariff of Rp 1,444.70 per kWh. 1337
Table 75.1 Four bread-pricing policies on the same 2,000 simulated days. 1361
Table 81.1 The parts of Ollama's HTTP API used in Part 9. 1454
Table 81.2 The files of Chapter 81. 1458
Table 81.3 Current open models in the Ollama library (sizes and context lengths as listed there, September 2026). 1479
Table 82.1 The five memory policies on the same ten-turn conversation (tinystub counts). 1498
Table 83.1 The six parts of a prompt, with an example for classifying reviews. 1502
Table 83.2 The test reviews each prompt got wrong (tinystub, temperature 0). 1511
Table 91.1 The features and the target of the turnaround model, one row per finished order. 1631
Table 94.1 Four ways to put a model in front of people, as used in Chapters 91 to 94. 1691
Table 97.1 The parts of our tracker and their counterparts in common tools. 1756
Table 99.1 Main obligations of UU 27/2022 and how the laundry's AI work meets them. 1777

List of Listings

Listing 1.1 `check_setup.py`: reports the Python version, whether a virtual environment is active and which pip it uses. 7
Listing 1.2 `guess_ai.py`: the halving guesser, playing against a person at the keyboard. 11
Listing 1.3 `guess_lab.py`: plays every secret from 1 to 100 against three strategies and reports the average, worst and best number of guesses. 14
Listing 1.4 `test_guess.py`: automatic tests for the guesser, including a simulated truthful player. 16
Listing 2.1 `statement.py`: reading bank and e-wallet CSV exports into one table. 28
Listing 2.2 `rules.py`: keyword rules and the cleaning of descriptions. 29
Listing 2.3 `learner.py`: the naive Bayes model and the rules-then-model-then-ask categorizer. 29
Listing 2.4 `budget.py`: the monthly summary, the month-end forecast and the budget alerts. 30
Listing 2.5 `categorize.py`: the application that imports, categorizes, summarizes and warns. 31
Listing 2.6 `lab.py`: measuring rules, model and hybrid on July to September. 35
Listing 2.7 `test_categorizer.py`: tests for importing, rules, the model and the budget alerts. 38
Listing 3.1 `grid.py`: the warehouse map, breadth-first search, depth-first search, A* and the flood fill. 49

Listing 3.2 `route.py`: loading stock and orders, cached distances, nearest neighbor, 2-opt, exact routes and batching. 53
Listing 3.3 `picker.py`: the pick list of one order in route order with a map, and the plan for the whole wave. 55
Listing 3.4 `lab.py`: comparing the searches, the routing rules, the batch sizes and the time needed for exact routes. 59
Listing 3.5 `test_picker.py`: tests on the four-by-six room. 62
Listing 4.1 `menu.py`: the data, the greedy rule, the linear program, the budget version and the whole-portion version. 74
Listing 4.2 `planner.py`: from data to a week's shopping list. 78
Listing 4.3 `lab.py`: the methods compared, the fiber target varied and the budget varied. 82
Listing 4.4 `test_menu.py`: tests based on the two-food example. 83
Listing 5.1 `csp.py`: the timetable as a CSP, backtracking with MRV and forward checking, and a checker. 94
Listing 5.2 `soft.py`: the soft penalty and the swap-based local search. 97
Listing 5.3 `timetable.py`: solve, improve, check, print and save the timetable. 99
Listing 5.4 `lab.py`: the search settings compared on two schools, and the effect of local search. 101
Listing 5.5 `test_timetable.py`: tests with the tiny school of the hand example. 102
Listing 6.1 `nlu.py`: language detection, normalization, rules, the intent classifier and slot extraction. 112
Listing 6.2 `bot.py`: the business data, the answers in two languages, and the dialog with forms and handoff. 115
Listing 6.3 `chatbot.py`: chatting in the terminal, replaying demo conversations and saving handoff tickets. 119
Listing 6.4 `lab.py`: intent accuracy on the test messages and the effect of the threshold. 122
Listing 6.5 `test_bot.py`: tests for understanding, the pickup form, order status and handoff. 123
Listing 7.1 `kb.txt`: the knowledge base of the stain advisor, 17 rules to identify the stain, 5 about fabrics, 12 methods and 6 warnings. 134
Listing 7.2 `engine.py`: the rule parser, MYCIN's combination, forward chaining, backward chaining and the "how" explanation. 137
Listing 7.3 `advisor.py`: the question-and-answer consultation with "why" explanations, advice in English or Indonesian, and a "how" explanation at the end. 140
Listing 7.4 `advisor_lab.py`: forward chaining over 14 recorded cases, comparing the identified stain with the expected one. 143
Listing 7.5 `test_engine.py`: tests for combination, parsing, forward chaining, backward questioning and the certainty threshold. 145
Listing 8.1 `citygraph.py`: the haversine distance, the rounding-up rule and the `CityGraph` class with its adjacency lists. 157
Listing 8.2 `routes.py`: A* on a weighted graph, returning the path, its cost and the places settled; Dijkstra's algorithm is A* with a zero heuristic. 158
Listing 8.3 `route_app.py`: finds the shortest and the fastest route with both algorithms, checks that they agree, and prints the legs. 159
Listing 8.4 `route_lab.py`: compares the work of Dijkstra's algorithm and A* on all 650 ordered pairs of places. 162
Listing 8.5 `test_routes.py`: tests of the haversine formula, the graph, the admissibility of the heuristic and two known routes. 163
Listing 9.1 `scheduler.py`: reading the jobs, list scheduling on parallel stations, weighted tardiness and the earliest-due-date rule. 173
Listing 9.2 `ga.py`: order crossover, swap mutation, the genetic algorithm of **Pseudocode 9.1**, and random search as a baseline. 174
Listing 9.3 `schedule_app.py`: the EDD rule, random search and the genetic algorithm on the twenty jobs, and the resulting schedule. 175
Listing 9.4 `ga_lab.py`: ten runs of the genetic algorithm and of random search, and a check against the exact optimum of a 9-job instance. 178

Listing 9.5 `test_ga.py`: tests for crossover, mutation, decoding and the behavior of the genetic algorithm. 179
Listing 10.1 `fuzzy.py`: triangular and trapezoidal membership functions, fuzzy variables, and a Mamdani controller with centroid defuzzification. 188
Listing 10.2 `fan.py`: the membership functions and rule base of the fan controller, and an explanation of one inference. 190
Listing 10.3 `tip.py`: the classic fuzzy tipping problem with three rules, two of them using OR. 193
Listing 10.4 `fuzzy_lab.py`: the control surface of the fuzzy fan, and the largest change in speed caused by a 0.1 °C step, for the fuzzy and the crisp controller. 194
Listing 10.5 `test_fuzzy.py`: tests for membership functions, fuzzification, the centroid, the fan's behavior and the tipping example. 195
Listing 11.1 `make_houses.py`: generating 300 houses with a hidden price rule and fixed seed. 207
Listing 11.2 `simple_fit.py`: the exact least-squares line for one feature. 208
Listing 11.3 `linreg.py`: linear regression from scratch, trained by gradient descent and by the normal equation. 208
Listing 11.4 `sklearn_fit.py`: the same model as a scikit-learn pipeline, on the same split. 211
Listing 11.5 `house_app.py`: the command-line house-price predictor. 212
Listing 11.6 `improve.py`: residuals per distance band, then the extra feature `dist_km` squared. 214
Listing 11.7 `test_linreg.py`: three tests for the from-scratch library. 216
Listing 11.8 `solutions/ex_stable_lr.py`: the largest stable learning rate for gradient descent on our data. 219
Listing 11.9 `solutions/ex_ridge.py`: ridge regression by a modified normal equation. 220
Listing 12.1 `textprep.py`: tokens, a stratified split and a 0/1 bag-of-words vectorizer. 227
Listing 12.2 `logreg.py`: logistic regression trained by gradient descent with an L2 penalty. 228
Listing 12.3 `sklearn_spam.py`: three text representations feeding scikit-learn's `LogisticRegression`. 231
Listing 12.4 `spam_app.py`: the spam filter as a command-line app that explains its verdict. 232
Listing 12.5 `threshold.py`: spam caught against genuine messages flagged, as the threshold moves. 234
Listing 12.6 `test_logreg.py`: four tests for the spam filter's building blocks. 235
Listing 12.7 `solutions/ex_lambda.py`: the effect of the L2 penalty strength. 238
Listing 13.1 `explore_iris.py`: counting the flowers and averaging each measurement per species. 244
Listing 13.2 `knn.py`: k-nearest neighbors from scratch, with a stratified split and test accuracy for several values of k. 244
Listing 13.3 `sklearn_knn.py`: choosing k by 5-fold cross-validation, then testing once. 246
Listing 13.4 `iris_app.py`: the iris classifier as a command-line app that shows its neighbors. 248
Listing 13.5 `improve.py`: the effect of units, scaling, distance weighting and feature choice on k-NN. 250
Listing 13.6 `test_knn.py`: tests for the distance, the vote and the tie-break. 251
Listing 13.7 `solutions/ex_loo.py`: leave-one-out accuracy of the scratch k-NN on raw centimeters. 253
Listing 14.1 `make_loans.py`: 600 invented loan applications and the hidden policy that decided them. 258
Listing 14.2 `tree.py`: a decision tree from scratch, with Gini impurity, exhaustive split search and recursive growth. 259
Listing 14.3 `loan_app.py`: the explainable loan advisor, with the decision path and counterfactual suggestions. 262
Listing 14.4 `improve.py`: adding the debt-service ratio, and measuring the difference. 265
Listing 14.5 `sklearn_tree.py`: training and test accuracy of trees of increasing depth. 267
Listing 14.6 `test_tree.py`: tests for the impurity, the split search and the growth of the tree. 268
Listing 14.7 `solutions/ex_depth4.py`: how deeper trees treat fair-history applicants with a DSR between 0.25 and 0.35. 271
Listing 15.1 `nb.py`: multinomial naive Bayes from scratch, with Laplace smoothing and log-space prediction. 277

Listing 15.2 `sklearn_nb.py`: `MultinomialNB` on the same split, the smoothing strength α by cross-validation, and logistic regression for comparison. 280
Listing 15.3 `sentiment_app.py`: the sentiment analyzer as a command-line app that explains its verdict. 281
Listing 15.4 `negation.py`: marking the word after a negator, and its effect on accuracy and on individual words. 284
Listing 15.5 `test_nb.py`: tests for log-sum-exp, negation marking and Laplace smoothing. 285
Listing 15.6 `solutions/ex_curve.py`: cross-validated accuracy for growing amounts of training data. 288
Listing 15.7 `solutions/ex_by_lang.py`: one bilingual model against one model per language. 288
Listing 16.1 `rfm.py`: building the recency–frequency–monetary table and its log-and-z-score features. 293
Listing 16.2 `kmeans.py`: k-means from scratch, with k-means++ starts, Lloyd's iterations and several restarts. 294
Listing 16.3 `choose_k.py`: inertia and silhouette score for $k = 2$ to 8. 296
Listing 16.4 `segment_app.py`: naming the segments, suggesting actions, and looking up one customer. 297
Listing 16.5 `improve.py`: clustering in raw units, and the stability of k-means with one start versus ten. 300
Listing 16.6 `test_kmeans.py`: tests for the distances, a clear two-group case, and monotone inertia. 301
Listing 16.7 `solutions/ex_profile.py`: service mix and outlet mix of each segment. 303
Listing 17.1 `pca.py`: PCA from scratch with an eigendecomposition of the covariance matrix, checked against the SVD, on the wine data. 309
Listing 17.2 `explorer.py`: the PCA data explorer for the wine, iris, breast cancer and digits data sets. 312
Listing 17.3 `improve.py`: compressing the digits with PCA, and k-NN on 64 pixels against 20 components. 314
Listing 17.4 `test_pca.py`: tests for orthonormality, explained variance, reconstruction and agreement with scikit-learn. 315
Listing 17.5 `solutions/ex_nostd.py`: PCA on the wine data with and without standardization. 318
Listing 18.1 `svm.py`: a linear SVM trained by Pegasos, one-vs-rest for ten digits, the shared data split, and the pixel-shift helper. 324
Listing 18.2 `sklearn_svm.py`: linear, polynomial and RBF kernels, and a cross-validated search for C and γ. 326
Listing 18.3 `digit_app.py`: the digit recognizer app for drawings in text files and for test images. 328
Listing 18.4 `improve.py`: training on shifted copies (data augmentation) and testing on shifted images 331
Listing 18.5 `test_svm.py`: tests for Pegasos, the pixel shift, and the drawing reader. 332
Listing 18.6 `solutions/ex_gamma.py`: training accuracy, test accuracy and support vectors for six values of γ. 335
Listing 19.1 `features.py`: monthly snapshots with eight features from the past and a 60-day churn label from the future. 340
Listing 19.2 `ensemble.py`: a random forest and gradient boosting built from single scikit-learn trees. 342
Listing 19.3 `compare.py`: four models compared by test AUC and by the number of real churners among the 50 highest-risk customers; permutation importance for the forest. 345
Listing 19.4 `churn_app.py`: the churn-risk app for Profitina Laundry. 347
Listing 19.5 `test_ensemble.py`: tests for the forest, boosting and the snapshot labels. 349
Listing 19.6 `solutions/ex_split.py`: the AUC of a random split of snapshots against a split in time. 352
Listing 20.1 `metrics.py`: the confusion matrix, derived scores, ROC curve, AUC two ways and stratified folds, from scratch. 358
Listing 20.2 `evaluate.py`: six classifiers evaluated with stratified 10-fold cross-validation, with out-of-fold scores saved for the dashboard. 361

Listing 20.3 `dashboard.py`: the model evaluation dashboard as a single HTML page, optionally served on port 5020. 362
Listing 20.4 `test_metrics.py`: tests for the confusion matrix, the two AUC computations and the stratified folds. 367
Listing 20.5 `solutions/ex_paired.py`: fold-by-fold differences between the SVM and logistic regression. 370
Listing 21.1 `tokenizer.py`: the tokenizer, the sentence splitter, and the Indonesian clitic splitter. 376
Listing 21.2 `stopwords.py`: small stop-word lists for Indonesian and English. 380
Listing 21.3 `wordcount.py`: token, type and frequency statistics for the corpus. 380
Listing 21.4 `zipf.py`: least-squares fits of Zipf's law and Heaps' law. 383
Listing 21.5 `clitics_demo.py`: naive suffix cutting against cutting only when the stem is a known word. 386
Listing 21.6 `tests/test_tokenizer.py`: four tests for money and numbers, reduplication and contractions, abbreviations, and clitics. 387
Listing 21.7 `solutions/phone_tokens.py`: extra token kinds for phone numbers, times and hashtags. 390
Listing 22.1 `edit_distance.py`: the dynamic-programming table, Levenshtein and Damerau distances, and the alignment. 395
Listing 22.2 `spell.py`: the frequency-based corrector and a function that corrects whole texts. 398
Listing 22.3 `noisy_channel.py`: a weighted distance with cheaper keyboard slips, swaps and dropped vowels, and the noisy-channel corrector. 401
Listing 22.4 `evaluate.py`: accuracy of the frequency and noisy-channel correctors on a file of typos. 403
Listing 22.5 `make_typos.py`: a reproducible generator of artificial typos. 404
Listing 22.6 `tests/test_spell.py`: tests for the distances, the candidate generator, the weighted distance and the corrector. 406
Listing 22.7 `solutions/context.py`: a context-aware corrector for real-word errors. 409
Listing 23.1 `tfidf.py`: TF-IDF weights and keywords, written from scratch. 415
Listing 23.2 `keywords.py`: a command-line keyword extractor with an explanation mode. 417
Listing 23.3 `evaluate.py`: precision at 5 and headline recall of five keyword methods. 421
Listing 23.4 `compare_sklearn.py`: our weights against scikit-learn's `TfidfVectorizer`. 422
Listing 23.5 `tests/test_tfidf.py`: tests based on the worked example. 423
Listing 23.6 `solutions/similar.py`: the most similar news items by cosine similarity of TF-IDF vectors. 426
Listing 24.1 `summarizer.py`: four sentence scorers, maximal marginal relevance, and the summarize function. 431
Listing 24.2 `summarize.py`: the command-line summarizer. 434
Listing 24.3 `rouge.py`: ROUGE-N recall, precision and F1. 437
Listing 24.4 `evaluate.py`: ROUGE of every method, with an option to shuffle the sentences. 437
Listing 24.5 `tests/test_summarizer.py`: tests for ROUGE, TextRank and the summarizer. 441
Listing 24.6 `solutions/compare_scores.py`: correlation between TextRank and centroid scores. 444
Listing 25.1 `naive_bayes.py`: multinomial naive Bayes with Laplace smoothing, from scratch. 449
Listing 25.2 `classify.py`: stratified cross-validation, confusion matrix, precision, recall and F1. 451
Listing 25.3 `predict.py`: classifying new headlines, with the words that decided. 454
Listing 25.4 `compare_models.py`: our naive Bayes against three scikit-learn models on the same folds. 457
Listing 25.5 `learning_curve.py`: accuracy as a function of the number of training items. 459
Listing 25.6 `tests/test_naive_bayes.py`: tests for smoothing, prediction and stratified folds. 460
Listing 25.7 `solutions/shared_words.py`: terms shared by both languages, and those whose topics differ. 463
Listing 25.8 `solutions/title_weight.py`: counting the headline two or three times. 464
Listing 26.1 `langid.py`: character n-grams, the rank-profile detector, the naive Bayes detector, and the marker-word rule. 469

Listing 26.2 `evaluate.py`: accuracy, confusion counts, and accuracy against text length. 472
Listing 26.3 `detect.py`: language scores for your own texts, with a "not sure" answer for close calls. 476
Listing 26.4 `tests/test_langid.py`: tests for n-grams, balanced training, clear cases and marker words. 477
Listing 26.5 `solutions/margin_curve.py`: accuracy of the answers that pass a margin threshold. 480
Listing 27.1 `make_corpus.py`: expanding the chat templates into a corpus of message–reply pairs. 486
Listing 27.2 `smartreply.py`: loading and splitting the chats, the per-reply bigram model with the shop prior, ranking and hit@k. 488
Listing 27.3 `suggest.py`: the suggestion app, with an optional explanation of every score. 491
Listing 27.4 `tests/test_smartreply.py`: unit tests for the tokenizer, the probabilities, the prior, hit@k and the clusters. 492
Listing 27.5 `evaluate.py`: choosing every setting on the development data, then measuring hit@1 and hit@3 on the test data. 495
Listing 27.6 `clusters.py`: grouping replies whose messages look alike, and one message model per cluster. 497
Listing 27.7 `solutions/mrr.py`: the mean reciprocal rank of the clustered model. 502
Listing 27.8 `solutions/learning_curve.py`: the catering shop's hit@3 with less and less of its own data. 503
Listing 28.1 `corpus.py`: reading annotations as tokens with BIO tags, and turning tags into entity spans. 508
Listing 28.2 `rules.py`: patterns and gazetteers for persons, places, organizations, dates and money. 508
Listing 28.3 `perceptron.py`: an averaged-perceptron BIO tagger with word, shape, context, rule and name features. 511
Listing 28.4 `evaluate.py`: entity-level precision, recall and F1, overall and per type. 514
Listing 28.5 `make_names.py`: a list of name parts built from the laundry's sample records. 517
Listing 28.6 `find.py`: marking the entities in new sentences. 518
Listing 28.7 `tests/test_ner.py`: tests for the corpus reader, the rules and the features. 520
Listing 28.8 `solutions/money_rule.py`: amounts written as words, such as "50 ribu" and "120 thousand rupiah". 523
Listing 29.1 `bm25.py`: an analyzer and the Okapi BM25 ranker. 528
Listing 29.2 `faqbot.py`: the FAQ bot, with a threshold and a polite handover. 530
Listing 29.3 `evaluate.py`: top-1 accuracy and MRR of four rankers, and the threshold trade-off. 532
Listing 29.4 `app.py`: the FAQ bot as a web page and a JSON API. 536
Listing 29.5 `client.py`: asking the running API. 537
Listing 29.6 `tests/test_faqbot.py`: tests for BM25, the stemmer, the bot and the web API. 538
Listing 29.7 `solutions/synonyms.py`: query expansion with a synonym list. 540
Listing 30.1 `shingles.py`: word and character shingles, Jaccard similarity and containment. 546
Listing 30.2 `minhash.py`: MinHash signatures with a seeded hash family, the Jaccard estimate, and LSH banding. 547
Listing 30.3 `check.py`: pairwise comparison of a folder of essays, with shared passages. 547
Listing 30.4 `lsh_demo.py`: near-duplicate search with LSH among 120 texts. 550
Listing 30.5 `tests/test_plagiarism.py`: tests for shingles, MinHash and LSH. 553
Listing 30.6 `solutions/char_vs_word.py`: 3-word shingles, 5-character shingles and single words compared. 556
Listing 31.1 `perceptron.py`: a complete perceptron with the weighted sum, the step function and Rosenblatt's learning rule. 563
Listing 31.2 `logic_gates.py`: training the perceptron on four logic gates. 564
Listing 31.3 `flower_sorter.py`: the flower sorter. It trains on 70 flowers, tests on 30, and classifies a flower given on the command line. 564
Listing 31.4 `test_perceptron.py`: three unit tests with the standard `unittest` module. 566
Listing 31.5 `pocket.py`: the plain, pocket and averaged perceptrons on versicolor versus virginica, compared with scikit-learn's `Perceptron`. 569
Listing 31.6 `sol_learning_rate.py`: training AND with three learning rates. 573

Listing 31.7 `sol_xor_two_layers.py`: XOR as AND(OR, NAND). 573
Listing 31.8 `sol_no_scaling.py`: the flower sorter with and without scaling. 573
Listing 32.1 `mlp.py`: a two-layer network with a tanh hidden layer and a softmax output, its hand-written backward pass, and a training loop with mini-batches and momentum. 581
Listing 32.2 `xor_mlp.py`: training a 2-3-2 network on XOR and printing the hidden activations. 583
Listing 32.3 `gradcheck.py`: comparing backpropagation with central differences for every weight. 583
Listing 32.4 `moons_app.py`: two moons, a straight line and a 2-16-2 network. 584
Listing 32.5 `test_mlp.py`: unit tests for the NumPy network. 584
Listing 32.6 `improve.py`: comparing full-batch, mini-batch and momentum training, and five sizes of hidden layer. 587
Listing 32.7 `sol_relu.py`: a ReLU hidden layer. 590
Listing 32.8 `sol_zero_init.py`: training XOR from all-zero weights. 591
Listing 32.9 `sol_learning_rate.py`: four learning rates on the moons. 592
Listing 33.1 `autograd_demo.py`: the hand-worked example of Chapter 32, differentiated by PyTorch. 598
Listing 33.2 `digits_data.py`: loading the digits, splitting 60/20/20, and wrapping them in tensors and a `DataLoader`. 598
Listing 33.3 `model.py`: the `DigitNet` module, an accuracy function and a training loop. 599
Listing 33.4 `train.py`: training, testing and saving the digit recognizer. 601
Listing 33.5 `predict.py`: the digit recognizer application, using the saved model. 602
Listing 33.6 `test_digits.py`: unit tests for the data, the model and a short training run. 602
Listing 33.7 `improve.py`: five configurations with early stopping on the validation set. 606
Listing 33.8 `sol_no_scaling.py`: scaled versus raw pixel values. 608
Listing 33.9 `sol_batch_size.py`: ten epochs with three batch sizes. 609
Listing 34.1 `ae_model.py`: data loading, the `Autoencoder` module, noise, training and the error measure. 615
Listing 34.2 `train_ae.py`: training and comparing the plain and denoising autoencoders. 616
Listing 34.3 `ae_app.py`: compressing and denoising test digits with the saved models. 617
Listing 34.4 `test_ae.py`: unit tests for the autoencoder. 618
Listing 34.5 `compare_sizes.py`: test error for five code sizes, PCA versus autoencoder. 621
Listing 34.6 `sol_noise_levels.py`: both models on three noise levels. 624
Listing 34.7 `sol_anomaly.py`: reconstruction error as an anomaly alarm. 625
Listing 35.1 `conv_by_hand.py`: Equation (35.1) with loops, compared with `torch.nn.functional.conv2d`. 630
Listing 35.2 `cnn_model.py`: data, shifting, the CNN, the MLP baseline, training and accuracy. 631
Listing 35.3 `train_cnn.py`: training the MLP and the CNN and testing them on plain and shifted digits. 634
Listing 35.4 `cnn_app.py`: shifting a test digit and asking three models. 634
Listing 35.5 `test_cnn.py`: unit tests for the CNN and the shift helper. 635
Listing 35.6 `improve.py`: both networks with and without shifted training images. 637
Listing 35.7 `sol_equivariance.py`: checking translation equivariance on the first layer. 640
Listing 35.8 `sol_shift_sizes.py`: accuracy for moves of 0, 1 and 2 pixels. 640
Listing 36.1 `make_corpus.py`: one person's messages, drawn from templates. 646
Listing 36.2 `ngram_kb.py`: splitting the messages, separating the typed text into context and partial word, and the trigram keyboard. 647
Listing 36.3 `charlm.py`: the character-level GRU, training on random windows with early stopping, and the keyboard that scores whole words with Equation (36.6). 648
Listing 36.4 `train_rnn.py`: training the character GRU and saving it with its vocabulary. 652
Listing 36.5 `keyboard.py`: suggestions from the three keyboards, greedy phrase completion, and sampling with a temperature. 653
Listing 36.6 `tests/test_keyboard.py`: unit tests for both keyboards, the mixture and the keystroke counter. 655

Listing 36.7 `evaluate.py`: accuracy, keystroke savings, latency and size of the trigram and the character GRU. 657
Listing 36.8 `mixed.py`: mixing the probabilities of the two keyboards. 660
Listing 36.9 `improve.py`: choosing the mixing weight, measuring the mixed keyboard, and rounding the GRU's weights to 8 bits. 661
Listing 36.10 `solutions/by_position.py`: top-3 accuracy for the first word of a message and for later words. 665
Listing 36.11 `solutions/fourgram.py`: a 4-gram keyboard compared with the trigram. 665
Listing 37.1 `make_corpus.py`: generating 4,000 template sentences with a fixed seed. 671
Listing 37.2 `word2vec.py`: vocabulary, training pairs, the skip-gram model with negative sampling, training and nearest neighbors. 673
Listing 37.3 `train_embeddings.py`: training the embeddings and checking their neighbors. 675
Listing 37.4 `embed_app.py`: nearest neighbors and the odd one out. 675
Listing 37.5 `test_word2vec.py`: unit tests for the pairs and the loss. 676
Listing 37.6 `improve.py`: count-based vectors against skip-gram, scored by how many of each word's five nearest neighbors share its category. 679
Listing 37.7 `sol_analogy.py`: four analogies by vector arithmetic. 682
Listing 38.1 `attention_by_hand.py`: scaled dot-product attention for one query and four words. 689
Listing 38.2 `attn_model.py`: three rearrangement tasks and a one-layer attention model with learned queries 689
Listing 38.3 `train_attention.py`: training the attention model on the three tasks. 691
Listing 38.4 `attn_app.py`: rearranging digits and drawing the attention weights. 692
Listing 38.5 `test_attention.py`: unit tests for the attention models and the tasks. 692
Listing 38.6 `lookup.py`: the dictionary-lookup task and an attention model that solves it. 694
Listing 38.7 `improve.py`: softmax saturation with and without the d scaling, and its effect on training 696
Listing 38.8 `sol_causal.py`: the rearrangement model with a causal mask. 699
Listing 39.1 `tiny_gpt.py`: causal self-attention, the Transformer block, the model with generation, the character data, and loss estimation. 705
Listing 39.2 `train_gpt.py`: training with a checkpoint at the best validation loss, then a sample. 709
Listing 39.3 `gpt_app.py`: continuing a prompt with the trained model. 709
Listing 39.4 `test_tiny_gpt.py`: unit tests, including a direct check that the future cannot influence the past 710
Listing 39.5 `improve.py`: a bigram baseline and three Transformer variants on the same text. 713
Listing 39.6 `sol_no_mask.py`: training with and without the causal mask. 716
Listing 40.1 `laundry_table.py`: one row per collected bill, with no direct identifiers, and the encoder that turns rows into vectors and back. 723
Listing 40.2 `tabgan.py`: the generator with Gumbel-softmax blocks, the critic, the gradient penalty and WGAN-GP training. 724
Listing 40.3 `train_gan.py`: the member/held-out split and GAN training with two saved generators 727
Listing 40.4 `measures.py`: marginal error, correlation error, train-on-synthetic R^2, nearest distances, and the privacy measures. 728
Listing 40.5 `tests/test_synthetic.py`: unit tests for the encoder, the generator, the penalty and the measures. 730
Listing 40.6 `evaluate.py`: utility and privacy measures for five releases of the bills. 732
Listing 40.7 `improve.py`: computing the amount of every synthetic bill from the public price list, and the measures before and after. 734
Listing 40.8 `release.py`: generating a synthetic copy of the bills and releasing it only when it passes the privacy and utility checks. 736
Listing 40.9 `solutions/bigger_gan.py`: a GAN twice as wide, measured like the releases of `evaluate.py` 740

Listing 41.1 `scene.py`: a test card drawn with Pillow, the photographs bundled with scikit-learn, and gray conversion. 748
Listing 41.2 `kernels.py`: box, Gaussian, sharpen, emboss, Sobel and Laplacian kernels. 749
Listing 41.3 `convolve.py`: padding, convolution with four nested loops, convolution with a sliding-window view, and color images. 751
Listing 41.4 `filters_app.py`: the filters app, with a full demo and a command-line mode. 752
Listing 41.5 `test_convolve.py`: four tests that pin down identity, flat regions, agreement with SciPy, and the sign of the Sobel response. 757
Listing 41.6 `exercises.py`: solutions to Exercises 4, 5 and 6 (separable Gaussian, motion blur, sharpening a noisy picture). 760
Listing 42.1 `scene.py`: a gray scene of four polygons and a circle with 17 known corners, plus the bundled photograph in gray. 767
Listing 42.2 `filters.py`: fast convolution, a Gaussian kernel sized by sigma, the Sobel kernels, and a local-maximum test. 768
Listing 42.3 `edges.py`: gradients, non-maximum suppression, hysteresis, and the Canny detector. 769
Listing 42.4 `corners.py`: the Harris response, picking corners as strong local maxima, and matching them against the true corners. 771
Listing 42.5 `detect_app.py`: the demo on the known scene and on a photograph, and a mode that marks edges and corners on any picture. 772
Listing 42.6 `test_detect.py`: the direction of the gradient, a flat picture, hysteresis on a one-row example, and the complete clean scene. 776
Listing 42.7 `exercises.py`: solutions to Exercises 4, 5 and 6 (Shi–Tomasi, rotated scenes, a histogram of edge directions). 780
Listing 43.1 `colors.py`: hex codes, the sRGB gamma curve in both directions, and the conversion between sRGB and CIELAB. 786
Listing 43.2 `kmeans.py`: squared distances, the k-means++ start, and Lloyd's algorithm with a record of the inertia after every step. 788
Listing 43.3 `palette.py`: pixel sampling, palette extraction in RGB or CIELAB, recoloring, and PSNR. 789
Listing 43.4 `palette_app.py`: palettes of the bundled photographs, a comparison with scikit-learn, the elbow table, recoloring quality, and the CIELAB palette. 790
Listing 43.5 `test_palette.py`: hex codes, the CIELAB round trip, k-means on two obvious groups, and a two-color picture. 794
Listing 43.6 `exercises.py`: solutions to Exercises 4, 5 and 6 (restarts and a rare color, choosing k automatically, comparing palettes in ΔE). 797
Listing 44.1 `products.py`: drawing a lid, its logo and the three kinds of defect, and a labeled, shuffled set of pictures. 803
Listing 44.2 `cnn.py`: `InspectNet`, training with optional class weights, probabilities in batches, and the recall of every class. 806
Listing 44.3 `train.py`: the picture sets, the class weights, and a plain and a weighted inspector. 808
Listing 44.4 `tests/test_inspect.py`: unit tests for the pictures, the labels and the network. 809
Listing 44.5 `evaluate.py`: recall per class, three thresholds and their cost, and the confusion matrix. 810
Listing 44.6 `improve.py`: eight views of every defective picture, a new weighted inspector, and its cost at the threshold chosen on validation pictures. 814
Listing 44.7 `inspect_app.py`: a simulated shift of the inspection line, with the reject log and the time per lid. 815
Listing 44.8 `solutions/few_defects.py`: test recall of each defect with 10, 25 and 50 training pictures per defect. 819
Listing 44.9 `solutions/noisy_camera.py`: the same inspector and threshold with a noisier camera. 820
Listing 45.1 `render.py`: the paths of the fonts that ship with matplotlib, the training and test font lists, and a renderer with optional tilt, blur and noise. 827
Listing 45.2 `segment.py`: the ink mask, runs of true values, cutting too-wide pieces, character boxes, and normalization to 16×16. 828

Listing 45.3 `ocr.py`: rendering the training glyphs, the template recognizer, k-nearest neighbors, and reading a line with spaces. 829
Listing 45.4 `ocr_app.py`: edit distance, receipt-like test lines, the character error rate under five conditions, and the command-line tools. 831
Listing 45.5 `test_ocr.py`: runs, segmentation into normalized glyphs, edit distance (including the classic "kitten" to "sitting" example, distance 3), and reading a training font perfectly. 836
Listing 45.6 `exercises.py`: solutions to Exercises 4, 5 and 6 (an automatic choice of blur, the most frequent confusions, printed templates on handwriting). 839
Listing 46.1 `scene.py`: placing buttons apart or touching, and drawing them with two or four thread holes on cloth. 846
Listing 46.2 `label.py`: the flood fill, union-find with path halving, the two-pass method, and area, centroid and bounding box of each component. 848
Listing 46.3 `count.py`: the foreground mask, components without specks, the area rule, counting distance peaks, and counting holes. 849
Listing 46.4 `count_app.py`: comparing the three labelers, the diagonal example, counting holes, the table of counts on ten trays, and the command-line tools. 851
Listing 46.5 `test_count.py`: both labelers agree with SciPy on random masks, a U-shape is one object, and the counts on a separated and a touching tray. 854
Listing 46.6 `exercises.py`: solutions to Exercises 4, 5 and 6 (button sizes, the color threshold, the peak radius). 857
Listing 47.1 `data.py`: the bundled digits scaled to 0 … 1 and split into gallery and queries, and a function that shifts images with blank filling. 863
Listing 47.2 `embed.py`: pixel and PCA embeddings, the `DigitNet` CNN with its 32-number embedding layer, training with optional random shifts, and extracting embeddings. 863
Listing 47.3 `index.py`: normalization, a vector index with top-k cosine search, saving and loading, and precision at k. 865
Listing 47.4 `similar_app.py`: evaluating four embeddings on original and shifted queries, timing and saving the index, showing results, and searching from the command line with a query number or a picture file. 866
Listing 47.5 `test_similar.py`: normalized dot product equals cosine, an item is its own nearest neighbor (also after saving and loading), precision and shifting, and the split sizes. 872
Listing 47.6 `exercises.py`: solutions to Exercises 4, 5 and 6 (Euclidean search, embedding size, a digit never seen in training). 875
Listing 48.1 `scene.py`: a paper backdrop lit from a random side, the outlines of a shirt, a bottle and a mug, and photos with their true masks. 881
Listing 48.2 `remove.py`: gray conversion, the border frame, Otsu's threshold, deciding the object side, the fixed and Otsu masks, the fitted backdrop, the backdrop mask, cleaning, IoU and the RGBA cutout. 883
Listing 48.3 `remove_app.py`: the IoU of four methods on seven products, the effect of smoothing, saving cutouts, and cutting out any photo from the command line. 885
Listing 48.4 `test_remove.py`: Otsu on two clear groups, the backdrop fit on a surface it can represent exactly, IoU of two overlapping squares and the alpha channel, and cleaning away specks. 888
Listing 48.5 `exercises.py`: solutions to Exercises 4, 5 and 6 (a contrasting backdrop, the choice of k, a real photograph). 891
Listing 49.1 `data.py`: scaling the 8 by 8 digits to 16 by 16, and a split with 10 training digits per class and every other digit for testing. 897
Listing 49.2 `augment.py`: shift, rotation, zoom, contrast, noise, cutout and horizontal flip, the recipes, and applying a recipe. 897
Listing 49.3 `model.py`: `SmallNet`, training with a newly augmented copy of every picture in every epoch (optionally with mixup), and accuracy. 899
Listing 49.4 `aug_lab.py`: the moved test set, training every recipe with several seeds and reporting mean and spread, saving augmented copies of one digit, and the command line. 901
Listing 49.5 `test_augment.py`: ten training digits per class with no overlap, every recipe keeps shape and value range, and single steps behave as intended. 904

Listing 49.6 `exercises.py`: solutions to Exercises 4, 5 and 6 (more data against augmentation, rotation strength, what mirroring breaks). 907
Listing 50.1 `letters.py`: sixteen fonts bundled with matplotlib, 52 letter classes, and one randomly thickened, tilted and shifted letter as a 16 by 16 picture. 912
Listing 50.2 `digits.py`: handwritten digits at 16 by 16, a split with a given number of labels per class, and the random small move used for the moved test and for augmentation. 914
Listing 50.3 `net.py`: `CharNet` with separate `features` and `head`, a training loop with optional augmentation and optional parameter selection, accuracy, and embeddings. 914
Listing 50.4 `pretrain.py`: generating 10,400 letters, training CharNet for five epochs, checking it on fresh letters, and saving the weights. 916
Listing 50.5 `transfer.py`: loading the pretrained features under a new head, six methods, and the comparison over label budgets and seeds on clean and moved test digits. 917
Listing 50.6 `test_transfer.py`: the letter dataset, copying the body and replacing the head, the digit split and the move, and a training loop that lowers the loss. 922
Listing 50.7 `exercises.py`: solutions to Exercises 4, 5 and 6 (freezing some layers, random against pretrained features, the letters the source network confuses). 925
Listing 51.1 `content_model.py`: loading the catalog, TF-IDF vectors, cosine similarity, taste profiles, MMR and explanations. 932
Listing 51.2 `app.py`: similar films, a personal list, and the same list re-ranked with MMR. 936
Listing 51.3 `check_sklearn.py`: our TF-IDF matrix compared with scikit-learn's. 940
Listing 51.4 `test_content_model.py`: four properties the recommender must keep. 941
Listing 51.5 `sol_weights.py`: the three most similar films under three genre weights. 944
Listing 51.6 `sol_new_film.py`: a film added today is recommended today. 945
Listing 51.7 `sol_lambda.py`: MMR from pure relevance to pure variety. 945
Listing 52.1 `make_ratings.py`: simulating 60 members with hidden tastes who rate some of the 48 films. 951
Listing 52.2 `cf.py`: user-based and item-based collaborative filtering in about 110 lines. 953
Listing 52.3 `evaluate.py`: two baselines and six collaborative filters on the same held-out ratings. 955
Listing 52.4 `app.py`: recommendations for one member, with the members and films behind them. 957
Listing 52.5 `test_cf.py`: five properties, including the worked example of Section 52.3 and the transpose identity. 958
Listing 52.6 `laundry_cf.py`: item-to-item filtering on laundry bills, tested by leave-one-out against popularity. 960
Listing 52.7 `sol_tiny.py`: the worked example of Section 52.3 computed by `cf.py`. 964
Listing 52.8 `sol_shrink.py`: RMSE of item-based CF for six shrinkage strengths. 964
Listing 52.9 `sol_new_member.py`: predictions for a member with only two ratings. 965
Listing 53.1 `mf.py`: biased matrix factorization by SGD, and implicit ALS. 970
Listing 53.2 `train.py`: biases only, three factorizations, item-based CF, and a blend, all on the same test ratings. 973
Listing 53.3 `explore_factors.py`: the films at the two ends of each learned factor, and the largest biases. 976
Listing 53.4 `test_mf.py`: training error falls, an exact rank-one matrix is recovered, predictions stay on the scale, and ALS finds two customer groups. 978
Listing 53.5 `laundry_als.py`: implicit ALS on visit counts, with the leave-one-out hit rate of Chapter 52. 979
Listing 53.6 `sol_early_stop.py`: choosing the number of epochs on a validation set. 982
Listing 53.7 `sol_recommend.py`: the top five films for member U03 by matrix factorization. 983
Listing 54.1 `make_chatlog.py`: a simulated support-chat log of 1,500 (message, article) pairs. 989
Listing 54.2 `semantic.py`: tokenizing and stemming, TF-IDF keyword search, latent semantic analysis, and the evaluation of Equation (54.6) and Equation (54.7). 990
Listing 54.3 `dense.py`: a dual encoder trained with the contrastive loss of Equation (54.4). 993
Listing 54.4 `search_app.py`: the same questions answered by keyword search, LSA and the dense encoder. 996

Listing 54.5 `evaluate_all.py`: precision, recall and MRR of keyword, LSA, dense and hybrid search. 997
Listing 54.6 `neighbors.py`: nearest words in LSA space, and the dense encoder's answer to a one-word question. 998
Listing 54.7 `test_search.py`: the stemmer, unit vectors, exact-word retrieval, unknown words and dense training. 999
Listing 54.8 `sol_k_sweep.py`: choosing k on one half of the questions and reporting on the other. 1003
Listing 54.9 `sol_new_article.py`: adding an article after training. 1004
Listing 55.1 `ranking.py`: fielded BM25, features, DCG and nDCG, evaluation, pairwise training data, and filtered search. 1011
Listing 55.2 `train_rank.py`: cross-validated learning to rank, and the weights used by the search box. 1014
Listing 55.3 `search_app.py`: the shop's search box, with BM25 and learned ranking side by side. 1016
Listing 55.4 `test_ranking.py`: DCG by hand, unknown words, idf ordering, mirrored pairs and filters. 1018
Listing 55.5 `sol_ablation.py`: feature ablation with 4-fold cross-validation over queries. 1022
Listing 55.6 `sol_missed.py`: judged products that retrieval never returns. 1023
Listing 56.1 `make_orders.py`: 2,000 simulated shop orders built from typical needs plus impulse purchases. 1029
Listing 56.2 `apriori.py`: support counting, candidate generation with pruning, the level-by-level search, and rule generation. 1030
Listing 56.3 `mine_orders.py`: frequent itemsets and the strongest rules in the shop's orders. 1032
Listing 56.4 `also_bought.py`: the "customers who bought this also bought" box for one product. 1034
Listing 56.5 `laundry_rules.py`: association rules between laundry services used in the same month. 1035
Listing 56.6 `test_apriori.py`: the worked example of Section 56.3, agreement with a brute-force counter, and pruning. 1036
Listing 56.7 `sol_support_sweep.py`: the effect of the minimum support. 1040
Listing 56.8 `sol_subset_count.py`: counting pairs directly, compared with Apriori. 1040
Listing 57.1 `make_songs.py`: a catalog of 80 invented songs with audio features. 1047
Listing 57.2 `playlist.py`: standardized distances, similar songs, greedy and 2-opt ordering, and beam search for an energy arc. 1048
Listing 57.3 `playlist_app.py`: songs like one seed, a smooth ordering, and the Saturday-morning arc. 1051
Listing 57.4 `taste.py`: a taste profile from finished and skipped songs, and new suggestions. 1055
Listing 57.5 `test_playlist.py`: symmetric distances, 2-opt never lengthens a path, and the arc obeys its rules and reports the right score. 1056
Listing 57.6 `sol_lambda.py`: the trade-off between following the arc and smooth transitions. 1059
Listing 57.7 `sol_beam.py`: the objective of the arc for four beam widths. 1060
Listing 58.1 `newsbandit.py`: the reader simulator, five bandit policies and the experiment loop. 1066
Listing 58.2 `simulate.py`: five policies, 20,000 visits, five seeds each. 1070
Listing 58.3 `inspect_linucb.py`: LinUCB's estimated click rates next to the true ones for two readers. 1072
Listing 58.4 `test_bandits.py`: Sherman–Morrison against a direct inverse, UCB1's first round, Thompson's preference and the sign of regret. 1072
Listing 58.5 `sol_alpha.py`: LinUCB's click rate for three levels of optimism. 1076
Listing 58.6 `sol_replay.py`: offline evaluation of two policies by replaying a randomly logged stream. 1076
Listing 59.1 `dupdetect.py`: question types, domain concepts, six pair features, the logistic detector, and training and test pairs. 1083
Listing 59.2 `evaluate.py`: pair-level scores and question-level matching for lexical and full detectors. 1087
Listing 59.3 `ask.py`: match a customer's question to the FAQ, or send it to the staff. 1090

Listing 59.4 `test_dup.py`: the Jaccard example by hand, types and concepts, symmetric features, and the number of pairs. 1091
Listing 59.5 `sol_threshold.py`: precision and recall of the full detector at five thresholds. 1094
Listing 59.6 `sol_interaction.py`: an interaction feature between question type and concepts. 1095
Listing 60.1 `make_log.py`: 4,000 simulated searches over 30 days with Zipf-distributed popularity. 1101
Listing 60.2 `autocomplete.py`: a trie with cached top-k lists, Levenshtein search in the trie, an interpolated bigram model and the combined suggester. 1102
Listing 60.3 `evaluate.py`: success at 5 and MRR by prefix length, keystrokes saved, and the fate of never-seen queries. 1105
Listing 60.4 `app_web.py`: a Flask server with a search page and a `/suggest` endpoint on port 5060. 1107
Listing 60.5 `try_web.py`: calling the web endpoint without a server. 1108
Listing 60.6 `test_autocomplete.py`: top-k order, typo tolerance, probabilities that sum to one, and the web endpoint. 1109
Listing 60.7 `sol_memory.py`: the size of the trie and of its top-k cache. 1112
Listing 60.8 `sol_top3.py`: keystrokes saved when accepting from the top 1, 3 or 5. 1113
Listing 61.1 `forecasters.py`: naive, moving average, SES and Holt's method, with SSE-based tuning and the MAE. 1118
Listing 61.2 `sales_forecast.py`: the weekly sales forecaster for Profitina Laundry. 1121
Listing 61.3 `improve.py`: a damped Holt method and a 95% interval for SES, with a coverage check. 1124
Listing 61.4 `test_forecasters.py`: small checks with answers known in advance. 1127
Listing 62.1 `demand_forecast.py`: daily orders, calendar features, Poisson regression and two baselines. 1134
Listing 62.2 `improve.py`: a payday feature test, a check of the Poisson assumption, and a staffing plan with a 90% upper bound. 1140
Listing 62.3 `test_demand.py`: checks on the daily series, the calendar features and the baseline. 1142
Listing 63.1 `arima.py`: simulation, differencing, ACF, PACF, Yule–Walker, CSS estimation, AIC, ψ weights and forecasting. 1151
Listing 63.2 `arima_demo.py`: difference, inspect, fit nine candidates, choose by AIC, forecast and test. 1155
Listing 63.3 `experiment.py`: the whole ARIMA procedure repeated on 30 simulated series. 1159
Listing 63.4 `test_arima.py`: checks of differencing, ACF, PACF, ψ weights and estimation. 1161
Listing 64.1 `detect_anomalies.py`: rules, z-scores, robust z-scores and an isolation forest over the laundry bills. 1168
Listing 64.2 `evaluate.py`: plant 40 anomalies of four kinds and measure every detector. 1173
Listing 64.3 `improve.py`: rules plus two one-sided robust checks. 1176
Listing 64.4 `test_detectors.py`: masking of the classic z-score and two facts about the laundry data. 1178
Listing 65.1 `make_data.py`: sixty washing cycles with two sensors and forty planted faults. 1184
Listing 65.2 `fault_detector.py`: expected readings, a robust noise level, five checks and an honest score. 1188
Listing 65.3 `tune_cusum.py`: detection delay against false alarms for six values of h. 1193
Listing 65.4 `test_faults.py`: the CUSUM is silent on 5,000 samples of noise and catches a shift of two units after seven samples. 1194
Listing 66.1 `make_data.py`: one year of hourly temperature and electricity use for a laundry outlet. 1201
Listing 66.2 `energy_predictor.py`: day-ahead features, three models and the error in rupiah. 1203
Listing 66.3 `improve.py`: the oracle that knows the recipe, and errors of hourly and daily predictions. 1207
Listing 66.4 `test_energy.py`: exact positions of the lag features and no cooling while closed. 1209
Listing 67.1 `queue_time.py`: time in the shop, Little's law, quantile models and the promise for a new order. 1216
Listing 67.2 `improve.py`: split conformal calibration of the 90% promise, and an Erlang C what-if for the front counter. 1221

Listing 67.3 `test_queue.py`: Erlang C for one server equals ρ, and the pinball loss is asymmetric as intended. 1224
Listing 68.1 `price_sim.py`: geometric Brownian motion with normal or fat-tailed shocks, and the questions a simulation answers. 1230
Listing 68.2 `convergence.py`: error of the Monte Carlo mean against the number of samples, plain and antithetic. 1234
Listing 68.3 `test_price_sim.py`: shape and start of the paths, the mean against theory, and the kurtosis of normal data. 1236
Listing 69.1 `detectors.py`: Welford warm-up, EWMA chart, two-sided CUSUM and Page–Hinkley, each with an `update(x)` method. 1242
Listing 69.2 `event_stream.py`: a generated request stream with three planted events, and a score for each detector. 1245
Listing 69.3 `laundry_events.py`: daily orders replayed as a stream, with a weekday baseline and a CUSUM. 1248
Listing 69.4 `tune_arl.py`: average run length without a change and detection delay after a small shift, for six thresholds. 1251
Listing 69.5 `test_detectors.py`: Welford against NumPy, and every detector alarms within 30 steps of a four-sigma jump. 1253
Listing 70.1 `backtest.py`: five forecasters, rolling-origin evaluation, five error measures by method and horizon, and the Diebold–Mariano test. 1260
Listing 70.2 `improve.py`: 90% intervals from past backtest errors, and the price of tuning on the test period. 1266
Listing 70.3 `test_backtest.py`: seasonal naive repeats the week, Holt–Winters learns a pure weekly pattern, no future data leaks into training, and the DM test prefers smaller errors. 1268
Listing 71.1 `bandits.py`: a fixed A/B split, epsilon-greedy, UCB1 and Thompson sampling behind one interface, plus the visitor simulator. 1277
Listing 71.2 `run_ab_test.py`: one detailed month of Thompson sampling, then 100 repetitions of all four rules. 1280
Listing 71.3 `test_bandits.py`: three quick checks of the decision rules. 1284
Listing 71.4 `improve.py`: a stopping rule based on the probability of being best, and a Thompson sampler whose memory fades. 1285
Listing 71.5 `sol_ucb.py`: UCB with the exploration bonus scaled by c, compared with UCB1 and Thompson sampling. 1290
Listing 72.1 `gridworld.py`: the laundry-room grid, its slippery transition model, and a way to print a policy as arrows. 1295
Listing 72.2 `agents.py`: value iteration (planning with the model), and Q-learning and SARSA (learning from experience). 1298
Listing 72.3 `train.py`: plan with value iteration, then learn with Q-learning and SARSA, and compare. 1299
Listing 72.4 `test_gridworld.py`: four checks of the world and the algorithms. 1302
Listing 72.5 `improve.py`: agreement between the learned and the planned policy as training grows. 1303
Listing 72.6 `sol_slip.py`: optimal policies for three slip probabilities. 1306
Listing 73.1 `baselines.py`: the Gymnasium loop, a random controller, and two hand-written rules. 1312
Listing 73.2 `reinforce.py`: a softmax policy network trained with REINFORCE and normalized returns. 1313
Listing 73.3 `seeds.py`: the same training recipe with five random seeds. 1318
Listing 73.4 `test_cartpole.py`: three checks of the returns, the policy network, and the rule. 1318
Listing 73.5 `robustness.py`: the learned policy and the rule in five altered worlds. 1319
Listing 73.6 `sol_hidden.py`: training networks with 2, 8 and 32 hidden units. 1322
Listing 74.1 `thermo_env.py`: a one-room thermal simulator with Surabaya-like weather, random occupancy and the PLN tariff. 1328
Listing 74.2 `baselines.py`: a thermostat, a fixed timer, an occupancy switch and a report line. 1331
Listing 74.3 `q_agent.py`: tabular Q-learning over (hour, temperature bucket, occupancy), sixteen simulated days at a time. 1332

Listing 74.4 `policy_net.py`: a softmax policy over the four AC levels, trained with REINFORCE on batches of 32 simulated days. 1333
Listing 74.5 `compare.py`: every controller on the same 30 test days and in a heat wave. 1335
Listing 74.6 `test_thermo.py`: checks of the meter, the room physics, the thermostat and the state index. 1339
Listing 74.7 `tradeoff.py`: the same Q-learning agent trained with four prices for one degree-hour of discomfort. 1341
Listing 74.8 `sol_outdoor.py`: a Q-table that also knows whether it is hotter than usual, trained on normal days and heat waves. 1344
Listing 75.1 `demand.py`: willingness-to-pay customers for iced coffee and a day of bread sales in two-hour blocks. 1351
Listing 75.2 `guardrails.py`: allowed prices for coffee and bread, and an audit of a day's posted bread prices. 1353
Listing 75.3 `bandit_price.py`: a fixed price, epsilon-greedy and Thompson sampling choosing the weekly coffee price for 52 weeks. 1353
Listing 75.4 `markdown_q.py`: Q-learning for markdowns, with exploring starts, visit-count step sizes and an option to switch the guardrails off. 1355
Listing 75.5 `audit.py`: the posted prices of both agents on three kinds of day, checked against the rules. 1358
Listing 75.6 `test_pricing.py`: the demand at the mean willingness, the allowed prices, the markdown rule, the audit and the state index. 1362
Listing 75.7 `sol_ceiling.py`: the weekly cost of the price ceiling in a normal week and in a festival week. 1365
Listing 76.1 `inventory.py`: daily bag use from `Bill.csv`, the item's costs, and the stockroom as a Markov decision process. 1372
Listing 76.2 `value_iteration.py`: value iteration for the Bellman equation, exact policy evaluation, and a readable description of the optimal rule. 1375
Listing 76.3 `ss_policy.py`: the (s, S) rule of Equation (76.7), and an exact search over all such rules. 1376
Listing 76.4 `mc_plan.py`: Monte Carlo planning with common random numbers and a base (s, S) rule. 1377
Listing 76.5 `mcts.py`: Monte Carlo tree search over reorder decisions, with UCB selection and base-rule rollouts. 1379
Listing 76.6 `replay.py`: every rule on the real year of bag use, with the costs split into bags, fees, holding and emergency purchases. 1380
Listing 76.7 `test_inventory.py`: checks of the demand data, one day of the stockroom, the (s, S) rule and the solver. 1385
Listing 76.8 `sol_courier.py`: the optimal rule when the courier comes the next morning with probability 0.8. 1389
Listing 76.9 `sol_detergent.py`: the same model for liquid detergent in liters. 1389
Listing 77.1 `routes.py`: distances, tour length, nearest neighbor, 2-opt, simulated annealing, Held–Karp, and cheapest insertion. 1395
Listing 77.2 `plan_route.py`: the morning plan computed four ways, with lengths and running times. 1398
Listing 77.3 `check_exact.py`: comparing the heuristics with the exact Held–Karp optimum on two 12-customer instances. 1400
Listing 77.4 `test_routes.py`: four checks of the route algorithms. 1401
Listing 77.5 `replan.py`: inserting three new orders into the remaining route, then polishing the rest with 2-opt. 1401
Listing 78.1 `market.py`: a regime-switching geometric Brownian motion that writes simulated prices. 1411
Listing 78.2 `backtest.py`: a paper-trading backtester with costs, risk metrics, and four simple strategies. 1412
Listing 78.3 `compare.py`: four rule-based strategies on the same simulated market. 1414

Listing 78.4 `rl_trader.py`: a Q-learning paper trader trained on the first 1,000 days and tested on the last 500. 1415
Listing 78.5 `luck.py`: 200 coin flippers on one market, and the Q-learning trader on 20 different simulated markets. 1417
Listing 78.6 `test_backtest.py`: five checks of the backtester and the features. 1419
Listing 79.1 `ring_road.py`: the Nagel–Schreckenberg ring road and the measurement of flow at different densities. 1427
Listing 79.2 `junction.py`: a two-road junction with Poisson arrivals, a fixed-time controller and an adaptive controller. 1428
Listing 79.3 `test_traffic.py`: three checks of the ring road and the junction. 1433
Listing 79.4 `improve.py`: the road's capacity for four values of the dawdling probability. 1433
Listing 79.5 `sol_webster.py`: fixed timers set by Webster's formula compared with the 30-second timer and the adaptive light. 1436
Listing 80.1 `strips.py`: STRIPS actions, breadth-first search, A*, and the goal-count and additive heuristics. 1441
Listing 80.2 `laundry_domain.py`: the laundry shop as STRIPS facts and actions, for any number of bags. 1444
Listing 80.3 `plan.py`: the one-bag plan, and four planners compared on one to three bags. 1444
Listing 80.4 `test_strips.py`: four checks of the STRIPS machinery and the laundry domain. 1446
Listing 80.5 `agent.py`: plan, act, monitor, replan: the dryer breaks down during the morning. 1447
Listing 81.1 `stub/tinylm.py`: the trigram language model, the sampling rules and the generation loop. 1458
Listing 81.2 `stub/router.py`: choosing between the rule-based skills and the trigram model, and imitating the context window. 1463
Listing 81.3 `stub_server.py`: tinystub, an HTTP server that answers Ollama's API paths with the trigram model and the rule-based skills. 1466
Listing 81.4 `llm.py`: a dependency-free client for Ollama's HTTP API; the one setting `OLLAMA_HOST` chooses the server. 1472
Listing 81.5 `hello_llm.py`: one request to `/api/generate`, and the speed computed with Equation (81.9). 1474
Listing 81.6 `stream_demo.py`: reading `/api/chat` as NDJSON, one object per token. 1475
Listing 81.7 `next_word.py`: one prediction step of the trigram model, reshaped by temperature and sampled. 1476
Listing 81.8 `official_client.py`: the official `ollama` package (version 0.6.2) talking to tinystub. 1478
Listing 81.9 `sol_speed.py`: median generation speed over five seeded requests. 1481
Listing 81.10 `sol_perplexity.py`: perplexity of three sentences under the stub's English model. 1481
Listing 82.1 `chat_memory.py`: full, window, budget and summary memory, and a chat session that measures what each request costs. 1486
Listing 82.2 `chat_app.py`: a terminal chat with a choice of memory, streaming replies, and save/load. 1490
Listing 82.3 `stub/skills_chat.py` (in `Chapter081`): the stub's greeting and recall rules; recall can only use the messages of the current request. 1491
Listing 82.4 `compare_memory.py`: the same scripted conversation under four memory policies. 1493
Listing 82.5 `profile_memory.py`: window memory plus a profile of facts extracted with structured output and pinned into the system message. 1496
Listing 82.6 `compare_profile.py`: window memory with and without a pinned profile. 1497
Listing 83.1 `prompts.py`: six prompt templates for the review task, and the parser for the answers. 1504
Listing 83.2 `prompt_lab.py`: every template on the same twelve test reviews. 1505
Listing 83.3 `stub/skills_prompt.py` (in `Chapter081`): the stub's rules for few-shot examples and fixed answer choices. 1506
Listing 83.4 `temperature_lab.py`: ten answers per temperature, scored for variety and relevance. 1508
Listing 83.5 `dynamic_shots.py`: the four most similar examples for each review, instead of the same eight for all. 1511
Listing 84.1 `rag.py`: chunking, indexing, cosine search and the grounded prompt. 1519

Listing 84.2 `stub/embed.py` (in `Chapter081`): embeddings by feature hashing, with a small bilingual concept list. 1521
Listing 84.3 `stub/skills_rag.py` (in `Chapter081`): extractive answers from the context, with the source in brackets. 1523
Listing 84.4 `eval_rag.py`: hit@k and MRR for two retrievers, and a check of every grounded answer. 1523
Listing 84.5 `tune_k.py`: grounded answers and prompt size for several values of *k* 1527
Listing 85.1 `doc_tools.py`: one-request and map-reduce summaries, and translation paragraph by paragraph. 1535
Listing 85.2 `stub/skills_docs.py` (in `Chapter081`): the stub's extractive summarizer and dictionary translator. 1536
Listing 85.3 `metrics.py`: ROUGE-1, ROUGE-L and chrF from their definitions. 1539
Listing 85.4 `evaluate.py`: ROUGE for four summaries and chrF for two translations. 1541
Listing 85.5 `protect_names.py`: placeholders keep names untranslated. 1543
Listing 86.1 `order_schema.py`: one laundry order as a Pydantic model, and the extraction instruction. 1551
Listing 86.2 `extract_orders.py`: structured output with validation, one retry with the error message, and a human review file. 1552
Listing 86.3 `stub/skills_json.py` (in `Chapter081`): the stub fills a JSON Schema with regular expressions and per-field heuristics. 1554
Listing 86.4 `compare_modes.py`: parse rate, validity and field accuracy for three ways of asking. 1557
Listing 86.5 `checks.py`: business-rule checks that catch valid but wrong orders. 1561
Listing 87.1 `tools.py`: four tools over the laundry's data, their JSON Schemas, and a gate that validates every call. 1569
Listing 87.2 `agent.py`: the agent loop with a step limit and a trace of every tool call. 1572
Listing 87.3 `stub/skills_tools.py` (in `Chapter081`): choosing tools by shared key terms and filling their arguments by rules. 1572
Listing 87.4 `safe_agent.py`: an action tool that runs only after a person confirms it. 1576
Listing 88.1 `samples/daily_report.py`: a short script with six planted bugs and some untidy style. 1584
Listing 88.2 `reviewer.py`: explanations as prose, reviews as validated JSON findings, a Markdown report and a build gate. 1586
Listing 88.3 `stub/skills_code.py` (in `Chapter081`): the stub explains and reviews Python code with the `ast` module and a dozen rules. 1588
Listing 88.4 `seeded_bugs.py`: the reviewer scored against six bugs planted on purpose. 1593
Listing 89.1 `harness.py`: test cases with checks, repeated runs, per-category pass rates with Wilson intervals, and latency percentiles. 1600
Listing 89.2 `gate.py`: a regression gate over per-category pass rates. 1603
Listing 89.3 `failures.py`: the first failing output of each case, read from `results.csv` 1607
Listing 90.1 `stub/skills_safety.py` (in `Chapter081`): the stub obeys classic injection phrasings, so that the guardrails have something real to stop. 1614
Listing 90.2 `guardrails.py`: redaction with a Luhn check, an injection detector, a token bucket, and an assistant wrapped in input and output guards. 1615
Listing 90.3 `attack_suite.py`: eleven attacks and nine benign prompts against the raw and the guarded assistant. 1619
Listing 90.4 `show_answers.py`: raw and guarded answers to three attacks. 1620
Listing 90.5 `rate_limit_demo.py`: the token bucket with a fake clock. 1622
Listing 90.6 `threshold_sweep.py`: detector scores, and caught attacks against false alarms for five thresholds. 1622
Listing 91.1 `eta_model.py`: loading orders, the time split, the two quantile models and the bundle that holds them. 1631
Listing 91.2 `train_model.py`: train on the old orders, evaluate on the new ones, save the bundle with a version label. 1634

Listing 91.3 `app.py`: the FastAPI service with startup loading, validated input, a timing middleware, four endpoints and offline documentation. 1635
Listing 91.4 `client.py`: calling the running service from another program. 1641
Listing 91.5 `bench.py`: latency of single requests versus batches. 1643
Listing 91.6 `test_app.py`: the health check, a sanity bound on predictions and the refusal of bad input. 1645
Listing 91.7 `sol_service_info.py`: a new endpoint added from outside `app.py`. 1649
Listing 91.8 `sol_baseline.py`: the per-service median rule as a baseline. 1649
Listing 91.9 `sol_api_key.py`: an API-key check as a FastAPI dependency. 1650
Listing 92.1 `texts.py`: every word the page shows, in English and Indonesian, under the same keys. 1656
Listing 92.2 `web.py`: the Flask application with the page, server-side validation and a JSON route for the live estimate. 1657
Listing 92.3 `templates/index.html`: the Jinja template of the page. 1660
Listing 92.4 `static/style.css`: the stylesheet. 1663
Listing 92.5 `static/live.js`: sending the form as JSON whenever it changes and showing the answer in one element. 1663
Listing 92.6 `test_web.py`: five tests of the front end, including the escaping of hostile input. 1666
Listing 92.7 `sol_health.py`: a health route added to the Flask application. 1669
Listing 92.8 `sol_dates.py`: a friendly ready time in English and Indonesian. 1670
Listing 92.9 `live_debounced.js`: the live estimate with a 300 ms debounce. 1671
Listing 93.1 `metrics.py`: loading the orders and computing the indicators, the daily series and the breakdowns. 1675
Listing 93.2 `dashboard.py`: the Streamlit dashboard, from language choice and filters to headline numbers, charts, table and the “what if?” estimate. 1677
Listing 93.3 `.streamlit/config.toml`: Streamlit settings for this dashboard. 1681
Listing 93.4 `timing.py`: the cost of the work the caches avoid, compared with the work every rerun does. 1684
Listing 93.5 `test_dashboard.py`: unit tests of the numbers and whole-page tests with `AppTest`. 1684
Listing 93.6 `sol_ticket.py`: the average ticket per outlet. 1687
Listing 93.7 `sol_growth.py`: the quarterly change per outlet over periods of 91 and 92 days. 1688
Listing 93.8 `sol_busiest.py`: orders by weekday and time of day over the whole year. 1688
Listing 94.1 `digit_model.py`: training the digit classifier on the bundled 8 by 8 digits, and turning any drawing into its 64 input numbers. 1693
Listing 94.2 `make_examples.py`: three example digits drawn with thick lines on white paper. 1694
Listing 94.3 `demo.py`: a Gradio Blocks app with a digit recognizer and the laundry ETA form, in English or Indonesian. 1695
Listing 94.4 `client.py`: calling the two endpoints of the running demo from Python. 1699
Listing 94.5 `test_demo.py`: tests of the preprocessing, the recognizer on the examples, and the ETA function. 1700
Listing 94.6 `sol_confusion.py`: the mistakes of the digit model on held-out data. 1702
Listing 94.7 `sol_no_crop.py`: the same drawing with and without cropping and centering. 1703
Listing 94.8 `sol_interface.py`: the ETA form as a one-call `gr.Interface` 1703
Listing 95.1 `pyproject.toml`: the build system, the package metadata, the dependencies, the command and the model file to include. 1708
Listing 95.2 `src/laundry_eta/__init__.py`: the package’s version, in one place. 1709
Listing 95.3 `src/laundry_eta/__main__.py`: running the package with `python -m`. 1709
Listing 95.4 `src/laundry_eta/cli.py`: the `laundry-eta` command with four subcommands, validated options, separate output channels and exit codes. 1709
Listing 95.5 `tests/test_cli.py`: five tests of the command, from the packaged model file to exit codes and error messages. 1717
Listing 95.6 `timing.py`: running `laundry-eta batch` on files of four sizes and fitting start-up cost and cost per order. 1718
Listing 95.7 `fast_batch.py`: one prediction call per order versus one call for all orders. 1719

Listing 95.8 `sol_fast_cli.py`: a batch that validates first and predicts once. 1722
Listing 96.1 `pytest.ini`: where the tests live and what they can import. 1729
Listing 96.2 `tests/conftest.py`: data, split and model prepared once per test session. 1729
Listing 96.3 `tests/test_features.py`: the feature code on a tiny file with known answers, and the time split. 1730
Listing 96.4 `validate.py`: data validation rules for `Bill.csv`. 1731
Listing 96.5 `tests/test_data.py`: the real data passes; broken data is caught. 1731
Listing 96.6 `tests/test_behavior.py`: a minimum functionality test, a directional expectation test and a property-based test with Hypothesis. 1732
Listing 96.7 `tests/test_quality.py`: better than the per-service median rule, error and coverage within bounds, and reproducible training. 1734
Listing 96.8 `unit_evidence.py`: turnaround by weight in the data, and the model's error with and without the weight feature. 1735
Listing 96.9 `mutation_demo.py`: mutation testing by hand, six planted bugs. 1737
Listing 96.10 `sol_test_extra.py`: a test of the missing-columns message and an invariance test. 1740
Listing 97.1 `tracker.py`: a run as a context manager that records parameters, metrics, fingerprints, environment and artifacts, and keeps an index of all runs. 1745
Listing 97.2 `experiments.py`: sixteen tracked runs, trained on October to April and scored on May and June. 1748
Listing 97.3 `show_runs.py`: the five best grid runs and the "final" run. 1751
Listing 97.4 `select_best.py`: the one and only look at the test period. 1752
Listing 97.5 `reproduce.py`: rerun a recorded run and report what, if anything, changed. 1753
Listing 97.6 `change_one_row.py`: one corrected finishing time in a copy of the data. 1754
Listing 97.7 `sol_pairs.py`: the effect of the weight feature in each of the eight pairs. 1757
Listing 97.8 `sol_peek.py`: the winner's validation score against its test score, and its rank on the test period. 1758
Listing 98.1 `drift.py`: the Population Stability Index, its numeric variant, the KS test and the PSI levels. 1763
Listing 98.2 `replay.py`: going live on January 1, 2026 and logging every prediction for nine months. 1764
Listing 98.3 `monitor.py`: the monthly health report with its alert rules. 1766
Listing 98.4 `sol_ks.py`: turnaround of wash-and-fold in February, March and April against December 2025. 1768
Listing 98.5 `retrain_compare.py`: never retraining versus retraining on the first day of every month. 1769
Listing 98.6 `sol_weekly.py`: weekly MAE and coverage around the March holidays. 1773
Listing 99.1 `privacy.py`: keyed pseudonyms, age bands, minimization and the k-anonymity check. 1779
Listing 99.2 `privacy_demo.py`: the customer table before and after minimization and generalization. 1780
Listing 99.3 `dp_counts.py`: counts published with differential privacy at three levels of ε. 1781
Listing 99.4 `fairness.py`: per-group selection rate, TPR and FPR, and the fairness summaries of Equation (99.4) and Equation (99.5). 1782
Listing 99.5 `voucher_model.py`: the voucher model and a fairness audit of three voucher policies. 1783
Listing 99.6 `model_card.py`: a model card generated from the model's own evaluation. 1786
Listing 99.7 `sol_kanon.py`: k-anonymity with ten-year age bands and with three broad bands. 1790
Listing 99.8 `sol_equalize.py`: group-specific thresholds that equalize the true positive rate. 1791
Listing 100.1 `faq.py`: BM25 search over the bilingual FAQ, with a minimum score below which it admits it has no answer. 1797
Listing 100.2 `forecast.py`: a seven-day forecast per outlet from an exponentially smoothed level and a weekday profile, and its backtest. 1798
Listing 100.3 `segments.py`: RFM features, k-means with a fixed seed, and segment names chosen from the cluster medians. 1799
Listing 100.4 `evaluate.py`: the quality of the ETA model, the forecast, the segments and the FAQ search. 1800

Listing 100.5 `llm.py`: a small client for Ollama's `/api/chat`, configured by `OLLAMA_HOST` and `LLM_MODEL`. 1802
Listing 100.6 `assistant.py`: intent routing, the four fact-gathering tools, the grounded prompt, and the honest fallback. 1803
Listing 100.7 `fallback_demo.py`: the answer when no language model is reachable. 1806
Listing 100.8 `app.py`: the chat page, `POST /api/ask`, and tinystub at `/stub/api/chat`. 1806
Listing 100.9 `client.py`: six questions in two languages. 1808
Listing 100.10 `tests/test_assistant.py`: six tests of the assistant. 1810
Listing 100.11 `sol_synonyms.py`: query expansion with a small synonym table. 1814

List of Pseudocode

Pseudocode 1.1 The halving guesser: the possibilities are the whole numbers from `low` to `high`, and every question removes at least half of them. 9
Pseudocode 2.1 Categorizing statements with rules, a learned model and questions, then checking the budget. 26
Pseudocode 3.1 A* search on the warehouse grid; with $w = 1$ and the Manhattan distance it returns a shortest path, and with $h = 0$ it behaves like breadth-first search. 48
Pseudocode 3.2 Planning the route of one trip: nearest neighbor, then 2-opt until no reversal shortens the route. 48
Pseudocode 4.1 The greedy rule: repeatedly add the step of food that closes the largest share of the remaining gap per rupiah. 73
Pseudocode 5.1 Backtracking search with the minimum-remaining-values rule and forward checking. 92
Pseudocode 5.2 Local search: keep any swap of two cells of one class that keeps the hard rules and lowers the penalty. 93
Pseudocode 6.1 Handling one customer message: rules, classifier, threshold, form filling and handoff. 111
Pseudocode 7.1 Backward chaining with certainty factors: conditions are established on demand, and the user is asked only when no rule can conclude a fact. 133
Pseudocode 8.1 A* search on a weighted graph; Dijkstra's algorithm is the special case $h = 0$. 155
Pseudocode 9.1 The genetic algorithm: tournament selection, order crossover, swap mutation and elitism. 171
Pseudocode 10.1 Mamdani fuzzy inference with min for AND, clipping, max aggregation and a sampled centroid. 188
Pseudocode 80.1 Forward state-space search over STRIPS states; the choice in line 3 turns it into breadth-first search or A*. 1440

Preface

A shopkeeper photographs a receipt and her phone files it under “stock”. A clinic’s schedule fills itself without two doctors in the same room. A small laundry answers “is my order ready?” at midnight without anyone awake. None of this needs a research lab. It needs a person who knows how to turn an everyday problem into a few hundred lines of Python — and that person can be you.

This book teaches artificial intelligence and machine learning the way a craft is taught: by building. There are one hundred chapters and one hundred applications, and every one of them is something people really use: an expense categorizer, a route planner, a spam filter, a loan advisor, a sentiment analyzer, a demand forecaster, an anomaly detector, a recommender, a document assistant that runs on your own computer, a model served as a web service. They are ordered from the very easy — a program that guesses a number by asking good questions — to the very hard — a local language model that answers from your own documents, a reinforcement-learning agent that saves electricity, and a complete AI assistant for a small business.

Who this book is for

Anyone who wants to build useful software with AI, starting from nothing. You do not need to know how to program: Chapter 1 begins with an empty computer, installs VS Code and Python on Windows, macOS or Linux, and ends with your first AI program running. From there every idea is explained in plain words first, then shown in code, then run, then explained line by line. If you can follow a recipe, you can follow this book.

How the book is organized

The hundred chapters are grouped in ten parts of ten: classic AI that thinks by searching and reasoning; learning from data; language; neural networks; vision; recommenders and search; time series and anomalies; agents and reinforcement learning; local language models and generative apps; and turning a notebook into a product. Each chapter opens with the real-life use of its application, builds it step by step, runs it on real or realistic data, improves it, and ends with how to use it for real on your own data, common mistakes, a summary, and exercises with complete solutions.

Everything runs offline on an ordinary laptop. The data the programs use ships with them, and the language-model chapters work with a local model through Ollama — no paid service and no data leaving your computer. Every program was run before its output was printed; the code is collected chapter by chapter in the accompanying `Code` folder, with a README in every chapter folder that explains how to run it in a terminal and in VS Code on Windows, macOS and Linux.

How to read it

With the computer on. Type the programs in, run them, change one number and run them again. When a result surprises you, that is the moment you are learning. Use the solutions at the end of each chapter after your own attempt, not instead of it.

Numbered figures, tables, listings and equations are live links: in the electronic edition, click "Listing 12.3" or "[4]" anywhere in the text and you are taken straight to it. The contents and the lists at the front of the book work the same way.

About the author

Irfan Subakti describes himself in one line — *Father | Educator | Entrepreneur | Bridging Tech & Nature: CS Lecturer × Crypto/Digital Business × AI/ML Specialist × Fruit Farmer | Storyteller* — and every part of that line has found its way into this book. He has taught in the Department of Informatics at Institut Teknologi Sepuluh Nopember (ITS), Surabaya, since 1998. He supervises and examines undergraduate theses, teaches MLOps for the IBM SkillsBuild program, and builds products: he founded Profitina and the Profitina Group. Away from the keyboard he tends the family fruit and durian orchard, where he learned that good software, like a good orchard, is grown patiently, one well-tended piece at a time. The storyteller in him is the reason this book prefers a story to a list whenever a story will do.

Acknowledgments

To the students who tried these applications in their first, rougher forms and said honestly where they broke; to the open-source communities behind Python, NumPy, scikit-learn, PyTorch, Ollama and the many libraries this book stands on; and to every reader who types in a program, runs it, and makes it their own.

Surabaya, September 2026

Chapter 1

Your Workbench and a Number-Guessing AI

This chapter opens Part 1 of the book, *Thinking Machines: Classic AI*, ten chapters in which programs behave intelligently without learning anything from data: they search, reason with rules, satisfy constraints and weigh vague evidence, exactly as the first generation of artificial intelligence did. Before any of that can happen you need a place to work, so the chapter does two things. First it sets up your workbench, step by step, on Windows, macOS and Linux: Python 3.14, Visual Studio Code with the Python extension, a virtual environment, pip, and optionally Jupyter notebooks. Then it uses that workbench to build the first application of the book, a small program that asks you to think of a number and always finds it in at most seven questions. By the end of the chapter you will be able to install and check a professional Python setup on any of the three operating systems, create and activate a virtual environment, run and debug a program in VS Code, explain why halving the possibilities is the smartest way to ask questions, prove that 100 numbers never need more than 7 guesses, measure three strategies against each other, and write automatic tests that check your program for you.

1.1 Why Start with a Guessing Game?

Think of a whole number between 1 and 100 and keep it to yourself. A friend is allowed to guess, and after every guess you answer only “higher”, “lower” or “correct”. How many guesses does your friend need?

A patient but unimaginative friend starts at 1, then tries 2, then 3, and so on. If you picked 100, that friend needs a hundred guesses. A careless friend shouts random numbers and often wastes guesses on numbers your earlier answers had already ruled out. A clever friend says “50” first. Whatever you answer, half of the numbers disappear at once. The clever friend then says “75” or “25”, and half of what is left disappears again. After seven answers there is nothing left to hide in.

This game is the whole of artificial intelligence in miniature. There is an *agent* (the guesser) that cannot see the thing it needs to know (your secret). It has a set of *possibilities* that are still consistent with everything it has observed. It chooses an *action* (a guess), receives a *percept* (your answer), and updates its possibilities. A good agent chooses the action that teaches it the most. Every program in Part 1 has the same skeleton: the expense categorizer of Chapter 2 considers possible categories for each transaction, the picking-route optimizer of Chapter 3 considers possible paths through the warehouse, the timetable scheduler of Chapter 5 considers possible slots for each lesson, and the fuzzy controller of Chapter 10 considers how strongly each rule applies. Here the possibilities are simply the numbers from `low` to `high`, and the best action is the one in the middle.

There is a second, very practical reason to start here. The program is short enough that nothing about it can hide a problem with your tools. If it does not run, the problem is in the setup, not in the code, and the setup is what this chapter must get right. So we set up the workbench first, prove that it works with a small checking program, and then build the guessing AI on top of it.

1.2 What "AI" Means in This Book

The phrase *artificial intelligence* is used today for everything from a thermostat to a chatbot, so we should say what we mean by it. Russell and Norvig's textbook, the standard reference of the field, defines AI as the study of *agents* that receive percepts from an environment and perform actions, and it calls an agent *rational* when it chooses the action that is expected to achieve the best outcome given what it knows [1]. That definition does not mention learning, neural networks or language models. A program that plays perfect tic-tac-toe by thinking ahead is intelligent in this sense, and so is our guesser.

> **DEFINITION.** An *agent* is a program that repeatedly observes its environment (a *percept*), decides what to do, and acts. Its *state of knowledge* is everything that is still possible given what it has observed. A *rational* agent picks, at each step, the action with the best expected result for its goal.

The book follows the history of the field. Part 1 is classic, "symbolic" AI: search, logic, rules and constraints, the ideas that dominated from the 1950s to the 1980s and that still run inside route planners, game engines, schedulers and industrial controllers. Part 2 teaches machines to learn from data. Later parts cover language, neural networks, vision, recommenders, time series, reinforcement learning, local language models and finally turning a model into a product. Each chapter builds one complete application that you can run on your own computer without an internet connection, and every output printed in the book is the output the program really produced.

1.3 Setting up VS Code and Python on Windows, macOS and Linux

A carpenter's first job in a new workshop is to set up the bench: tools in reach, light in the right place, a vice that holds the work still. Our bench has four parts, summarized in **Table 1.1**. The versions are the current ones as of September 2026; newer patch releases (for example 3.14.8) work exactly the same way.

Table 1.1 The tools of the workbench and the versions used throughout the book.

Tool	What it is	Version used in this book
Python	The language and its interpreter, the program that runs `.py` files	3.14.7 (released August 5, 2026) [2]
pip	Python's package installer, bundled with Python	26.2.1
venv	Python's built-in tool for making a private, per-project environment	part of Python 3.14
Visual Studio Code	A free code editor from Microsoft for Windows, macOS and Linux	1.139 (September 2026) [3]
Python extension for VS Code	Adds running, debugging, IntelliSense (Pylance) and environment management	installed from the Extensions view
Jupyter (optional)	Notebooks: code, output and notes in one document	Jupyter extension + `ipykernel` 7.3

Python 3.14 was first released on October 7, 2025, and brought, among other things, template strings (`t"..."`), deferred evaluation of annotations, a free-threaded build without the global interpreter lock, and a colorful interactive shell with syntax highlighting [4]. None of the programs in Part 1 need those new features: they use plain, long-established Python, so they also run on Python 3.10 or newer. We still install 3.14, because it is the current version and because later chapters use libraries that are tested against it.

1.3.1 Windows 10 and 11

On Windows, Python is now installed with the **Python install manager**, a small program that downloads, updates and switches between Python versions for you. It replaces the old one-version-at-a-time installer, which remains available during the 3.14 and 3.15 releases [5]. You can get the install manager in any of three ways:

1. open the **Microsoft Store**, search for "Python Install Manager" and click **Install**;
2. download it from `https://www.python.org/downloads/windows/` (the file ends in `.msix`; double-click it and choose **Install**);
3. or, in a PowerShell window, type the `winget` command below.

```
winget install 9NQ7512CXL7T -e --accept-package-agreements --disable-interactivity
```

Now open a new **PowerShell** window (press the Windows key, type `powershell`, press Enter) and ask the manager for Python 3.14, then list what is installed:

```
PS C:\Users\you> py install 3.14
PS C:\Users\you> py list
PS C:\Users\you> python --version
Python 3.14.7
```

After installation three commands work in every terminal: `python` starts the current default version, `py` does the same and lets you pick a version (for example `py -V:3.14`), and `python3` is accepted too, so instructions written for macOS and Linux do not trip you up [5]. If `python --version` instead opens the Microsoft Store or prints an older version, close every terminal, open a new one and try again; the manager also offers to fix your settings with `py install --configure`.

One more Windows detail matters later. PowerShell refuses to run scripts by default, and activating a virtual environment runs a small script. Allow scripts that you created yourself, once, with:

```
PS C:\Users\you> Set-ExecutionPolicy -Scope CurrentUser RemoteSigned
```

1.3.2 macOS

macOS may already contain a `python3` command, but it is an older version provided for Apple's own tools; do not build on it. Use one of these two routes:

- **The python.org installer.** Download the macOS package for Python 3.14.7 from `https://www.python.org/downloads/macos/` and double-click it. It is a universal package that runs natively on Apple silicon and Intel Macs. At the end, the installer opens a folder in **Applications › Python 3.14**; double-click **Install Certificates.command** there once, so that Python can make secure web connections.
- **Homebrew**, if you already use it: `brew install python@3.14`.

Then open **Terminal** (Spotlight: Cmd+Space, type "Terminal") and check:

```
you@mac ~ % python3 --version
Python 3.14.7
```

On macOS and Linux the command is `python3`, not `python`, until a virtual environment is active; inside an environment both names work.

1.3.3 Linux

Most Linux distributions ship Python already, and the recent ones ship 3.14. Ubuntu 26.04 LTS, for example, uses Python 3.14 as its default `python3`, but it leaves out pip and venv, which come as separate packages [6]:

```
$ sudo apt update
$ sudo apt install python3 python3-venv python3-pip
$ python3 --version
Python 3.14.7
```

On Fedora the equivalent is `sudo dnf install python3 python3-pip`. If your distribution still provides an older Python (Ubuntu 24.04 ships 3.12), you have two good options: keep it, because every program in Part 1 runs on 3.10 or newer, or install 3.14 alongside it with a tool such as `uv` (`uv python install 3.14`), which downloads a ready-made build into your home folder without touching the system Python. Never remove or replace the system Python on Linux: parts of the operating system depend on it.

1.3.4 Visual Studio Code and the Python extension

Download Visual Studio Code from `https://code.visualstudio.com`. On Windows run the installer and tick **Add to PATH** and **Add "Open with Code" action**; on macOS drag the app into **Applications**; on Linux install the `.deb` or `.rpm` package (Ubuntu also offers it through **App Center** and the `snap` store). The current version in September 2026 is 1.139, released on September 23 [3]. VS Code updates itself every month, and nothing in this book depends on a particular month's release.

Start VS Code, click the **Extensions** icon in the Activity Bar on the left (or press Ctrl+Shift+X, on macOS Cmd+Shift+X), search for **Python** and install the extension published by **Microsoft** (identifier `ms-python.python`). It brings two companions with it: **Pylance**, which gives completion and error highlighting while you type, and **Python Debugger**, which lets you stop a running program and look inside it [7]. The **Python Environments** extension, which shows your interpreters and virtual environments in a side panel, works alongside it [8].

Figure 1.1 shows the parts of the window you will use in every chapter. The Activity Bar (1) switches between Explorer, Search, Extensions and the debugger. The Explorer (2) shows the files of the folder you opened. The editor (3) is where you type code. The Run button (4) runs the current file in the terminal. The integrated terminal (5), opened with **Terminal › New Terminal** or Ctrl+`, is an ordinary PowerShell, zsh or bash window that already sits in your project folder. The Status Bar (6) shows which Python interpreter VS Code uses; clicking it lets you choose another.

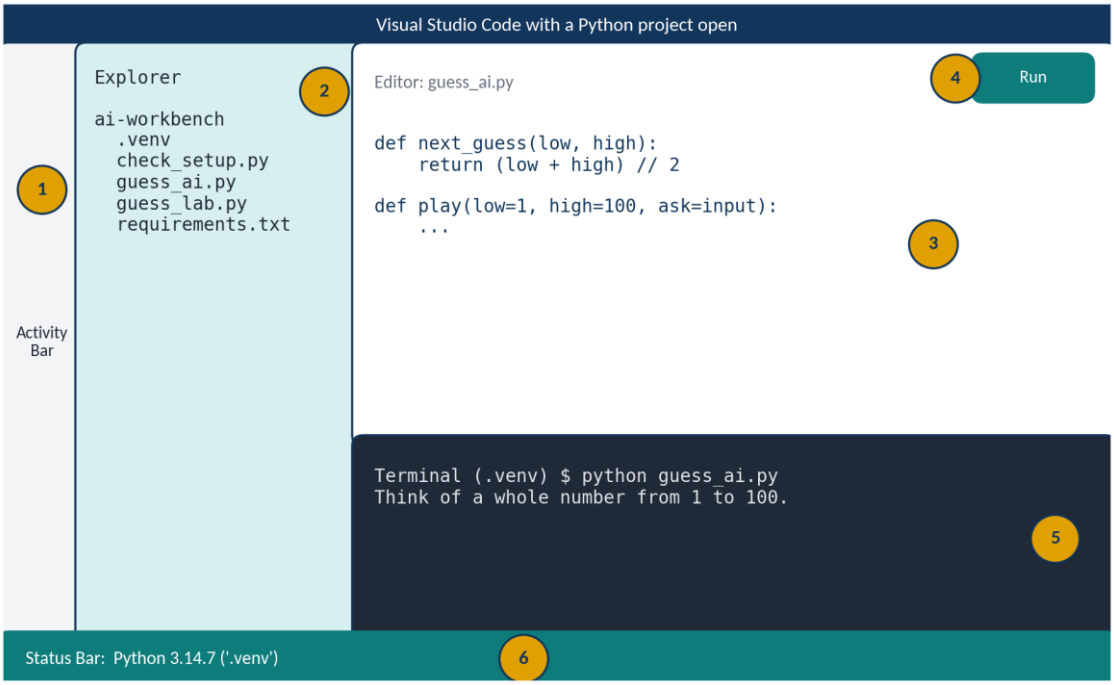

Figure 1.1 The parts of Visual Studio Code used in this book: (1) Activity Bar, (2) Explorer, (3) editor, (4) Run button, (5) integrated terminal, (6) Status Bar with the selected interpreter.

1.3.5 A project folder and a virtual environment

Every application in this book lives in its own folder, and every folder gets its own *virtual environment*. A virtual environment is a small directory, by convention called `.venv`, that contains its own `python` command and its own place for installed packages [9]. When it is *active*, `python` and `pip` refer to the copies inside `.venv`, and anything you install goes into `.venv` and nowhere else. Why bother? Because Chapter 33 needs PyTorch, Chapter 93 needs Streamlit, and a program you wrote two years ago may need an older version of a library than the program you write today. Separate environments keep those needs from colliding, and deleting a `.venv` folder removes everything in it without a trace.

Figure 1.2 shows the folder we build now. Create a folder called `ai-workbench` anywhere you like (for example in Documents), then, in VS Code, choose **File › Open Folder** and open it. Open the integrated terminal and create the environment:

```
python -m venv .venv          (Windows)
python3 -m venv .venv         (macOS and Linux)
```

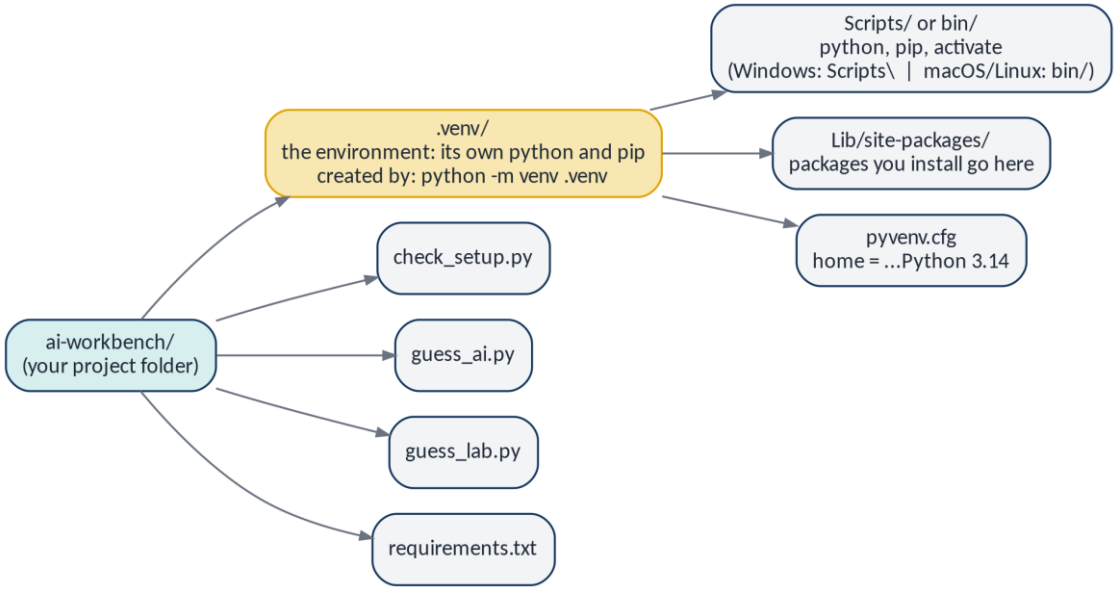

Figure 1.2 A project folder with its virtual environment: `.venv` holds a private `python`, `pip` and the packages installed for this project only.

Creating the environment is done once. *Activating* it is done in every new terminal, with the command for your system in **Table 1.2**. When the environment is active, the prompt starts with `(.venv)`. To leave it, type `deactivate`.

Table 1.2 Activating the virtual environment on each operating system.

System and shell	Activate the environment	You see
Windows, PowerShell	`.venv\Scripts\Activate.ps1`	`(.venv) PS C:\...\ai-workbench>`
Windows, Command Prompt	`.venv\Scripts\activate.bat`	`(.venv) C:\...\ai-workbench>`
macOS (zsh) and Linux (bash)	`source .venv/bin/activate`	`(.venv) you@host ai-workbench $`

VS Code can do all of this for you. Open the Command Palette (Ctrl+Shift+P, on macOS Cmd+Shift+P), run **Python: Create Environment**, choose **Venv** and Python 3.14, and it creates `.venv` and selects it [8]. From then on, every terminal VS Code opens in this folder activates the environment automatically, and the Status Bar shows `3.14.7 ('.venv')`. If the Status Bar shows some other Python, run **Python: Select Interpreter** and pick the one inside `.venv`.

1.3.6 pip and requirements.txt

`pip` installs packages from the Python Package Index (PyPI). Always call it as `python -m pip` rather than plain `pip`: the long form guarantees that the packages go to the Python you are actually running, which avoids the most common installation mystery of all [10]. The four commands you will use most are:

```
python -m pip install numpy==2.5.3        install one package, pinned to a version
python -m pip install -r requirements.txt install everything a project lists
python -m pip list                        show what is installed here
python -m pip show numpy                  show the version and location of one package
```

Every chapter folder in the book's code contains a `requirements.txt` that lists the exact versions the chapter was run with, one per line, such as `numpy==2.5.3`. Pinning versions is what makes a program reproducible: a reader who installs the same versions gets the same output. The programs of Part 1 need nothing beyond Python's standard library, so their `requirements.txt`

contains only comments, and `pip install -r requirements.txt` simply succeeds without installing anything.

1.3.7 Checking the workbench

Rather than trusting that everything went well, we write a first program that checks. Create a file `check_setup.py` in `ai-workbench` and type **Listing 1.1**.

Listing 1.1 `check_setup.py`: reports the Python version, whether a virtual environment is active and which pip it uses.

```
"""Check that the workbench is ready: Python, the virtual environment and pip."""
import platform
import sys
from importlib import metadata

RECOMMENDED = (3, 14)  # the version this book is written for
MINIMUM = (3, 10)      # the oldest version the book's code still runs on

def main():
    version = sys.version_info[:2]
    print(f"Python version : {platform.python_version()}")
    print(f"System         : {platform.system()} ({platform.machine()})")
    in_venv = sys.prefix != sys.base_prefix
    where = f"yes, folder '{sys.prefix.replace(chr(92), '/').split('/')[-1]}'"
    print(f"Virtual env.   : {where if in_venv else 'NO - activate .venv first'}")
    try:
        print(f"pip version    : {metadata.version('pip')}")
    except metadata.PackageNotFoundError:
        print("pip version    : not found - run: python -m ensurepip")
    if version < MINIMUM:
        print("Result         : too old, please install Python 3.14")
    elif version < RECOMMENDED:
        print("Result         : works, but Python 3.14 is recommended")
    elif not in_venv:
        print("Result         : Python is fine; now create and activate .venv")
    else:
        print("Result         : your workbench is ready")

if __name__ == "__main__":
    main()
```

The program uses three modules from the standard library. `sys` knows about the running interpreter: `sys.version_info` is the version as numbers that can be compared, `(3, 14)` with `(3, 10)`, and `sys.prefix` is the folder of the environment in use. Inside a virtual environment `sys.prefix` points into `.venv` while `sys.base_prefix` still points to the Python it was made from, so the two differ exactly when an environment is active. `platform` names the operating system and processor, and `importlib.metadata` reads the version of an installed package. The expression `chr(92)` is the backslash character; replacing it with `/` lets the same line pick the last folder name out of a Windows path and a macOS or Linux path.

Here is a complete session on Linux, from a fresh folder to a ready workbench. The commands are the ones from Sections 1.3.3 to 1.3.6; on Windows only the activation line differs.

```
$ python3 --version
Python 3.14.7
$ python3 -m venv .venv
$ source .venv/bin/activate
(.venv) $ python --version
Python 3.14.7
(.venv) $ python -m pip --version
pip 26.2.1 from /home/you/ai-workbench/.venv/lib/python3.14/site-packages/pip (python
3.14)
(.venv) $ python -m pip install -r requirements.txt
(.venv) $ python check_setup.py
Python version : 3.14.7
System         : Linux (x86_64)
Virtual env.   : yes, folder '.venv'
pip version    : 26.2.1
Result         : your workbench is ready
```

If you forget to activate the environment, the program says so:

```
Python version : 3.14.7
System         : Linux (x86_64)
Virtual env.   : NO - activate .venv first
pip version    : 26.2.1
Result         : Python is fine; now create and activate .venv
```

Run it in VS Code as well: open `check_setup.py` and click the Run button (4 in **Figure 1.1**). The output appears in the terminal (5). Then try the debugger once, because you will need it: click in the margin to the left of the line `version = sys.version_info[:2]` to set a red breakpoint dot, press F5, choose **Python File**, and the program stops on that line. Hover over `sys.version_info` to see its value, press F10 to step to the next line, and F5 to let it run to the end. Stepping through a program and watching its variables is the fastest way to understand code you did not write, including every program in this book.

1.3.8 Jupyter notebooks (optional)

A Jupyter notebook is a document of *cells*: a code cell runs and shows its output right below it, and a text cell holds notes. Notebooks are popular for experiments, and many AI tutorials are written as notebooks. This book uses plain `.py` files, which are easier to test, to version and to turn into applications, but you can open any of its programs in a notebook if you prefer. Install the **Jupyter** extension (publisher Microsoft) in VS Code, and install the kernel package into your environment:

```
(.venv) $ python -m pip install ipykernel
```

Then choose **File › New File › Jupyter Notebook**, click **Select Kernel** in the top right corner and pick `.venv` [11]. Type `import sys; sys.version` in the first cell and press Shift+Enter; it should print `3.14.7`. A full notebook server (`pip install jupyterlab`, then `jupyter lab`) is also available if you want to work in the browser, but inside VS Code the extension is all you need.

1.4 The Idea: Halve What Is Still Possible

Back to the game. The guessing AI keeps its knowledge in two numbers: `low`, the smallest number that is still possible, and `high`, the largest. At the start they are 1 and 100. It guesses the middle, `(low + high) // 2`. If you say “higher”, every number up to and including the guess is ruled out, so `low` becomes `guess + 1`. If you say “lower”, `high` becomes `guess - 1`. If you say “correct”, the game is over. If `low` ever becomes larger than `high`, no number fits all your answers, which means you made a mistake or changed your number.

Imagine a becak driver looking for a friend's house in a street of 100 houses, where every neighbor can tell him only "further up" or "further down". Asking at house 1, then 2, then 3 wastes his whole afternoon. Asking in the middle of the part of the street that is still possible sends him to the right house after at most seven stops. That is the idea of this chapter in one sentence: *each question should cut what is still possible in half*.

Pseudocode 1.1 writes the idea as pseudocode, the language-free notation we use in this book for the core of an algorithm before we write it in Python.

Pseudocode 1.1 The halving guesser: the possibilities are the whole numbers from `low` to `high`, and every question removes at least half of them.

```
HALVING-GUESSER(low, high)
1  guesses = 0
2  while low ≤ high
3      guess = ⌊(low + high) / 2⌋
4      guesses = guesses + 1
5      answer = ASK(guess)
6      if answer == "correct"
7          return guesses
8      elseif answer == "higher"
9          low = guess + 1
10     else high = guess − 1
11 return FAIL          // the answers contradict each other
```

Why the middle? Because we do not know which answer is coming. If we guess near the bottom, a "higher" leaves almost everything still possible. The middle is the only guess whose *worst* answer is as good as its best one: whichever way you answer, half the numbers vanish. Computer scientists call this *binary search*, and Knuth traces it back to the 1940s [12].

1.5 The Math, Gently

We now prove the promise made at the start: 100 numbers never need more than 7 guesses. No step is skipped.

How many numbers survive one guess? Suppose n numbers are still possible. The guess takes one of them, the middle one. The others split into those below the guess and those above it, and the two groups differ in size by at most one. So after an answer of "higher" or "lower", the number of possibilities left is at most

$$n' \le \left\lfloor \frac{n}{2} \right\rfloor \tag{1.1}$$

where $\lfloor x \rfloor$, read "floor of x", means x rounded down to a whole number. Check it with $n = 100$: the guess is 50, the numbers below are 1 to 49 (that is 49 of them) and the numbers above are 51 to 100 (50 of them), and indeed $50 = \lfloor 100/2 \rfloor$. Equation (1.1) says the AI's uncertainty at least halves with every answer.

Logarithms in plain words. How many times can you halve 100 before less than one remains? The *base-2 logarithm* answers exactly that kind of question:

$$2^x = N \quad \Leftrightarrow \quad x = \log_2 N \tag{1.2}$$

Equation (1.2) reads: $\log_2 N$ is the power you must raise 2 to in order to get N. So $\log_2 8 = 3$ because $2^3 = 8$, and $\log_2 128 = 7$ because $2^7 = 128$. For 100, which lies between $2^6 = 64$ and $2^7 = 128$, the logarithm is about 6.64.

How many numbers can k guesses handle? Look at the problem from the other side, with the tree in **Figure 1.3**. It draws every game with the numbers 1 to 15. The first guess is always 8, at the top. The answer "l" (lower) leads left to the next guess, 4, and "h" (higher) leads right to 12. Every number appears exactly once in the tree, and the number of guesses needed for a number is its level: one guess for 8, two for 4 and 12, three for 2, 6, 10 and 14, four for the eight numbers at the bottom.

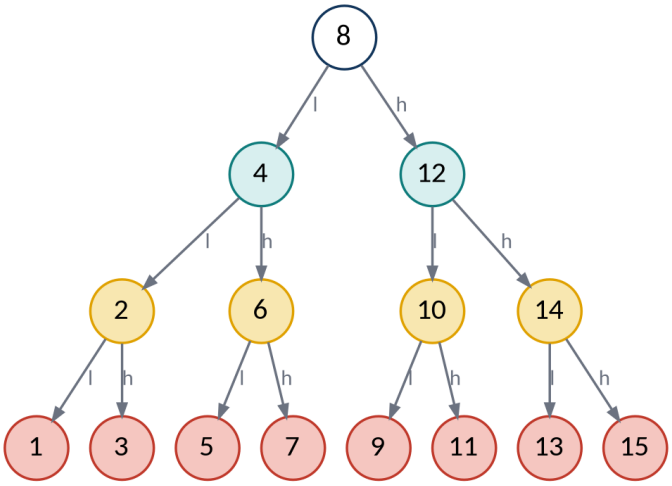

Figure 1.3 Every possible game of the halving guesser on the numbers 1 to 15: the first guess is 8 and each answer, lower (l) or higher (h), moves one level down.

Level 1 holds 1 number, level 2 holds 2, level 3 holds 4, and each level holds twice as many as the one above. So with k guesses the AI can tell apart at most

$$1 + 2 + 4 + \cdots + 2^{k-1} = 2^k - 1 \tag{1.3}$$

numbers. To see why the sum is $2^k - 1$, add 1 to it: $1 + 1 = 2$, $2 + 2 = 4$, $4 + 4 = 8$, and so on, each step doubling, until the last term gives $2^{k-1} + 2^{k-1} = 2^k$. Since we added 1, the sum itself is $2^k - 1$. For $k = 4$ that is 15, exactly the 15 numbers in **Figure 1.3**.

The worst case. Seven guesses cover $2^7 - 1 = 127$ numbers, six guesses only 63. So 100 numbers need 7 guesses in the worst case, and no strategy at all could promise 6, because six yes-or-no-style answers can only tell apart 63 situations. In general, with N numbers the halving guesser needs at most

$$g_{\max}(N) = \lceil \log_2 (N + 1) \rceil \tag{1.4}$$

guesses, where $\lceil x \rceil$, "ceiling of x", is x rounded up. For $N = 100$: $\log_2 101 \approx 6.66$, rounded up, 7. Equation (1.4) grows astonishingly slowly: a million numbers need only 20 guesses and eight billion numbers, one for every person on Earth, only 33.

The average case. In the game on 1 to 100, how many guesses does the AI need on average, if every secret is equally likely? The tree of 1 to 100 has 1 number at level 1, 2 at level 2, 4 at level 3, 8, 16 and 32 at levels 4, 5 and 6, and the remaining $100 - 63 = 37$ numbers at level 7. The average is the total number of guesses over all 100 games, divided by 100:

$$\bar{g} = \frac{1 \cdot 1 + 2 \cdot 2 + 3 \cdot 4 + 4 \cdot 8 + 5 \cdot 16 + 6 \cdot 32 + 7 \cdot 37}{100} = \frac{580}{100} = 5.80 \tag{1.5}$$

The linear friend who tries 1, 2, 3, … needs s guesses for the secret s, so its average is

$$\bar{g}_{\text{linear}} = \frac{1 + 2 + \cdots + N}{N} = \frac{N(N+1)/2}{N} = \frac{N+1}{2} \tag{1.6}$$

which is 50.5 for $N = 100$. The formula $1 + 2 + \cdots + N = N(N+1)/2$ comes from writing the sum twice, once forwards and once backwards, and adding the two rows column by column: every column adds to $N + 1$, there are N columns, and we counted everything twice. We will see both averages, 5.80 and 50.50, come out of the program in Section 1.8.

Why halving is the best possible. Each answer of "higher" or "lower" is one of two outcomes, and Shannon's information theory measures the information in a choice among N equally likely possibilities as

$$H = \log_2 N \text{ bits} \tag{1.7}$$

A question with two equally likely answers gives at most one bit [13]. Our secret carries $\log_2 100 \approx 6.64$ bits, so no strategy can find it in fewer than 6.64 questions on average when only two-way answers count; halving asks questions whose two answers are as close to equally likely as possible, which is why it gets so close to the limit. ("Correct" is a small third answer, which is why the true average, 5.80, is even a little below 6.64.) Equation (1.7) will come back in Part 2, where decision trees choose their questions by exactly this measure.

1.6 Building the Guessing AI Step by Step

Now we turn **Pseudocode 1.1** into Python. Create `guess_ai.py` in `ai-workbench` and type **Listing 1.2**. It is short, but every line has a job, so we go through it slowly afterwards.

Listing 1.2 `guess_ai.py`: the halving guesser, playing against a person at the keyboard.

```
"""A number-guessing AI: you think of a number, the computer finds it by halving."""
import sys

def next_guess(low, high):
    """The middle of the numbers that are still possible."""
    return (low + high) // 2

def play(low=1, high=100, ask=input):
    """Play one game; return the number of guesses, or None if answers clash."""
    print(f"Think of a whole number from {low} to {high}. I will find it.")
    guesses = 0
    while low <= high:                          # some numbers are still possible
        guess = next_guess(low, high)
        guesses += 1
        answer = ask(f"Guess {guesses}: is it {guess}? "
                     "(h = higher, l = lower, c = correct) ").strip().lower()
        if answer.startswith("c"):
            print(f"Found it: {guess}, in {guesses} guesses.")
            return guesses
        if answer.startswith("h"):              # the secret is above the guess
            low = guess + 1
        elif answer.startswith("l"):            # the secret is below the guess
            high = guess - 1
        else:
            print("Please answer h, l or c.")
            guesses -= 1                        # a typo does not cost a guess
            continue
        left = high - low + 1                   # how many numbers remain
        if left > 1:
            print(f"   Still possible: {low} to {high} ({left} numbers)")
        elif left == 1:
            print(f"   Only {low} is left.")
    print("No number fits all your answers. Did you change your mind?")
    return None

if __name__ == "__main__":
    lo, hi = (int(a) for a in sys.argv[1:3]) if len(sys.argv) >= 3 else (1, 100)
    play(lo, hi)
```

The first line is a *docstring*, a string that describes the module; VS Code shows it when you hover over the module's name. `import sys` gives access to the command-line arguments.

`next_guess(low, high)` is the whole strategy in one line. The operator `//` is *integer division*: it divides and throws away the fraction, so `(1 + 100) // 2` is `50`, not `50.5`. Keeping the strategy in its own function has a purpose: in Section 1.8 we will swap in other strategies, and in Section 1.9 we will test this one on its own.

`play(low=1, high=100, ask=input)` runs one game. The *default arguments* mean you can call `play()` with no arguments for the normal game. The parameter `ask` deserves a moment. By default it is Python's `input` function, which prints a prompt and waits for the person to type a line. But a test can pass a different function that answers automatically, so the same game can be played by a person or by a program. This small trick, passing in the thing a function talks to instead of hard-wiring it, is called *dependency injection*, and it is what makes the program testable.

The `while low <= high` loop runs while at least one number is still possible. Inside, the AI computes its guess, counts it, and asks. The answer is cleaned with `.strip()` (remove spaces and the newline) and `.lower()` (so that `H`, `h` and `Higher` all work), and only its first letter is checked with `startswith`. An answer that is not `h`, `l` or `c` is politely refused, and `guesses -= 1` takes back

the count, because a typo should not cost a guess; `continue` jumps back to the top of the loop so the same guess is asked again. After a real answer the program reports how many numbers are left, using `left = high - low + 1`: from 51 to 100 there are $100 - 51 + 1 = 50$ numbers, not 49, a classic off-by-one trap.

If the loop ends without a "correct", `low` has passed `high`: every number has been ruled out, so the answers contradict each other, and `play` returns `None` rather than a count. The final block, `if __name__ == "__main__":`, runs only when the file is started as a program, not when another file imports it. It reads an optional range from the command line, so `python guess_ai.py 1 1000` plays with a thousand numbers.

1.7 Running It

In the terminal, with the environment active, type `python guess_ai.py` and play. Here is a real game in which the secret was 71; the player also made a typo on the second guess:

```
Think of a whole number from 1 to 100. I will find it.
Guess 1: is it 50? (h = higher, l = lower, c = correct) h
   Still possible: 51 to 100 (50 numbers)
Guess 2: is it 75? (h = higher, l = lower, c = correct) yes
Please answer h, l or c.
Guess 2: is it 75? (h = higher, l = lower, c = correct) l
   Still possible: 51 to 74 (24 numbers)
Guess 3: is it 62? (h = higher, l = lower, c = correct) h
   Still possible: 63 to 74 (12 numbers)
Guess 4: is it 68? (h = higher, l = lower, c = correct) h
   Still possible: 69 to 74 (6 numbers)
Guess 5: is it 71? (h = higher, l = lower, c = correct) c
Found it: 71, in 5 guesses.
```

Figure 1.4 draws the same game. Each bar is the set of numbers still possible before a guess, and the triangle is the guess. The first bar covers all 100 numbers; each later bar is at most half as long as the one above it, just as Equation (1.1) promised, and the fifth guess lands on 71.

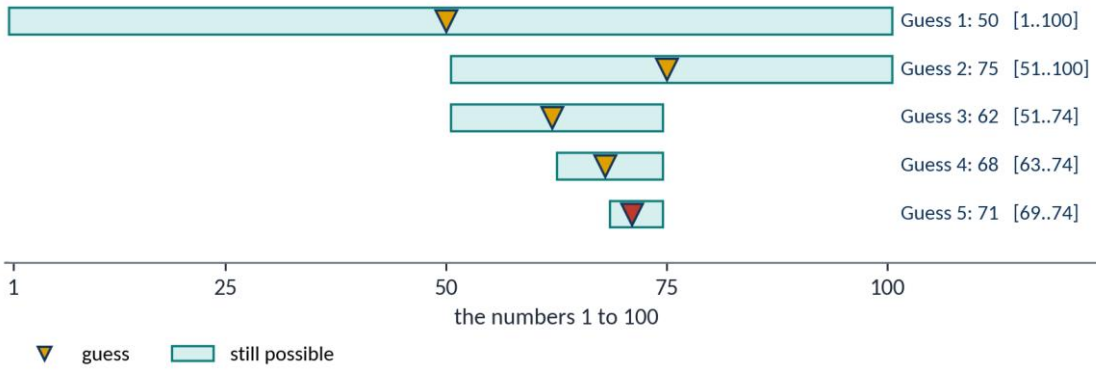

Figure 1.4 The real game above: the numbers still possible before each guess (bars) and the guess itself (triangles); the secret 71 is found on the fifth guess.

And here is what happens when the player is not consistent. With the range 1 to 10 and the secret supposedly above 9, the player then claims it is below 10:

```
Think of a whole number from 1 to 10. I will find it.
Guess 1: is it 5? (h = higher, l = lower, c = correct) h
   Still possible: 6 to 10 (5 numbers)
Guess 2: is it 8? (h = higher, l = lower, c = correct) h
   Still possible: 9 to 10 (2 numbers)
Guess 3: is it 9? (h = higher, l = lower, c = correct) h
   Only 10 is left.
Guess 4: is it 10? (h = higher, l = lower, c = correct) l
No number fits all your answers. Did you change your mind?
```

The AI does not crash or loop forever. Its state of knowledge became empty, and it says so. Noticing that the evidence no longer fits any possibility is itself a form of intelligence; the expert system of Chapter 7 will do the same with contradictory facts.

1.8 Measuring Three Strategies

A claim such as “halving is best” should be measured, not believed. **Listing 1.3** plays every secret from 1 to 100 against three strategies: *linear* always tries the smallest possible number, *random* tries any possible number at random, and *halving* tries the middle. The player is simulated and always truthful.

Listing 1.3 `guess_lab.py`: plays every secret from 1 to 100 against three strategies and reports the average, worst and best number of guesses.

```
"""Compare three guessing strategies on every secret number from 1 to 100."""
import math
import random

def count_guesses(secret, low, high, choose):
    """Play one game against a truthful player; return how many guesses it took."""
    guesses = 0
    while True:
        guess = choose(low, high)
        guesses += 1
        if guess == secret:
            return guesses
        if secret > guess:
            low = guess + 1
        else:
            high = guess - 1

def linear(low, high):
    return low                                  # always try the smallest candidate

def halving(low, high):
    return (low + high) // 2                    # always try the middle

def make_random(seed):
    rng = random.Random(seed)                   # fixed seed: same result every run
    return lambda low, high: rng.randint(low, high)

def main(n=100):
    strategies = {"linear": linear, "random": make_random(2026),
                  "halving": halving}
    print(f"Secrets 1..{n}, a truthful player, one game per secret")
    print(f"{'strategy':<9}{'average':>9}{'worst':>7}{'best':>6}")
    results = {}
    for name, choose in strategies.items():
        counts = [count_guesses(s, 1, n, choose) for s in range(1, n + 1)]
        results[name] = counts
        print(f"{name:<9}{sum(counts) / n:>9.2f}{max(counts):>7}{min(counts):>6}")
    bound = math.ceil(math.log2(n + 1))
    print(f"Worst case promised by halving: ceil(log2({n} + 1)) = {bound}")
    for size in (1_000, 1_000_000, 8_000_000_000):
        print(f"  numbers from 1 to {size:>13,}: at most "
              f"{math.ceil(math.log2(size + 1))} guesses")
    return results

if __name__ == "__main__":
    main()
```

Listing 1.3 (Continued) *guess_lab.py: plays every secret from 1 to 100 against three strategies and reports the average, worst and best number of guesses.*

`count_guesses` is the game loop again, but the "player" is now simply the comparison `secret > guess`. The strategy is passed in as a function `choose(low, high)`, so the same loop serves all three. In Python a function is a value like any other: `linear` and `halving` are named with `def`, and `make_random` *returns* a new function built with `lambda`, a way of writing a small function in one expression. The random strategy uses `random.Random(2026)`, a random-number generator with a fixed *seed*: it produces the same "random" sequence on every run, so the numbers in this book are exactly the numbers you will see. The list comprehension `[count_guesses(s, 1, n, choose)`

`for s in range(1, n + 1)` plays the hundred games in one line. The format specifications such as `{name:<9}` and `{x:>9.2f}` pad text to the left or right and print two decimals, which lines up the table. `math.log2` and `math.ceil` compute Equation (1.4), and `{size:>13,}` prints large numbers with thousands separators. Run it:

```
Secrets 1..100, a truthful player, one game per secret
strategy   average  worst  best
linear       50.50    100     1
random        7.59     15     3
halving       5.80      7     1
Worst case promised by halving: ceil(log2(100 + 1)) = 7
  numbers from 1 to         1,000: at most 10 guesses
  numbers from 1 to     1,000,000: at most 20 guesses
  numbers from 1 to 8,000,000,000: at most 33 guesses
```

The measurements agree with the mathematics to the last digit: the linear average is 50.50, as Equation (1.6) predicted, the halving average is 5.80, as Equation (1.5) predicted, and the halving worst case is 7, as Equation (1.4) predicted. Random guessing is not terrible, with an average of 7.59, because each random guess still removes a random share of the possibilities, but its worst case is 15 and it is never better than halving on average. **Figure 1.5** shows the whole distribution: the halving bars follow the doubling pattern 1, 2, 4, 8, 16, 32 and then the remaining 37, while random guessing spreads over a long tail.

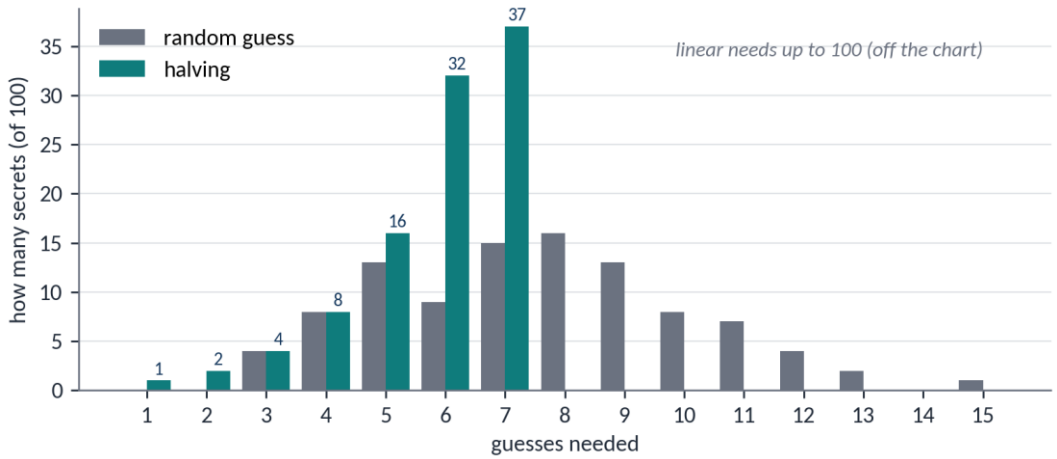

Figure 1.5 How many guesses each of the 100 secrets needed, for random guessing and for halving (real run of `guess_lab.py`); the halving counts double level by level up to the last level.

1.9 Testing It Automatically

Playing a game by hand checks one secret. A test checks all of them, in a fraction of a second, every time you change the code. Python's standard library includes the `unittest` module for exactly this [14]. Create `test_guess.py` next to the other files and type **Listing 1.4**.

Listing 1.4 `test_guess.py`: automatic tests for the guesser, including a simulated truthful player.

```
"""Automatic checks for the guessing AI. Run: python -m unittest -v"""
import io
import unittest
from contextlib import redirect_stdout

from guess_ai import next_guess, play
from guess_lab import count_guesses, halving

def truthful(secret):
    """A pretend player who always answers honestly about `secret`."""
    def ask(prompt):
        guess = int(prompt.split("is it ")[1].split("?")[0])
        if guess == secret:
            return "c"
        return "h" if secret > guess else "l"
    return ask

class GuessTests(unittest.TestCase):
    def test_middle(self):
        self.assertEqual(next_guess(1, 100), 50)
        self.assertEqual(next_guess(51, 100), 75)

    def test_every_secret_within_seven(self):
        for secret in range(1, 101):
            self.assertLessEqual(count_guesses(secret, 1, 100, halving), 7)

    def test_play_matches_lab(self):
        with redirect_stdout(io.StringIO()):  # keep the test output quiet
            for secret in range(1, 101):
                self.assertEqual(play(1, 100, ask=truthful(secret)),
                                 count_guesses(secret, 1, 100, halving))

    def test_contradiction_detected(self):
        with redirect_stdout(io.StringIO()):
            self.assertIsNone(play(1, 3, ask=lambda prompt: "h"))

if __name__ == "__main__":
    unittest.main()
```

A test class inherits from `unittest.TestCase`, and every method whose name starts with `test_` is one test. `assertEqual(a, b)` fails the test if `a` and `b` differ; `assertLessEqual` and `assertIsNone` work the same way. The function `truthful(secret)` builds a pretend player: it reads the guess out of the prompt text (the part between `"is it "` and `"?"`) and answers as an honest person would. This is the dependency injection of Section 1.6 paying off: `play` does not know or care that nobody is typing. `redirect_stdout(io.StringIO())` catches the messages that `play` prints, so that the test report stays readable. The four tests check the middle guess, the promise of at most 7 guesses for every secret, that the interactive game and the laboratory count the same number of guesses for all 100 secrets, and that contradictory answers are detected. Run them from the terminal:

```
(.venv) $ python -m unittest -v
```

```
test_contradiction_detected (test_guess.GuessTests.test_contradiction_detected) ... ok
test_every_secret_within_seven (test_guess.GuessTests.test_every_secret_within_seven) ...
ok
test_middle (test_guess.GuessTests.test_middle) ... ok
test_play_matches_lab (test_guess.GuessTests.test_play_matches_lab) ... ok

----------------------------------------------------------------------
Ran 4 tests in 0.001s

OK
```

In VS Code you can also click the **Testing** icon (the flask) in the Activity Bar, choose **Configure Python Tests**, **unittest**, the folder `.` and the pattern `test_*.py`; the tests then appear in a tree with a green tick or a red cross each, and you can run or debug any one of them with a click.

1.10 Improving It

The guesser is complete, but a few improvements teach useful ideas for the rest of the book.

Any range. The program already accepts a range: `python guess_ai.py 1 1000` asks at most 10 questions, as Equation (1.4) predicts. Try `1 1000000` and count; it never needs more than 20.

Detecting inconsistency earlier. The version in **Listing 1.2** notices a contradiction only when nothing is left. A stricter version could also refuse an answer that is impossible on its face, such as "higher" when the guess already equals `high`. The final result is the same, but the player learns about the mistake one question sooner.

A player who may lie once. Suppose the player is allowed to lie at most once. Halving alone then fails, because a single lie can throw away the half that holds the secret. The fix is to keep, for every number, a count of how many answers it contradicts, and to keep a number possible as long as that count is at most 1. The state of knowledge is then no longer an interval but a table of scores, and the best guess is the one that splits the total "possibility weight" in half. This problem, known as Ulam's game, is a beautiful example of reasoning under unreliable evidence, the theme of Chapters 7 and 10.

Swapping the roles. Let the computer pick the secret with `random.randint` and let the person guess, while the program counts how many guesses the person needed and compares that with $g_{\max}$. Exercise 4 asks you to write it.

Learning the player's habits. People do not choose numbers uniformly: many avoid 1, 50 and 100 and favor numbers that "feel random". If the AI had counts of the numbers real players chose, it could guess the *weighted* middle of what is still possible instead of the plain middle, and its average would drop below 5.80 for those players, although its worst case could rise. That is the step from classic AI to machine learning, and it is where Part 2 begins.

1.11 Common Mistakes, and How to Avoid Them

Installing into the wrong Python. You run `pip install something`, then `import something` fails. The `pip` you ran belonged to another Python. Always use `python -m pip`, always with the environment active, and check the Status Bar in VS Code.

Forgetting to activate the environment. A new terminal window starts without the environment. Look for `(.venv)` at the start of the prompt; if it is missing, activate with the command from **Table 1.2**, or let VS Code do it by selecting the `.venv` interpreter.

Blocked activation on Windows. The message "running scripts is disabled on this system" means PowerShell's execution policy has not been set. Run `Set-ExecutionPolicy -Scope CurrentUser RemoteSigned` once, as in Section 1.3.1.

Using `python3` on Windows or `python` on macOS/Linux outside an environment. On macOS and Linux, `python` may not exist or may be an old version; use `python3` until the environment is active. On Windows with the install manager, both work.

Committing `.venv` to version control or copying it to another computer. A virtual environment contains paths of the machine it was made on. Share `requirements.txt` instead and let the other person run `python -m venv .venv` and `python -m pip install -r requirements.txt`.

Off-by-one errors. Writing `low = guess` instead of `low = guess + 1` makes the loop ask the same guess forever when `low` and `high` are neighbors; writing `high - low` instead of `high - low + 1` miscounts what is left. When a loop narrows a range, check it by hand on a range of one and two numbers.

Using `/` instead of `//`. In Python 3, `/` always produces a float: `(1 + 100) / 2` is `50.5`, which is not a valid guess. Use `//` for whole-number division.

1.12 Chapter Summary

- Classic AI treats intelligence as an agent choosing actions to achieve a goal from what it knows; a rational agent picks the action with the best expected result.
- The workbench of this book is Python 3.14 (installed with the Python install manager on Windows, the python.org package or Homebrew on macOS, and the distribution's packages on Linux), Visual Studio Code with Microsoft's Python extension, one virtual environment per project, pip called as `python -m pip`, and a `requirements.txt` with pinned versions. Jupyter notebooks are optional.
- `check_setup.py` verifies the setup: version, active environment and pip.
- The halving guesser keeps the possible numbers as an interval and always guesses its middle; each answer removes at least half of them (Equation (1.1)).
- With k guesses at most $2^k - 1$ numbers can be told apart (Equation (1.3)), so N numbers need at most $\lceil \log_2(N+1) \rceil$ guesses (Equation (1.4)): 7 for 100, 20 for a million.
- On 1 to 100 the measured averages are 50.50 for linear guessing, 7.59 for random guessing and 5.80 for halving, matching Equation (1.6) and Equation (1.5).
- Passing the `ask` function into `play` lets people and tests play the same game; `unittest` checks all 100 secrets in a millisecond.

1.13 Exercises

1. Without running any code, list the guesses the halving AI makes when the secret is 1, and when it is 100. How many guesses does each need?
2. Use Equation (1.4) to find the largest range $1..N$ for which the halving guesser never needs more than 10 guesses.
3. Change `next_guess` to `return (low + 2 * high) // 3` (a guess two thirds of the way up). Run `guess_lab.py` with this strategy added. What happens to the average and the worst case, and why?

4. Write `you_guess.py`, in which the computer chooses a secret from 1 to 100 with `random.Random(seed)` and the person guesses. After each guess print "higher", "lower" or "correct", and at the end print the number of guesses next to the best possible worst case, 7.
5. Extend `test_guess.py` with a test that plays every secret from 1 to 1000 with `count_guesses(..., halving)` and checks that none needs more than 10 guesses.
6. Make the AI smarter at the end of a game: as soon as only one number is left, it should announce that number instead of asking about it. Modify `play` accordingly. How do the worst case and the average for 1 to 100 change?
7. Explain in two or three sentences why it is a bad idea to install packages without an active virtual environment, using the words *project*, *version* and *collision*.

1.14 Solutions to the Exercises

1. Secret 1: the guesses are 50, 25, 12, 6, 3, 1 (after 3 the range is 1 to 2, whose middle is $\lfloor 3/2 \rfloor = 1$), so 6 guesses. Secret 100: 50, 75, 88, 94, 97, 99, 100, so 7 guesses. The asymmetry comes from rounding down: the middle of an even-sized range is the lower of its two middle numbers, so the upper half is always the larger one.

2. We need $\lceil \log_2(N+1) \rceil \le 10$, that is $N + 1 \le 2^{10} = 1024$, so $N = 1023$. By Equation (1.3), ten levels hold exactly $2^{10} - 1 = 1023$ numbers.

3. Add `"thirds": lambda low, high: (low + 2 * high) // 3` to the `strategies` dictionary. The run gives an average of 6.06 guesses and a worst case of 9, both worse than halving's 5.80 and 7. The reason is Equation (1.1) in reverse: when the guess is not in the middle, the answer "lower" leaves two thirds of the numbers, and the worst case follows the larger part. Only the middle guarantees that the worst answer removes half.

4. One possible solution:

```
import random

rng = random.Random(7)
secret = rng.randint(1, 100)
count = 0
while True:
    count += 1
    guess = int(input(f"Guess {count}: "))
    if guess == secret:
        print(f"correct, in {count} guesses (halving never needs more than 7)")
        break
    print("higher" if secret > guess else "lower")
```

A careful version also catches `ValueError` from `int()` when the person types something that is not a number, and asks again without counting the guess.

5. Add this method to `GuessTests`:

```
    def test_thousand_within_ten(self):
        for secret in range(1, 1001):
            self.assertLessEqual(count_guesses(secret, 1, 1000, halving), 10)
```

It passes, because $\lceil \log_2 1001 \rceil = 10$.

6. Inside the loop, before guessing, check `if low == high:`, print `f"It must be {low}."` and return the count. The AI then never asks about a number it already knows. Counting the same way as `guess_lab.py` for all 100 secrets, the worst case falls from 7 to 6 questions and the

average from 5.80 to 5.43: every secret that used to need its seventh question was the only number left at that point.

7. Without an environment, every package goes into one shared Python. Different projects often need different versions of the same library, and installing the version one project needs silently replaces the version another project was using, a collision that breaks the older project. A virtual environment per project keeps each project's versions separate.

Chapter 2

A Smart Expense Categorizer for Bank and E-Wallet Statements

At the end of the month many of us open the banking app, scroll through a long list of cryptic lines such as `QRIS 0304 BAKSO PAK MAN` and `TRSF E-BANKING DB 0104/FTSCY/WS95051`, and wonder where the money went. In this chapter we build a program that answers that question. It reads the statement files that your bank and your e-wallet let you download, puts every transaction into a category such as food, groceries or transport, tells you what you spent per category and per month, and warns you when a category is heading over its budget before the month is over. It starts with hand-written keyword rules, then *learns* from the transactions you have already labeled, and it is honest enough to ask you when it is not sure. By the end of the chapter you will be able to read CSV exports with different layouts into one table, write keyword rules, explain and compute a naive Bayes classifier by hand, choose a confidence threshold by measuring its effect, forecast a month's spending, and test the whole program automatically.

2.1 Where Does the Money Go?

Indonesians have moved their daily spending onto phones at remarkable speed. According to Bank Indonesia's economic report for 2025, the QRIS standard for paying by scanning a code had 59.53 million users and 42.75 million merchants by the end of 2025, and its transaction volume grew by almost 140 percent in a single year [1]. Warung, bakso carts and parking attendants now accept QRIS. That is convenient, but it also means that one person's month is spread over hundreds of small payments, in a bank account and in one or two e-wallets, each described by a line of text that was written for a computer, not for a person.

Having an account is not the same as understanding it. The 2025 national survey of financial literacy and inclusion by the Financial Services Authority (OJK) and Statistics Indonesia (BPS) found that 80.51 percent of Indonesians use at least one financial product or service, but only 66.46 percent are financially literate [2]. The gap between those two numbers is, among other things, the gap between *having* a statement and *reading* it. A household that knows it spends 1.7 million rupiah a month on groceries and 1.0 million on ojek and fuel can make real decisions; a household that only sees a list of 70 transactions cannot.

That is why expense categorization is built into almost every personal-finance app and into the apps of many banks, and why accountants and small-business owners do the same job for their bookkeeping every month, often by hand in a spreadsheet. The program of this chapter does it for you, with your own files, on your own computer. It saves an hour or two of tedious work each month, and more importantly it turns the statement into three things you can act on: a table of spending per category, a list of the transactions it could not place, and early warnings such as "groceries: 94 percent of the budget used on the 20th".

The method is also a gentle introduction to the two great families of AI. The first version is *knowledge written by hand*: rules that a person types in. The second version *learns from data*: it looks at examples that you labeled and discovers which words go with which category. We will

see that each is good at something the other is bad at, and that the most useful program combines them.

2.2 The Idea in Plain Words

Imagine you give your statement to a careful friend and ask her to sort it. She would start with the obvious lines. Anything that says INDOMARET, ALFAMART or SUPERINDO is groceries. Anything that says GORIDE or SPBU is transport. PLN and PDAM are bills. That is a *keyword rule*: if the description contains this word, the category is that. Rules are quick to write, easy to check and never surprising. Their weakness is that they know only the words you thought of. The day a new clinic, a new marketplace or a new stall appears on the statement, no rule fires.

Your friend would then do something cleverer with the lines she does not recognize. She would remember the months she has already sorted with you and reason from experience: "The word QRIS appeared mostly on food payments and sometimes on groceries; the word KEDAI I have seen only on food; this one is probably food." That is *learning from examples*. It needs no rules, only labeled transactions, and it handles words that look like ones it has seen before. Its weakness is that it is sometimes confidently wrong, and it has no idea what to do with words it has never seen.

A good friend would also know when to stop guessing. If a line says `BLIBLI.COM 6869` and she has never seen Blibli before, she would ask you rather than invent an answer. Asking costs you a few seconds; a wrong guess silently corrupts the monthly totals. So our program works in three steps, as **Figure 2.1** shows: rules first, the learned model second, and a question to you third. Everything you answer becomes a new labeled example, so next month the model knows more.

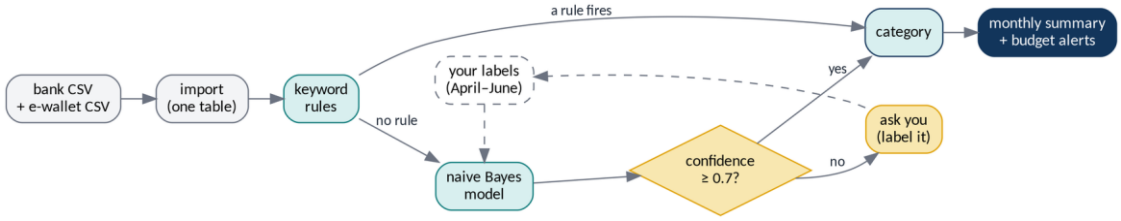

Figure 2.1 The categorizer: keyword rules decide first, a naive Bayes model learned from your labels decides the rest when it is confident enough, and everything else is left for you to label.

Once every transaction has a category, the rest is arithmetic. We add up the spending per category and month, compare this month with the budget, and forecast where the month will end if you keep spending at the same pace.

> **DEFINITION.** A *classifier* is a program that assigns one of a fixed set of labels (here, categories) to an input (here, a transaction description). It is *trained* on examples whose labels are known and *tested* on examples it has not seen.

2.3 The Math, Gently

2.3.1 From a description to words

A computer cannot compare meanings, but it can compare words. Our first step turns every description into a clean list of words: upper case, digits and punctuation removed, hyphens dropped. `QRIS 0304 MIE GACOAN RUNGKUT` becomes the words QRIS, MIE, GACOAN, RUNGKUT, and `GoRide - Perjalanan ke ITS` becomes GORIDE, PERJALANAN, KE, ITS. The digits are

dropped on purpose: `0304` is a date and `6869` a reference number, and they change on every line, so they would only confuse the learner. The learned model keeps only words of at least two letters; the list of all different words seen in the training examples is its *vocabulary*, and we write V for its size. In our data $V = 119$.

2.3.2 Naive Bayes

We want the category c that is most probable for a description d. Probability is a number between 0 and 1 that measures how often something happens: a probability of 0.62 means "62 times in 100". We write $P(c \mid d)$, read "the probability of c given d". Bayes' rule, a result from the eighteenth century, turns this around into things we *can* count:

$$P(c \mid d) = \frac{P(c)\,P(d \mid c)}{P(d)} \tag{2.1}$$

Here $P(c)$ is how common the category is in the labeled examples (the *prior*), and $P(d \mid c)$ is how likely a description like d is among the examples of category c. The denominator $P(d)$ is the same for every category, so to compare categories we can ignore it and divide by the total at the end.

Nobody has seen the exact description d often enough to count it, so we make a bold simplification: we pretend that the words $w_1, w_2, \ldots, w_n$ of the description appear independently of each other once the category is known. This is the "naive" in naive Bayes, and it gives

$$P(c \mid d) \propto P(c) \prod_{i=1}^{n} P\,(w_i \mid c) \tag{2.2}$$

The sign $\propto$ means "is proportional to", and $\prod$ means "multiply all of these". The independence assumption is plainly false (the word GOFOOD almost always comes with a restaurant name), yet the classifier works remarkably well in practice, because we only need the *largest* score to be on the right category, not the scores to be exactly right [3].

Both kinds of probability are estimated by counting. $P(c)$ is the number of examples of c divided by the number of all examples, N. For $P(w \mid c)$ we count how many times the word w occurs in the examples of category c, written $\text{count}(w, c)$, and how many words those examples contain altogether, written $\text{words}(c)$. One more trick is needed: a word that never occurred in category c would get probability 0, and one zero in the product of Equation (2.2) would wipe out all other evidence. So we pretend that we saw every word of the vocabulary once more in every category. This is *add-one* or *Laplace smoothing*:

$$P(w \mid c) = \frac{\text{count}(w, c) + 1}{\text{words}(c) + V} \tag{2.3}$$

Words that are not in the vocabulary at all, such as KLINIK when nobody ever labeled a clinic, are simply ignored.

Let us work one real case by hand, the September payment `QRIS 0807 KLINIK PRATAMA SEHAT`. After cleaning, only the word QRIS is in the vocabulary; KLINIK, PRATAMA and SEHAT were never seen. The model was trained on $N = 206$ transactions from April to June. **Table 2.1** lists what we need for the three categories in which QRIS occurred.

Table 2.1 Counts from the 206 labeled transactions of April to June, for the word QRIS and four categories.

Category c	Examples of c	words(c)	count(QRIS,c)
food	58	244	29
groceries	33	136	13
fun	10	35	7
transport	34	149	0

For food, Equation (2.3) gives $P(\text{QRIS} \mid \text{food}) = (29 + 1)/(244 + 119) = 30/363 = 0.0826$, and the prior is $58/206 = 0.2816$. By Equation (2.2) the score is $0.2816 \times 0.0826 = 0.02327$. For groceries: $(33/206) \times (14/255) = 0.1602 \times 0.0549 = 0.00880$. For fun: $(10/206) \times (8/154) = 0.0485 \times 0.0519 = 0.00252$. Transport never saw QRIS, but smoothing still gives it a small score: $(34/206) \times (1/268) = 0.00062$. The remaining nine categories add another 0.00224, so the scores of all thirteen categories sum to 0.03745. Dividing each score by that sum turns the scores into probabilities: food $0.02327/0.03745 = 0.62$, groceries 0.235, fun 0.067, and the rest share what is left.

So the model says "food, with probability 0.62". It is wrong: the payment was at a clinic. But look at *why* it says food: the only thing it knows is that QRIS payments are usually food. It is guessing from the prior, and 0.62 is not very sure. That observation leads directly to the next idea.

2.3.3 Knowing when to ask

Let $\hat{c}$ be the category with the largest probability and $p_{\max}$ that probability. We accept the model's answer only if it is confident enough:

$$\text{decision}(d) = \begin{cases} \hat{c} & \text{if } p_{\max} \geq \theta \\ \text{ask the user} & \text{otherwise} \end{cases} \tag{2.4}$$

The number θ (the Greek letter theta) is the *threshold*. A low threshold lets the model decide almost everything and make more mistakes; a high threshold makes it ask more often. There is no formula for the right value; we will choose it in Section 2.7 by measuring both kinds of cost on months the model has not seen. With $\theta = 0.7$, the clinic payment above ($p_{\max} = 0.62$) is correctly left for you.

2.3.4 Measuring the categorizer

To judge a categorizer honestly we must test it on transactions it did not learn from. We train on April to June and test on July to September, exactly as you would use it: label the first months, then let it work. If T is the number of test transactions and R the number it placed in the right category, the *accuracy* is

$$\text{accuracy} = \frac{R}{T} \tag{2.5}$$

For the rules we also want to know how often they fire at all. If a rule fired for F of the T transactions, the *coverage* is

$$\text{coverage} = \frac{F}{T} \tag{2.6}$$

and for the hybrid of **Figure 2.1** we count three outcomes: right, wrong, and asked. A wrong answer is worse than a question, because nobody notices it.

2.3.5 Forecasting the month

On day t of a month with D days you have spent S_t in a category. If you keep spending at the same average rate, S_t/t per day, the month ends at

$$\hat{S}_D = S_t \cdot \frac{D}{t} \tag{2.7}$$

For example, 600,000 rupiah spent on food by the 12th of a 30-day month forecasts $600{,}000 \times 30/12 = 1{,}500{,}000$. This straight-line forecast makes sense only for categories that are spent bit by bit: food, groceries, transport, fun and shopping. An electricity bill paid once on the 3rd would be "forecast" at ten times its size on the 3rd, so for once-a-month categories the program simply uses what has been spent.

2.4 The Algorithm as Pseudocode

Pseudocode 2.1 puts the pieces together. Lines 1 to 3 learn, lines 4 to 11 categorize each new transaction as in **Figure 2.1**, and lines 12 to 16 produce the budget check with Equation (2.7).

Pseudocode 2.1 Categorizing statements with rules, a learned model and questions, then checking the budget.

```
CATEGORIZE-AND-CHECK(statements, labels, budget, today, θ)
1  table = all rows of all statements, with amounts signed (spending < 0)
2  train = rows of table that have a label
3  learn P(c) and P(w | c) from train                    // counting, with add-one
4  for each unlabeled row r of table
5      c = first category whose keyword occurs in r.description
6      if c exists: r.category = c
7      else
8          compute P(c | r.description) for every c      // naive Bayes
9          if the largest probability ≥ θ: r.category = that c
10         else r.category = "ask"; add r to the questions
11 summary = sum of spending per category and month
12 for each category c in budget
13     S = spending in c this month up to today
14     F = S · D / t if c is spent daily, else S          // forecast
15     if S > limit(c): OVER
16     else if S ≥ 0.8 · limit(c) or F > limit(c): WARN
```

2.5 Building It Step by Step

Create a folder `Chapter002`, open it in VS Code and create a virtual environment exactly as in Chapter 1, Section 1.3. This chapter needs three libraries: pandas for tables, scikit-learn for the classifier and numpy, which both use. Put them in `requirements.txt` and install them with `python -m pip install -r requirements.txt`.

```
# Chapter 2: versions this chapter was tested with (Python 3.14.7)
numpy==2.5.3
pandas==3.0.6
scikit-learn==1.9.1
```

2.5.1 The data

Real statements contain real names and account numbers, so the book comes with a household we invented: six months, April to September 2026, of a Surabaya family's bank account and GoPay-style e-wallet, 428 transactions in all, written by `make_data.py` with a fixed random seed. The descriptions imitate how Indonesian banks and e-wallets print them. The first lines of the bank export look like this:

```
Tanggal,Keterangan,Jumlah,DB/CR
01/04/2026,BPJS KESEHATAN VA 888881003,132000.00,DB
03/04/2026,QRIS 0304 BAKSO PAK MAN,38500.00,DB
03/04/2026,QRIS 0304 KOPI KENANGAN GALAXY MALL,80500.00,DB
04/04/2026,BIAYA KARTU DEBIT,5500.00,DB
```

The bank writes the date day first, keeps the amount positive and marks the direction in a separate column: DB (debit) for money going out, CR (credit) for money coming in. The e-wallet export has a different layout, with a time, a signed amount and descriptions in mixed case:

```
Waktu,Deskripsi,Nominal
2026-04-03 13:52,GoCar - Perjalanan ke Juanda,-54500
2026-04-03 16:06,GoCar - Perjalanan ke Juanda,-30000
2026-04-03 18:31,GoFood - Nasi Padang Sederhana,-32000
```

The two files cover the same life, so they overlap: a `TOPUP GOPAY` of 214,500 rupiah in the bank reappears as `Top Up dari BCA` of 214,500 in the wallet. That money is spent only when it later leaves the wallet, as GoFood or GoRide payments, so both top-up lines must be kept out of the spending totals. We give them their own category, `topup`. **Table 2.2** lists all thirteen categories.

Table 2.2 The thirteen categories of the sample household, with typical descriptions.

Category	Examples of descriptions	Counts as spending
food	QRIS … WARUNG BU SRI, GoFood - Nasi Padang Sederhana	yes
groceries	KARTU DEBIT INDOMARET KENJERAN, QRIS … TOKO SEMBAKO BAROKAH	yes
transport	GoRide - Perjalanan ke Kampus ITS, KARTU DEBIT SPBU PERTAMINA	yes
bills	BYR VIA E-BANKING PLN PRABAYAR, … PDAM SURYA SEMBADA	yes
phone_internet	TELKOM INDIHOME, Pulsa Telkomsel 50rb	yes
health	BPJS KESEHATAN VA …, KARTU DEBIT APOTEK K-24 MANYAR	yes
education	TRSF E-BANKING DB …/SPP SMP NEGERI 12, RUANGGURU	yes
shopping	TOKOPEDIA, SHOPEE ID, LAZADA ID	yes
fun	NETFLIX.COM, QRIS … CGV TUNJUNGAN PLAZA	yes
family	TRSF E-BANKING DB …/FTSCY/… IBU SITI AMINAH	yes
bank_fee	BIAYA ADM, BIAYA KARTU DEBIT	yes
topup	TOPUP GOPAY …, Top Up dari BCA	no: own money moved
income	TRSF E-BANKING CR …/GAJI PT SURYA ABADI, BUNGA	no: money in

The file `labels.csv` is the answer key: the true category of every transaction, one line `id,category` each. In real life you would have labels only for the months you sorted yourself; the program uses only those up to a date you choose, and the lab uses the rest to measure how well it does. From July on, the family starts paying at places that did not exist in the first three months: a clinic, a traditional market, Blibli, a new soto stall, a Shell station. That is deliberate, because it is exactly what happens in real life and it is what tests a categorizer.

2.5.2 Importing statements

Listing 2.1 reads either layout and returns one table with the same five columns: an `id` such as `bank-150`, the `date`, the `description`, the signed `amount` and the `source`.

Listing 2.1 `statement.py`: reading bank and e-wallet CSV exports into one table.

```
"""Read bank and e-wallet statement exports (CSV) into one table."""
import pandas as pd

# Each export names its columns differently; we map them to ours.
FORMATS = {
    "bank": {"date": "Tanggal", "text": "Keterangan", "amount": "Jumlah",
             "sign": "DB/CR", "dayfirst": True},
    "wallet": {"date": "Waktu", "text": "Deskripsi", "amount": "Nominal",
               "sign": None, "dayfirst": False},
}

def detect(columns):
    """Name the format whose date and text columns are both present."""
    for name, f in FORMATS.items():
        if f["date"] in columns and f["text"] in columns:
            return name
    raise ValueError(f"unknown statement layout: {list(columns)}")

def load_statement(path):
    """Return a table with columns id, date, description, amount, source.

    Spending is negative, money coming in is positive, as on a bank book.
    """
    raw = pd.read_csv(path, dtype=str)
    source = detect(raw.columns)
    f = FORMATS[source]
    amount = raw[f["amount"]].str.replace(",", "", regex=False).astype(float)
    if f["sign"]:                                  # bank: DB means money went out
        amount = amount.where(raw[f["sign"]].str.strip() == "CR", -amount)
    return pd.DataFrame({
        "id": [f"{source}-{i}" for i in range(1, len(raw) + 1)],
        "date": pd.to_datetime(raw[f["date"]],
                               dayfirst=f["dayfirst"]).dt.normalize(),
        "description": raw[f["text"]].str.strip(),
        "amount": amount,
        "source": source,
    })

def load_all(paths):
    """Several statements, one table sorted by date."""
    table = pd.concat([load_statement(p) for p in paths], ignore_index=True)
    return table.sort_values(["date", "id"], kind="stable").reset_index(drop=True)
```

The dictionary `FORMATS` describes each layout by the names of its columns, so supporting another bank means adding one entry, not writing new code. `detect` looks at the header and picks the layout whose date and text columns are present. `load_statement` reads everything as text first (`dtype=str`, see the pandas documentation [4]), because amounts such as `132000.00` and codes such as `08121234` should not be guessed at by pandas. For the bank, `amount.where(condition, -amount)` keeps the amount where the row is a credit and negates it elsewhere, so that spending is negative in every source. `dayfirst=True` tells pandas that `03/04/2026` is the 3rd of April, not March 4th, a classic source of silent errors. `.dt.normalize()` drops the time of day. `load_all` stacks several statements with `pd.concat` and sorts them by date.

2.5.3 Keyword rules

Listing 2.2 is the hand-written knowledge.

Listing 2.2 `rules.py`: keyword rules and the cleaning of descriptions.

```
"""Keyword rules: the first version of the categorizer, written by hand."""
import re

# category -> words that give it away (checked in this order, first match wins)
RULES = {
    "topup": ["TOPUP", "TOP UP"],              # moving our own money: not spending
    "income": ["GAJI", "BUNGA"],
    "bank_fee": ["BIAYA ADM", "BIAYA KARTU"],
    "family": ["IBU ", "ADIK "],
    "food": ["GOFOOD", "KOPI", "WARUNG", "BAKSO", "MIE ", "KFC", "AYAM"],
    "groceries": ["INDOMARET", "ALFAMART", "SUPERINDO", "SEMBAKO", "GOMART"],
    "transport": ["GORIDE", "GOCAR", "SPBU", "ETOLL"],
    "bills": ["PLN", "PDAM"],
    "phone_internet": ["INDIHOME", "TELKOMSEL", "PULSA", "PAKET DATA"],
    "health": ["BPJS", "APOTEK"],
    "education": ["SPP", "RUANGGURU"],
    "shopping": ["TOKOPEDIA", "SHOPEE", "LAZADA"],
    "fun": ["NETFLIX", "SPOTIFY", "CGV", "TIMEZONE", "YOUTUBE"],
}

def clean(text):
    """Upper case, numbers and punctuation removed, single spaces."""
    text = re.sub(r"[^A-Z ]", " ", text.upper().replace("-", ""))
    return " ".join(text.split()) + " "        # the final space lets 'MIE ' match

def rule_category(text):
    """The first category with a matching keyword, or None if no rule fires."""
    t = clean(text)
    for category, words in RULES.items():
        if any(word in t for word in words):
            return category
    return None
```

`RULES` maps each category to the words that give it away. Python dictionaries keep the order in which entries were written, and `rule_category` returns the *first* category with a matching word, so the order matters: `topup` and `income` come first because moving your own money or receiving a salary must win over any later rule that happens to share a word with the description. `clean` implements Section 2.3.1 with a *regular expression*: `re.sub(r"[^A-Z ]", " ", …)` replaces every character that is not a capital letter or a space by a space, and `" ".join(text.split())` squeezes repeated spaces. The final extra space lets a keyword such as `"MIE "` match the whole word MIE without also matching, say, MIETTA. The hyphen is removed before the other characters, so `E-TOLL` becomes `ETOLL` and `GoRide - …` becomes `GORIDE …`.

These rules were written by looking at the first month of statements, which is exactly what a person would do. They are right whenever they fire, but they know nothing about Blibli, clinics or markets.

2.5.4 The learned model

Listing 2.3 builds the naive Bayes model of Section 2.3.2 and the three-step categorizer.

Listing 2.3 `learner.py`: the naive Bayes model and the rules-then-model-then-ask categorizer.

```
"""A classifier that learns categories from transactions you have labeled."""
from sklearn.feature_extraction.text import CountVectorizer
from sklearn.naive_bayes import MultinomialNB
from sklearn.pipeline import make_pipeline

from rules import clean, rule_category

def make_model(alpha=1.0):
    """Words -> counts -> naive Bayes. alpha is the add-one (Laplace) smoothing."""
    words = CountVectorizer(preprocessor=clean, lowercase=False,
                            token_pattern=r"[A-Z]{2,}")
    return make_pipeline(words, MultinomialNB(alpha=alpha))

class Categorizer:
    """Rules first, then the learned model, and 'ask' when neither is sure."""

    def __init__(self, threshold=0.7):
        self.model = make_model()
        self.threshold = threshold              # the least confidence we accept

    def fit(self, descriptions, categories):
        self.model.fit(list(descriptions), list(categories))
        return self

    def predict_one(self, text):
        """Return (category, how it was decided, confidence)."""
        by_rule = rule_category(text)
        if by_rule:
            return by_rule, "rule", 1.0
        probs = self.model.predict_proba([text])[0]
        best = probs.argmax()
        if probs[best] >= self.threshold:
            return self.model.classes_[best], "model", float(probs[best])
        return "ask", "unsure", float(probs[best])

    def predict(self, texts):
        return [self.predict_one(t) for t in texts]
```

scikit-learn does the counting for us [5]. `CountVectorizer` turns each description into word counts; we hand it our own `clean` function as `preprocessor`, so the model and the rules see the same words, and `token_pattern=r"[A-Z]{2,}"` says that a word is two or more capital letters. `MultinomialNB` is naive Bayes for counts, and `alpha=1.0` is exactly the add-one smoothing of Equation (2.3). `make_pipeline` glues the two steps together, so that `fit` and `predict_proba` accept plain text.

`Categorizer.predict_one` follows lines 5 to 10 of **Pseudocode 2.1**. `predict_proba` returns one probability per category, in the order of `model.classes_`; `argmax` finds the position of the largest. The method returns three values, the category, *how* it was decided (`"rule"`, `"model"` or `"unsure"`) and the confidence, so that the application can report where each answer came from. The default threshold is 0.7, the value Section 2.7 will justify.

2.5.5 Summary and budget alerts

Listing 2.4 does the arithmetic.

Listing 2.4 `budget.py`: the monthly summary, the month-end forecast and the budget alerts.

```
"""Monthly summary and budget alerts."""
import calendar

import pandas as pd

NOT_SPENDING = {"income", "topup"}             # money in, or moving our own money
DAILY = {"food", "groceries", "transport", "fun", "shopping"}   # spent bit by bit

def monthly_summary(table):
    """Spending per category (rows) and month (columns), in rupiah."""
    spend = table[~table["category"].isin(NOT_SPENDING) & (table["amount"] < 0)]
    months = spend["date"].dt.strftime("%Y-%m")
    summary = (-spend["amount"]).groupby([spend["category"], months]).sum()
    table = summary.unstack(fill_value=0).astype(int)
    table.columns.name = "month"
    return table

def projected(spent, day, days_in_month):
    """Straight-line projection of this month's total from the first `day` days."""
    return spent * days_in_month / day

def budget_alerts(table, budget, today, warn_at=0.8):
    """Compare this month so far with the budget. Returns rows sorted by use."""
    month = table[(table["date"].dt.year == today.year) &
                  (table["date"].dt.month == today.month) &
                  (table["date"] <= today)]
    spend = month[~month["category"].isin(NOT_SPENDING) & (month["amount"] < 0)]
    spent = (-spend["amount"]).groupby(spend["category"]).sum()
    days = calendar.monthrange(today.year, today.month)[1]
    rows = []
    for category, limit in budget.items():
        s = float(spent.get(category, 0))
        p = projected(s, today.day, days) if category in DAILY else s
        if s > limit:
            status = "OVER"
        elif s >= warn_at * limit or p > limit:
            status = "WARN"
        else:
            status = "ok"
        rows.append((category, s, limit, s / limit, p, status))
    rows.sort(key=lambda r: -r[3])
    return pd.DataFrame(rows, columns=["category", "spent", "limit", "used",
                                       "projected", "status"])
```

`monthly_summary` drops income and top-ups, keeps negative amounts, and uses `groupby` with two keys, the category and the month written as `2026-07`, to add up the spending; `unstack` turns the months into columns. `projected` is Equation (2.7). `budget_alerts` keeps the rows of the current month up to `today`, adds up the spending per category, and assigns a status: `OVER` when the limit is already exceeded, `WARN` when 80 percent is used or the forecast is over the limit, `ok` otherwise. The forecast is applied only to the categories in `DAILY`, as Section 2.3.5 explained. The monthly limits live in `data/budget.csv`, one line per category, so you can change them without touching the code.

2.5.6 The application

Listing 2.5 ties everything together into the program you run each month.

Listing 2.5 `categorize.py`: the application that imports, categorizes, summarizes and warns.

```
"""Smart expense categorizer: import statements, categorize, summarize, alert.

python categorize.py                          (uses the sample data in data/)
python categorize.py my_bank.csv my_wallet.csv --today 2026-09-20
"""
import argparse
from pathlib import Path

import pandas as pd

from budget import budget_alerts, monthly_summary
from learner import Categorizer
from rules import clean
from statement import load_all

HERE = Path(__file__).parent
SAMPLE = [HERE / "data/bank_2026.csv", HERE / "data/ewallet_2026.csv"]

def main():
    ap = argparse.ArgumentParser(description=__doc__.splitlines()[0])
    ap.add_argument("statements", nargs="*", default=SAMPLE)
    ap.add_argument("--labels", default=HERE / "data/labels.csv")
    ap.add_argument("--budget", default=HERE / "data/budget.csv")
    ap.add_argument("--learn-until", default="2026-06-30")
    ap.add_argument("--today", default="2026-09-20")
    args = ap.parse_args()

    table = load_all(args.statements)
    labels = pd.read_csv(args.labels)
    known = table.merge(labels, on="id")
    known = known[known["date"] <= args.learn_until]      # what you labeled so far
    print(f"{len(table)} transactions read; learning from {len(known)} "
          f"labeled ones up to {args.learn_until}")

    cat = Categorizer().fit(known["description"], known["category"])
    todo = table[table["date"] > args.learn_until].copy()
    todo[["category", "how", "confidence"]] = cat.predict(todo["description"])
    print("decided by:", todo["how"].value_counts().to_dict())
```

Listing 2.5 (Continued) *categorize.py: the application that imports, categorizes, summarizes and warns.*

```
    ask = todo[todo["how"] == "unsure"]
    if len(ask):
        print("\nPlease label these (add them to labels.csv):")
        once = ask[~ask["description"].map(clean).duplicated()]  # ask only once
        for _, r in once.iterrows():
            print(f"  {r['id']:<11} {r['description']:<38} {-r['amount']:>10,.0f}")

    print("\nSpending per month (rupiah):")
    print(monthly_summary(todo).to_string())

    today = pd.Timestamp(args.today)
    limits = pd.read_csv(args.budget).set_index("category")["monthly_limit"]
    alerts = budget_alerts(todo, limits.to_dict(), today)
    print(f"\nBudget check on {today:%d %B %Y}:")
    for r in alerts.itertuples():
        if r.status != "ok":
            print(f"  {r.status:<4} {r.category:<15} {r.spent:>10,.0f} of "
                  f"{r.limit:>10,.0f} ({r.used:4.0%}), month-end forecast "
                  f"{r.projected:>10,.0f}")

    out = HERE / "out"
    out.mkdir(exist_ok=True)
    todo.to_csv(out / "categorized.csv", index=False)
    print("\nwrote out/categorized.csv")

if __name__ == "__main__":
    main()
```

`argparse` reads the command line; every argument has a default, so `python categorize.py` works on the sample data, and `python categorize.py my_bank.csv my_wallet.csv` works on yours. `merge(labels, on="id")` attaches the known categories to the transactions, and the date filter keeps only those labeled up to `--learn-until`. Assigning the list of triples returned by `predict` to three columns at once fills `category`, `how` and `confidence`. The questions are printed once per distinct cleaned description, so ten Blibli purchases produce one question, not ten. Finally the categorized table is written to `out/categorized.csv`, which you can open in a spreadsheet.

2.6 Running It

Run the application with the defaults. It learns from April to June and categorizes July to September; the budget is checked on 20 September 2026.

```
428 transactions read; learning from 206 labeled ones up to 2026-06-30
decided by: {'rule': 197, 'model': 14, 'unsure': 11}

Please label these (add them to labels.csv):
  bank-150    QRIS 0807 KLINIK PRATAMA SEHAT           135,000
  bank-169    QRIS 2107 PASAR PUCANG SAYUR             317,500
  bank-206    BLIBLI.COM 6869                           53,000

Spending per month (rupiah):
month           2026-07  2026-08  2026-09
category
ask              452500  1200500  1151000

Budget check on 20 September 2026:
  WARN groceries        1,604,500 of  1,700,000 ( 94%), month-end forecast  2,406,750
  WARN transport          929,000 of  1,000,000 ( 93%), month-end forecast  1,393,500
  WARN education          358,500 of    400,000 ( 90%), month-end forecast    358,500
  WARN family           1,220,500 of  1,500,000 ( 81%), month-end forecast  1,220,500

wrote out/categorized.csv
```

Of the 222 new transactions, rules placed 197, the model placed 14 and 11 were left for you; the program lists one example of each kind of question. The questions are exactly the new places: a clinic, a traditional market and a marketplace the rules and the labels never mentioned. The row `ask` in the summary is a useful reminder that 1,200,500 rupiah of August spending is still unexplained, and that August's shopping, which shows 0, is certainly not zero: it is hidden in that row until you label the Blibli purchases.

The budget check found four categories to watch. Groceries have used 94 percent of the limit by the 20th, and at the same pace will reach 2,406,750 rupiah, far above the limit of 1,700,000. Transport is in the same situation. Education and family have no forecast because they are paid once a month; they are flagged only because most of the limit has been used, which is expected and harmless. **Figure 2.2** draws the same check for every category.

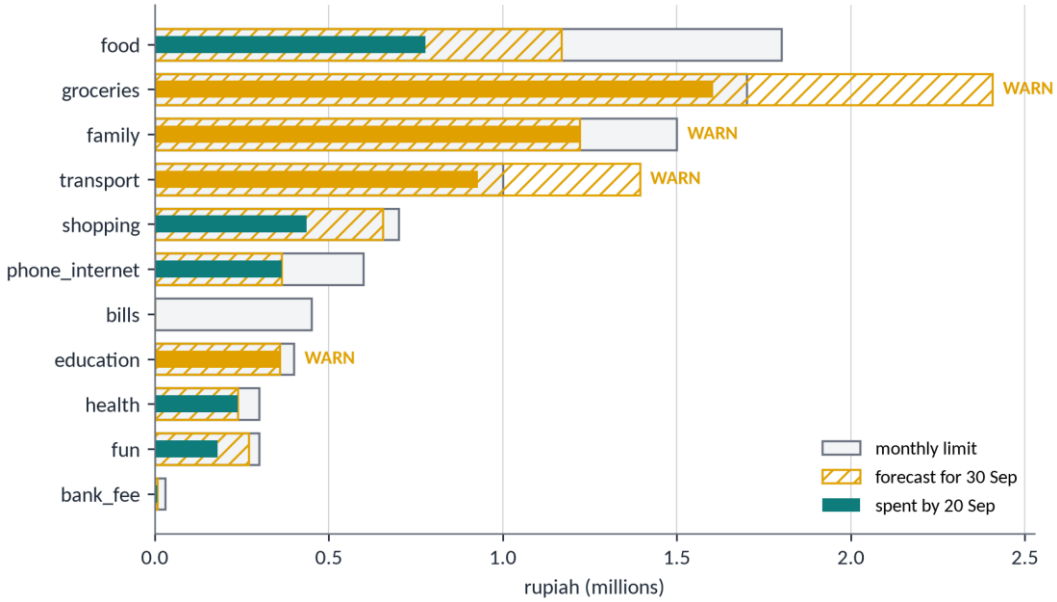

Figure 2.2 The budget check on 20 September 2026: spending so far (solid), the month-end forecast (hatched) and the monthly limit (grey frame); amber marks a warning.

The chart makes the priorities obvious in a way the numbers do not. Food looks worrying in the table because it is the largest category, but it is well within its limit; groceries and transport are the two to talk about at home this week.

2.7 Measuring It

How good is the categorizer, and was 0.7 a good threshold? **Listing 2.6** answers both questions on the three months that the model did not learn from, using the answer key.

Listing 2.6 `lab.py`: measuring rules, model and hybrid on July to September.

```
"""Measure the categorizer on July-September, using the answer key.

Trains on the months you labeled (April-June) and counts how often each
method is right on the three months it has never seen.
"""
from pathlib import Path

              f"right {ok}/{n} ({ok / n:.1%}), asked {asked}")

if __name__ == "__main__":
    main()
```

```
train: 206 transactions (Apr-Jun), test: 222 (Jul-Sep)
rules only : a rule fired for 197/222 (88.7%); right 197/197; overall accuracy 88.7%
model only : right 191/222, accuracy 86.0%

hybrid (rules, then model if confident enough):
  threshold 0.5: decided 218/222, wrong 7, asked 4
  threshold 0.6: decided 218/222, wrong 7, asked 4
  threshold 0.7: decided 211/222, wrong 0, asked 11
  threshold 0.8: decided 209/222, wrong 0, asked 13
  threshold 0.9: decided 209/222, wrong 0, asked 13

what the model said when no rule fired (threshold 0.7):
  ok  KARTU DEBIT ALFAMIDI NGINDEN 0707    -> groceries 0.76 (true groceries)
  ASK QRIS 0807 KLINIK PRATAMA SEHAT       -> ask       0.62 (true health)
  ok  GrabBike - Perjalanan ke Galaxy Mall -> transport 0.93 (true transport)
  ASK QRIS 2107 PASAR PUCANG SAYUR         -> ask       0.62 (true groceries)
  ASK BLIBLI.COM 6869                      -> ask       0.16 (true shopping)

learning curve (hybrid, threshold 0.7):
  labeled up to 2026-04-30:  74 examples, right 209/222 (94.1%), asked 13
  labeled up to 2026-05-31: 142 examples, right 211/222 (95.0%), asked 11
  labeled up to 2026-06-30: 206 examples, right 211/222 (95.0%), asked 11
```

Read the output from the top. The rules fired for 197 of the 222 transactions, a coverage of 88.7 percent by Equation (2.6), and they were right every time. The model on its own was right for 191, an accuracy of 86.0 percent by Equation (2.5): worse than the rules, because it confuses categories that share words. Neither alone is good enough.

The hybrid table shows the trade-off of Equation (2.4). With a threshold of 0.6 or lower, the program decides 218 transactions and gets 7 of them wrong; with 0.7 it gets none wrong and asks

about 11. **Figure 2.3** draws the same numbers. Seven wrong answers means seven payments silently counted as food, among them 317,500 rupiah at the market and 191,500 at the clinic; eleven questions means about a minute of your time once a month. For a household budget the choice is easy, and it is why 0.7 is the default. Above 0.7 the program only asks more without being right more often.

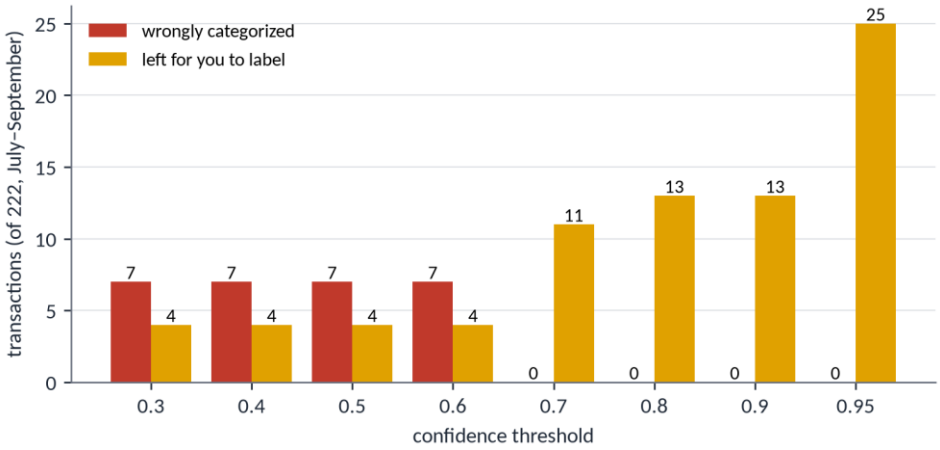

Figure 2.3 The effect of the confidence threshold on the 222 test transactions: below 0.7 seven are categorized wrongly, from 0.7 on none are, at the price of more questions.

The list of model decisions explains everything we saw by hand in Section 2.3.2. `ALFAMIDI` and `GrabBike` were decided correctly because their other words (KARTU DEBIT, PERJALANAN) are strongly tied to groceries and transport. The clinic and the market sit at exactly 0.62, the probability we computed by hand, because QRIS is the only known word. Blibli, with no known word at all, gets only the largest prior, 0.16, and is asked about.

Finally the learning curve: with only April labeled (74 examples) the hybrid is already right for 209 of 222 transactions; more labels mainly reduce the number of questions. Because the rules do most of the work, a few weeks of labels are enough to be useful, which matters, because nobody wants to label six months before a program helps them.

2.8 Testing It

A program that handles money deserves automatic tests. **Listing 2.7** checks the signs of imported amounts, the cleaning and the rules, the ask behavior of the model and the alert logic.

Listing 2.7 `test_categorizer.py`: tests for importing, rules, the model and the budget alerts.

```
"""Tests for the expense categorizer. Run: python -m unittest -v"""
import unittest
from pathlib import Path

import pandas as pd

from budget import budget_alerts, projected
from learner import Categorizer
from rules import clean, rule_category
from statement import load_statement

HERE = Path(__file__).parent

class CategorizerTests(unittest.TestCase):
    def test_bank_signs(self):
        t = load_statement(HERE / "data/bank_2026.csv")
        salary = t[t["description"].str.contains("GAJI")]
        self.assertTrue((salary["amount"] > 0).all())        # CR is money in
        self.assertTrue((t[t["description"] == "BIAYA ADM"]["amount"] < 0).all())

    def test_clean_and_rules(self):
        self.assertEqual(clean("QRIS 0304 MIE GACOAN"), "QRIS MIE GACOAN ")
        self.assertEqual(rule_category("GoRide - Perjalanan ke ITS"), "transport")
        self.assertEqual(rule_category("TOPUP GOPAY 08121234"), "topup")
        self.assertIsNone(rule_category("BLIBLI.COM 1234"))

    def test_model_or_ask(self):
        cat = Categorizer(threshold=0.6).fit(
            ["QRIS SOTO", "QRIS SOTO AYAM", "GRABBIKE ITS", "GRABBIKE MERR"],
            ["food", "food", "transport", "transport"])
        self.assertEqual(cat.predict_one("KFC MERR")[1], "rule")
        self.assertEqual(cat.predict_one("GRABBIKE PAKUWON")[0], "transport")
        self.assertEqual(cat.predict_one("BLIBLI.COM 99")[0], "ask")  # 50:50

    def test_projection_and_alerts(self):
        self.assertEqual(projected(300000, 10, 30), 900000)
        table = pd.DataFrame({
            "date": pd.to_datetime(["2026-09-02", "2026-09-05", "2026-09-06"]),
            "amount": [-500000.0, -200000.0, 8500000.0],
            "category": ["food", "fun", "income"]})
        alerts = budget_alerts(table, {"food": 1000000, "fun": 150000},
                               pd.Timestamp("2026-09-10"))
        status = dict(zip(alerts["category"], alerts["status"]))
        self.assertEqual(status, {"fun": "OVER", "food": "WARN"})  # 1.5 M forecast
```

Listing 2.7 (Continued) *test_categorizer.py: tests for importing, rules, the model and the budget alerts.*

```
if __name__ == "__main__":
    unittest.main()
```

The model test trains on four tiny examples, two per category, so that we can check the answers by hand with Equation (2.2) and Equation (2.3). The vocabulary has six words (QRIS, SOTO, AYAM, GRABBIKE, ITS, MERR); the food examples contain five words and the transport examples four. For `GRABBIKE PAKUWON`, only GRABBIKE is known: food scores $0.5 \times (0+1)/(5+6) = 0.045$ and transport $0.5 \times (2+1)/(4+6) = 0.15$, so transport wins with $0.15/0.195 = 0.77$, above the threshold of 0.6. For `BLIBLI.COM 99` no word is known, both categories score their prior of 0.5, and the program asks. The alert test uses three hand-made rows: fun has spent 200,000 of 150,000 and is `OVER`; food has spent 500,000 of 1,000,000 by the 10th, which is only 50 percent, but Equation (2.7) forecasts 1,500,000 for the month, so it is `WARN`. Run the tests with `python -m unittest -v`:

```
test_bank_signs (test_categorizer.CategorizerTests.test_bank_signs) ... ok
test_clean_and_rules (test_categorizer.CategorizerTests.test_clean_and_rules) ... ok
test_model_or_ask (test_categorizer.CategorizerTests.test_model_or_ask) ... ok
test_projection_and_alerts (test_categorizer.CategorizerTests.test_projection_and_alerts)
... ok

----------------------------------------------------------------------
Ran 4 tests in 0.015s

OK
```

2.9 Improving It

Learn from the answers. When you answer a question, append the line `id,category` to `labels.csv` and move `--learn-until` forward. The next run knows the new merchant. A small loop that asks in the terminal and appends each answer to the file automatically is a good first extension; until then, a spreadsheet works.

Add rules for what you answer often. If you label Blibli three times, add `"BLIBLI"` to the shopping rule. Rules and labels grow together; Exercise 3 shows that three new keywords remove every question in our data.

Split a transaction. A supermarket receipt may be half groceries and half household goods. A `split` file with an id and several categories and amounts can override the categorizer for such rows.

Recurring payments. The same amount to the same payee every month (a school fee, an internet bill, a transfer to parents) can be detected and shown as “fixed costs”, separated from the day-to-day spending that a budget can actually change.

Better text features. Chapters 23 and 25 show other ways of turning text into numbers, and Exercise 6 of this chapter tries character sequences, which recognize parts of words. As you will see there, a more accurate model is not always a more useful one.

2.10 Using It for Real

Get your statements. Most Indonesian banking apps and internet banking sites let you download the mutation list (*mutasi rekening*) for a chosen period as CSV or Excel, and most e-wallets offer a transaction history export or at least a monthly e-mail statement. If you receive Excel, open it and save it as CSV. If you receive only PDF, many banks let you choose CSV on their internet banking website instead; copying tables out of PDF is error-prone.

Teach it your layout. Open the CSV in a text editor and look at the header line. If the column names differ from ours, add an entry to `FORMATS` in **Listing 2.1**. Some banks use separate Debit and Kredit columns instead of a DB/CR flag; Exercise 5 shows the few lines that handle that.

Label a few weeks. Run the program once; it prints the ids of the transactions it cannot place. Write your categories for the first two to four weeks into a labels file. Use categories that match your decisions: a family that wants to cut down on eating out needs “food delivery” separate from “warung”, while a student may be happy with “food”.

Set a realistic budget. Start with the average of the last three months from the summary, not with a wish. A limit that is always exceeded teaches you to ignore the warnings.

Run it monthly, or weekly. A check on the 10th and the 20th of each month is when the forecast of Equation (2.7) is most useful: early enough to change something, late enough to be reliable.

Keep it private. Statements are personal financial data. Indonesia's Personal Data Protection Law (UU PDP, Law No. 27 of 2022) requires anyone who processes other people's personal data to protect it [6]. The program runs entirely on your own computer and sends nothing anywhere, which is the simplest way to stay safe; if you adapt it for customers, for instance as a bookkeeping service for small shops, you become responsible for how their data are stored and who can see them.

For a small business. The same program sorts a shop's business account into stock purchases, salaries, rent, utilities and sales, which is the first step of any bookkeeping. Replace the categories and rules, label a month, and the summary becomes a simple profit-and-loss view.

2.11 Common Mistakes, and How to Avoid Them

Counting top-ups as spending. Moving money from the bank to an e-wallet is not spending; the spending happens when it leaves the wallet. Counting both doubles the total. Keep transfers between your own accounts in their own category and exclude them, as `NOT_SPENDING` does.

Getting the sign or the date wrong. Banks mark debits and credits in different ways and write dates day first. Always check a few imported rows against the app: a salary must be positive, and 03/04 must be April 3rd.

Testing on the training data. A model tested on the examples it learned from looks perfect and tells you nothing. Always hold out later months, as the lab does.

Trusting a confident-looking guess. A probability of 0.62 sounds precise but may come from one word and the prior alone. Look at which words a decision rests on, and let the program ask.

Letting rules and model disagree silently. If a keyword is ambiguous (KOPI appears on coffee shops and on a coffee-bean shop), a rule will be wrong every time. Review what the rules decide now and then, not only what the model decides.

Forecasting a monthly bill as if it were daily. Equation (2.7) assumes steady spending. Use it only for categories that behave that way.

2.12 Chapter Summary

- Statement lines are text; cleaning them into words (Section 2.3.1) is the first step of every text classifier.
- Keyword rules are precise but incomplete; a naive Bayes model learns from labeled examples with Equation (2.1), Equation (2.2) and add-one smoothing Equation (2.3).
- A confidence threshold Equation (2.4) turns the model's uncertainty into questions; in our data 0.7 removed all seven wrong answers at the cost of eleven questions.
- Honest measurement uses months the model has not seen: rules covered 88.7 percent and were always right, the model alone was 86.0 percent accurate, and the hybrid made no mistakes.
- A straight-line forecast Equation (2.7) of daily categories gives early budget warnings; income and transfers between your own accounts must be excluded from spending.

2.13 Exercises

1. Using **Table 2.1**, compute by hand the probability that the model gives to the category *groceries* for `QRIS 2107 PASAR PUCANG SAYUR`. Explain why it is the same as for the clinic payment.
2. On the 12th of a 30-day month a family has spent 600,000 rupiah on transport with a limit of 1,400,000. What status does `budget_alerts` give, and why? What would it give if the same amount had been spent on bills?
3. Add the keywords BLIBLI (shopping), KLINIK (health) and PASAR (groceries) to `rules.py` and run `lab.py` again. What changes?
4. A top-up of 214,500 rupiah from the bank to GoPay is followed by GoFood orders of 64,000 and 48,500 rupiah. How much food spending should the summary show, and what would a program that treated top-ups as spending show?
5. Some banks export Debit and Kredit in two columns, for example `Tanggal Transaksi,Uraian,Debit,Kredit`. Extend `statement.py` to read that layout.
6. In `make_model`, replace the word tokens by character sequences: `analyzer="char_wb", ngram_range=(3, 5)` instead of `token_pattern`. Run `lab.py` and compare with the results of Section 2.7.

2.14 Solutions to the Exercises

1. Like the clinic line, the market line has only one known word, QRIS; PASAR, PUCANG and SAYUR never occurred in April to June. The scores therefore depend only on QRIS and are exactly those of Section 2.3.2: groceries $(33/206) \times (14/255) = 0.00880$, and dividing by the total 0.03745 gives 0.235. Food wins with 0.62, which is below the threshold of 0.7, so the program asks. The model cannot tell a market from a clinic, because for it both lines are simply "a QRIS payment".

2. $600{,}000/1{,}400{,}000 = 43$ percent is used, below the 80 percent warning level, but transport is a daily category and Equation (2.7) forecasts $600{,}000 \times 30/12 = 1{,}500{,}000$, above the limit, so the status is `WARN`. For bills the forecast is just the 600,000 already spent, which is under the limit, so the status is `ok`.

3. The rules now fire for 208 of the 222 transactions (93.7 percent) and are still always right, and the first line of the hybrid table becomes

```
  threshold 0.5: decided 222/222, wrong 0, asked 0
```

Up to a threshold of 0.7 every transaction is decided and none is wrong. This is the normal life of the program: questions become labels, frequent labels become rules.

4. Only the orders are spending: $64{,}000 + 48{,}500 = 112{,}500$ rupiah of food. A program that counted the top-up as spending would show $214{,}500 + 112{,}500 = 327{,}000$ rupiah, almost three times too much, and would do so every month for every top-up.

5. Add a layout with two amount columns and compute the amount as credit minus debit:

```
    "debitcredit": {"date": "Tanggal Transaksi", "text": "Uraian",
                    "debit": "Debit", "credit": "Kredit", "dayfirst": True},
```

and in `load_statement` replace the first two lines that compute `amount` by

```
    if "debit" in f:                            # two columns instead of a sign
        num = lambda c: raw[c].fillna("0").str.replace(",", "").astype(float)
        amount = num(f["credit"]) - num(f["debit"])
    else:
        amount = raw[f["amount"]].str.replace(",", "", regex=False).astype(float)
    if f.get("sign"):
```

`fillna("0")` turns the empty cell of the unused column into zero, and `f.get("sign")` returns `None` for the new layout instead of failing. A two-line test file with `"25,000"` in Debit and `"8,500,000"` in Kredit gives −25,000 and +8,500,000, and the two sample statements still load all 428 rows.

6. The lab prints

```
model only : right 201/222, accuracy 90.5%

hybrid (rules, then model if confident enough):
  threshold 0.5: decided 222/222, wrong 11, asked 0
  threshold 0.6: decided 222/222, wrong 11, asked 0
  threshold 0.7: decided 222/222, wrong 11, asked 0
  threshold 0.8: decided 218/222, wrong 7, asked 4
```

The model alone is more accurate (90.5 instead of 86.0 percent), because pieces of words such as GRAB or MIDI carry information that whole words miss. But the hybrid becomes *worse*: it now places the clinic under fun with confidence 0.98 and Blibli under fun with 0.80, and asks about nothing. Character sequences produce many small pieces of evidence that the naive independence assumption multiplies together, which makes the probabilities overconfident. The lesson is worth remembering: what matters is not the accuracy of the model alone, but the number of wrong answers the whole program lets through.

Chapter 3

A Warehouse Picking-Route Optimizer: BFS, DFS and A*

Every online order that reaches your door started with somebody walking through a warehouse with a trolley, taking one item from this shelf and two from that one. In this chapter we build the program that tells that person where to walk. It reads a map of the warehouse and the day's orders, finds the shortest walking path between any two places with graph search, puts the shelves of an order into a sensible sequence, and groups several orders into one trolley trip. On the morning wave of our sample shop it cuts the walking of 40 orders from 1,954 meters to 787 meters. By the end of the chapter you will be able to describe a floor plan as a graph, implement breadth-first search, depth-first search and A* and explain why they behave so differently, prove that A* with the Manhattan distance still finds shortest paths, order the stops of a route with the nearest-neighbor rule and 2-opt, batch orders, and measure every step against the best possible answer.

3.1 Every Step Costs Money

Indonesians buy more and more of their daily goods online. According to the e-Conomy SEA 2025 report by Google, Temasek and Bain, Indonesia's digital economy approached a gross merchandise value of US$100 billion in 2025, and e-commerce alone was expected to reach US$71 billion, growing by more than 14 percent in a year [1]. Behind each of those orders stands a warehouse: a large fulfillment center of a marketplace, the stockroom of a minimarket chain's distribution center, or the back room of a small online shop that sells groceries through WhatsApp and a marketplace app.

In most of these warehouses people still pick the goods by hand, and picking is expensive. A classic review of the research on warehouses found that order picking accounts for as much as 55 percent of a warehouse's operating cost, and that about half of a picker's time is spent simply *walking* between shelves [2]. Walking produces no value. Every meter saved is time that can be spent on more orders, earlier deliveries, or a shorter and less tiring shift.

The typical small warehouse does not optimize anything. The picker receives a list printed in the order in which the customer added items to the cart, walks to the first item, then to the second, and so on, often crossing the hall several times. Nobody would plan a trip to five shops in a city that way, yet it happens every day in stockrooms. Large companies buy warehouse management systems whose routing modules do what this chapter does. Here we build the core of such a module ourselves, on a map of the kind any shop owner can draw on squared paper.

The problem also introduces the most important idea of classic AI: *search*. A program that cannot see the answer directly explores possibilities in a systematic way until it finds one, and the order in which it explores makes all the difference. Chapter 8 will use the same algorithms on the road map of Surabaya.

3.2 The Idea in Plain Words

Draw the warehouse on squared paper. Each square is either floor, where a person can walk, or a shelf bay, which holds one product. The picker walks from square to square, up, down, left or right, and takes a product while standing on the floor square beside its bay. The packing table, where every trip starts and ends, is called the *depot*.

The program has three jobs, one inside the other.

Find a path between two squares. Imagine pouring water on the depot square. It spreads to the neighboring floor squares, then to their neighbors, one ring at a time, and never runs into shelves. The first ring the water reaches the target in tells you the shortest distance, and following the flow backwards gives the path. This is *breadth-first search*. Its opposite, *depth-first search*, is like a person who always takes the next unexplored corridor and walks as far as possible before turning back; it finds a way out, but often a long one. *A** is breadth-first search with a sense of direction: it explores first the squares that look closest to the target.

Put the stops of one order in a good sequence. Knowing the distance between every pair of stops, the program chooses the order of the visits. A simple rule works well: always walk to the nearest stop not yet visited. A second step then looks for crossings and detours in that route and removes them.

Put several orders on one trolley. If four orders all need products from the same corner of the hall, one trip with four boxes on the trolley is much shorter than four trips. The program groups orders whose shelves are close together.

> **DEFINITION.** A *graph* is a set of *nodes* joined by *edges*. In our warehouse graph every floor square is a node, and an edge joins two floor squares that share a side. A *path* is a sequence of nodes in which consecutive nodes are joined by an edge; its *length* is its number of edges, here the number of steps.

3.3 The Math, Gently

3.3.1 Squares, steps and distances

We write a square as (r, c), its row and column, counted from 0 at the top left. The four neighbors of (r, c) are $(r-1, c)$, $(r+1, c)$, $(r, c-1)$ and $(r, c+1)$, whenever they are floor. The *distance* $d(a, b)$ between two squares is the length of the shortest path between them. On our map one step is 1.2 meters of floor, so meters are $1.2 \cdot d$.

3.3.2 Breadth-first search

Breadth-first search (BFS) keeps a *queue*, a waiting line in which the first to arrive is the first to leave. It puts the start square in the queue; then, again and again, it takes the square at the front, and puts every neighbor that it has not seen before at the back, remembering which square it came from (its *parent*). Because of the queue, all squares at distance 1 leave before any square at distance 2, all at distance 2 before any at distance 3, and so on. The squares are processed ring by ring, and the first time the goal leaves the queue, it has been reached by a path with the fewest possible steps.

Let us run it by hand on a tiny room of four rows and six columns, where `#` marks shelves:

```
......
.##.#.
.##.#.
......
```

Start at the bottom-left corner (3,0) and look for the top-right corner (0,5). The rings are:

```
distance 0: (3,0)
distance 1: (2,0) (3,1)
distance 2: (1,0) (3,2)
distance 3: (0,0) (3,3)
distance 4: (0,1) (2,3) (3,4)
distance 5: (0,2) (1,3) (3,5)
distance 6: (0,3) (2,5)
distance 7: (0,4) (1,5)
distance 8: (0,5)
```

The goal is in ring 8, so the shortest path has 8 steps, and following the parents back from (0,5) gives up the left wall and along the top: (3,0), (2,0), (1,0), (0,0), (0,1), … , (0,5). Filling the whole map ring by ring in this way is also called a *flood fill*; the same idea colors regions in a paint program, and it gives the distances from one square to all others in one pass.

3.3.3 Depth-first search

Depth-first search (DFS) is the same procedure with a *stack* instead of a queue: the last square put on is the first taken off, like a pile of plates. It keeps going deeper along the newest square and backs up only when it is stuck. On the tiny room above it happens to walk along the bottom row and up the right wall, which is also 8 steps; on the real warehouse, as we will see in Section 3.7, it usually finds paths two or three times longer than necessary. DFS is still useful when any path will do or when memory is scarce, but it is the wrong tool for shortest paths.

3.3.4 A* and the Manhattan distance

BFS is correct but wasteful: it spreads in every direction, also away from the goal. A*, published by Hart, Nilsson and Raphael in 1968 [3], gives each square n a priority

$$f(n) = g(n) + h(n) \tag{3.1}$$

where $g(n)$ is the number of steps already taken from the start to n, and $h(n)$ is an *estimate* of the steps still needed from n to the goal. A* always expands the square with the smallest f next. For h we use the *Manhattan distance*, named after the grid of streets in that city:

$$h(n) = |r_n - r_{\text{goal}}| + |c_n - c_{\text{goal}}| \tag{3.2}$$

It is the number of steps a picker would need if there were no shelves in the way. For example, from the depot at (13,10) to the square (1,3) it is $|13-1| + |10-3| = 12 + 7 = 19$.

A* finds a shortest path provided that h never *overestimates* the true remaining distance. Such an h is called *admissible*:

$$h(n) \le d(n,\text{goal}) \quad \text{for every square } n \tag{3.3}$$

The Manhattan distance is admissible for an obvious reason: every step changes the row or the column by exactly one, so a path from n to the goal needs at least $|r_n - r_{\text{goal}}|$ vertical and $|c_n - c_{\text{goal}}|$ horizontal steps, and shelves can only make it longer. A stronger property makes the program simpler. h is *consistent* if for every square n and every neighbor n'

$$h(n) \leq 1 + h(n') \tag{3.4}$$

that is, one step can reduce the estimate by at most one. The Manhattan distance is consistent, because moving one square changes one coordinate by one, and so changes the sum in Equation (3.2) by exactly one, up or down. With a consistent heuristic, the first time A* takes a square from its priority queue it has already found the shortest path to it, so the square never has to be looked at again [4]. That is why our program can keep a set `done` of finished squares and simply skip them.

A useful variant multiplies the heuristic by a weight $w > 1$ and expands the square with the smallest $g(n) + w \cdot h(n)$. This *weighted A** rushes toward the goal and expands fewer squares, but it gives up the guarantee: the estimate is no longer admissible, and the path found may be a little longer than the shortest. Section 3.7 measures both effects.

3.3.5 The length of a route

An order with k stops $s_1, s_2, \ldots, s_k$, visited in that order from the depot D and back, makes the picker walk

$$L = d(D, s_1) + \sum_{i=1}^{k-1} d\,(s_i, s_{i+1}) + d(s_k, D) \tag{3.5}$$

steps. The symbol $\sum_{i=1}^{k-1}$ means "add up the terms for $i = 1,2, \ldots, k-1$". We want the order of the stops that makes L smallest. This is the famous *traveling salesman problem*, and its difficulty is the number of possible orders:

$$k! = k \times (k-1) \times \cdots \times 2 \times 1 \tag{3.6}$$

For 6 stops that is 720 orders, which a computer tries in a moment; for 9 stops it is 362,880; for 15 stops it is more than a million million. Trying all orders becomes hopeless very quickly. Computer scientists describe such growth with the *big-O notation*: the work of trying every order grows like $O(k!)$, read "order k factorial", which means "at most a constant times $k!$". The notation ignores constant factors and keeps only how the work grows as the input grows.

3.3.6 Nearest neighbor and 2-opt

The *nearest-neighbor* rule builds a route by always walking to the closest stop not yet visited. It needs about k choices of k candidates, $O(k^2)$ distance lookups, instead of $k!$ orders. It is often good but sometimes greedy in a bad way: it takes a close stop now and must later cross the hall for a stop it passed by.

2-opt, proposed by Croes in 1958 [5], repairs such mistakes. It takes a piece of the route, from position i to position j, and reverses it. If the reversed route is shorter, it keeps it, and it repeats until no reversal helps. Reversing a piece of the route replaces two legs of the walk by two others; when two legs cross each other, this reversal always uncrosses them and shortens the route. One pass over all pairs (i, j) costs $O(k^2)$ reversals, and a few passes are usually enough.

3.3.7 Batching

If a trolley carries the boxes of m orders, one trip replaces m trips. The walk to the far part of the hall and back is shared, which is where most of the saving comes from. Our grouping rule, a *seed*

rule common in the literature [2], starts a batch with the order whose shelves are farthest from the depot, then repeatedly adds the order whose shelves are closest to the shelves already in the batch, until the trolley is full.

3.4 The Algorithms as Pseudocode

Pseudocode 3.1 is A* as our program implements it. Line 6 is where the consistency of Equation (3.4) pays off: an old entry for a square that is already finished is simply skipped.

Pseudocode 3.1 A* search on the warehouse grid; with $w = 1$ and the Manhattan distance it returns a shortest path, and with $h = 0$ it behaves like breadth-first search.

```
A-STAR(grid, start, goal, w)
1  g[start] = 0; parent[start] = none
2  heap = {(w · h(start), start)}                  // priority queue on f
3  done = empty set
4  while heap is not empty
5      take the entry (f, n) with the smallest f from heap
6      if n in done: continue                       // an outdated entry
7      add n to done
8      if n == goal: return the path by following parent from goal
9      for each floor neighbor m of n
10         if g[n] + 1 < g[m]                       // g[m] = ∞ if unseen
11             g[m] = g[n] + 1; parent[m] = n
12             put (g[m] + w · h(m), m) into heap
13 return no path
```

Pseudocode 3.2 plans the route of one trip with the nearest-neighbor rule followed by 2-opt.

Pseudocode 3.2 Planning the route of one trip: nearest neighbor, then 2-opt until no reversal shortens the route.

```
PLAN-ROUTE(D, stops)
1  route = empty list; here = D; left = stops
2  while left is not empty                          // nearest neighbor
3      s = the stop in left with the smallest d(here, s)
4      append s to route; remove s from left; here = s
5  repeat                                           // 2-opt
6      improved = false
7      for i = 1 to k − 1
8          for j = i + 1 to k
9              new = route with positions i..j reversed
10             if L(new) < L(route): route = new; improved = true
11 until improved is false
12 return route
```

3.5 Building It Step by Step

Create a folder `Chapter003`, open it in VS Code and create a virtual environment as in Chapter 1, Section 1.3. The programs of this chapter use only the standard library of Python, so `requirements.txt` lists nothing to install.

3.5.1 The data

Our sample is the stockroom of a small online grocery shop in Surabaya: 14 rows and 22 columns of squares, seven double racks with ten bays each, three cross aisles, and the packing table `D` at the bottom. The file `data/warehouse.txt` is the map itself, exactly as you would type it:

```
....................
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
....................
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
.##.##.##.##.##.##.##.
....................
..........D.........
```

The file `data/stock.csv` says which of the 48 products lies in which bay, by row and column, and `data/orders.csv` holds one morning's wave of 40 orders with 139 order lines, one line per product and order:

```
sku,name,row,col
P001,Beras 5 kg,5,2
P002,Minyak goreng 2 L,8,13
P003,Gula pasir 1 kg,9,8

order,sku,qty
SO-025,P002,2
SO-025,P003,1
SO-025,P005,1
```

The small program `make_data.py` wrote these files with a fixed random seed. It places the products on random bays, as in a shop that put things wherever there was room, and it makes a few products much more popular than the rest, as in every real shop: rice, cooking oil and sugar appear in many orders.

3.5.2 The grid and the three searches

Listing 3.1 is the map and everything that walks on it.

Listing 3.1 `grid.py`: the warehouse map, breadth-first search, depth-first search, A* and the flood fill.

```
"""The warehouse as a grid, and three ways to find a path through it."""
import heapq
from collections import deque

MOVES = [(-1, 0), (1, 0), (0, -1), (0, 1)]     # up, down, left, right

def load_layout(path):
    """Read the map: '.' is floor, '#' a shelf bay, 'D' the depot."""
    grid = [line.rstrip("\n") for line in open(path, encoding="utf-8")]
    depot = next((r, row.index("D")) for r, row in enumerate(grid) if "D" in row)
    return grid, depot

def neighbors(grid, cell):
    """Floor cells next to `cell` that a picker can walk to."""
    r, c = cell
    for dr, dc in MOVES:
        nr, nc = r + dr, c + dc
        if 0 <= nr < len(grid) and 0 <= nc < len(grid[0]) and grid[nr][nc] != "#":
            yield (nr, nc)

def access_point(grid, bay):
    """Where the picker stands to take from a shelf bay: the floor beside it."""
    r, c = bay
    for cell in [(r, c - 1), (r, c + 1)]:       # the aisle left or right
        if 0 <= cell[1] < len(grid[0]) and grid[cell[0]][cell[1]] != "#":
            return cell
    raise ValueError(f"bay {bay} cannot be reached from an aisle")

def shelf_label(grid, bay):
    """A name people can find: rack letter (by column) and bay number (by row)."""
    cols = sorted({c for row in grid for c, ch in enumerate(row) if ch == "#"})
    rows = sorted({r for r, row in enumerate(grid) if "#" in row})
    return f"{chr(ord('A') + cols.index(bay[1]))}{rows.index(bay[0]) + 1:02d}"

def path_to(parent, goal):
    """Follow the parent links back from the goal and reverse them."""
    path = [goal]
    while parent[path[-1]] is not None:
        path.append(parent[path[-1]])
    return path[::-1]
```

Listing 3.1 (Continued) *grid.py: the warehouse map, breadth-first search, depth-first search, A\ and the flood fill.*

```
def bfs(grid, start, goal):
    """Breadth-first search: the shortest path. Returns (path, cells expanded)."""
    parent = {start: None}

    expanded = 0
    while queue:
        cell = queue.popleft()                # the oldest cell first
        expanded += 1
        if cell == goal:
            return path_to(parent, goal), expanded
        for nxt in neighbors(grid, cell):
            if nxt not in parent:
                parent[nxt] = cell
                queue.append(nxt)
    return None, expanded

def dfs(grid, start, goal):
    """Depth-first search: finds *a* path, not necessarily a short one."""
    parent = {start: None}
    stack = [start]
    expanded = 0
    while stack:
        cell = stack.pop()                    # the newest cell first
        expanded += 1
        if cell == goal:
            return path_to(parent, goal), expanded
        for nxt in neighbors(grid, cell):
            if nxt not in parent:
                parent[nxt] = cell
                stack.append(nxt)
    return None, expanded

def manhattan(a, b):
    return abs(a[0] - b[0]) + abs(a[1] - b[1])
```

Listing 3.1 (Continued) *grid.py: the warehouse map, breadth-first search, depth-first search, A\ and the flood fill.*

```
def astar(grid, start, goal, weight=1.0):
    """A*: expands the cell with the smallest g + weight * h first."""
    g = {start: 0}
    parent = {start: None}
    heap = [(weight * manhattan(start, goal), 0, start)]
    done = set()
    expanded = 0
    while heap:
        _, cost, cell = heapq.heappop(heap)
        if cell in done:                        # an outdated entry: skip it
            continue
        done.add(cell)
        expanded += 1
        if cell == goal:
            return path_to(parent, goal), expanded
        for nxt in neighbors(grid, cell):
            new = cost + 1                      # every step costs one cell
            if new < g.get(nxt, float("inf")):
                g[nxt] = new
                parent[nxt] = cell
                f = new + weight * manhattan(nxt, goal)
                heapq.heappush(heap, (f, new, nxt))
    return None, expanded

def distances_from(grid, start):
    """Steps from `start` to every floor cell (one breadth-first flood fill)."""
    dist = {start: 0}
    queue = deque([start])
    while queue:
        cell = queue.popleft()
        for nxt in neighbors(grid, cell):
            if nxt not in dist:
                dist[nxt] = dist[cell] + 1
                queue.append(nxt)
    return dist
```

`load_layout` reads the map as a list of strings, so `grid[r][c]` is the character at row `r` and column `c`, and finds the depot. `neighbors` is a *generator*: the keyword `yield` hands back one neighbor at a time to the loop that asks for them. The long condition checks that the neighbor lies inside the map and is not a shelf. `access_point` returns the floor square beside a bay, where the picker stands. `shelf_label` turns a bay into the name printed on the shelf, such as `E09`: rack E (the fifth column of bays), bay 9 (the ninth row of bays).

`bfs` and `dfs` are the same function except for one line. BFS uses `deque`, a double-ended queue from the standard library whose `popleft` takes the oldest square quickly; DFS uses a plain list whose `pop` takes the newest. Both store in `parent` where each square was reached from, which serves two purposes: `nxt not in parent` means "not seen yet", and `path_to` follows the parents back from the goal to rebuild the path. Both also count the squares they *expand*, that is, take out and process, which is our measure of work.

`astar` implements **Pseudocode 3.1**. `heapq` keeps a list arranged so that `heappop` always returns the smallest entry [6]; our entries are tuples `(f, g, square)`, compared first by `f`. Python's `heapq` cannot lower the priority of an entry already in the heap, so when a shorter way to a square is found we push a new entry and leave the old one; the set `done` makes the loop skip the outdated one later. The parameter `weight` is the *w* of weighted A*. Finally `distances_from` is the flood fill of Section 3.3.2: a BFS without a goal that records the distance of every square.

3.5.3 Routes and batches

Listing 3.2 turns distances into routes.

Listing 3.2 `route.py`: loading stock and orders, cached distances, nearest neighbor, 2-opt, exact routes and batching.

```
"""Pick routes: the order in which to visit the shelves, and order batching."""
import csv
from itertools import permutations

from grid import access_point, distances_from

def load_stock(path, grid):
    """sku -> (product name, shelf bay, the floor cell where it is picked)."""
    stock = {}
    with open(path, encoding="utf-8") as f:
        for r in csv.DictReader(f):
            bay = (int(r["row"]), int(r["col"]))
            stock[r["sku"]] = (r["name"], bay, access_point(grid, bay))
    return stock

def load_orders(path):
    """order id -> list of (sku, quantity), in the order the customer typed."""
    orders = {}
    with open(path, encoding="utf-8") as f:
        for r in csv.DictReader(f):
            orders.setdefault(r["order"], []).append((r["sku"], int(r["qty"])))
    return orders

class Distances:
    """Walking steps between any two cells, one flood fill per cell, cached."""

    def __init__(self, grid):
        self.grid = grid
        self.cache = {}

    def __call__(self, a, b):
        if a not in self.cache:
            self.cache[a] = distances_from(self.grid, a)
        return self.cache[a][b]

def route_length(depot, stops, dist):
    """Depot -> every stop in the given order -> back to the depot."""
    tour = [depot] + list(stops) + [depot]

`load_stock` stores for every product its name, its bay and the square from which it is picked. `load_orders` uses `setdefault`, which returns the list of an order and creates an empty one the first time, to collect the lines of each order.

`Distances` is a small class that behaves like a function: because it defines `__call__`, we can write `dist(a, b)`. The first time it is asked about a square `a`, it runs one flood fill from `a` and keeps the result in `cache`; every later question about `a` is answered from memory. A morning wave touches only a few dozen different squares, so a few dozen flood fills answer every question.

`route_length` is Equation (3.5). `nearest_neighbor` follows lines 1 to 4 of **Pseudocode 3.2**; the key `(dist(here, s), s)` breaks ties between equally close stops by the smaller square, so the result is always the same. `two_opt` follows lines 5 to 11: `best[i:j + 1][::-1]` is the piece from position `i` to `j`, reversed. `plan_route` combines them, and `best_route` tries all $k!$ orders with `itertools.permutations`, which is how we check the others on small orders.

`batch_orders` implements Section 3.3.7. The seed is the order with the farthest stop; `near` is the order whose stops, added up, lie closest to the stops already in the batch, where the closeness of one stop is its distance to the nearest stop in the batch.

3.5.4 The application

Listing 3.3 is the program the warehouse uses.

Listing 3.3 `picker.py`: the pick list of one order in route order with a map, and the plan for the whole wave.

```

The three constants turn steps into time: 1.2 meters per square, a walking speed of one meter per second with a trolley, and 12 seconds to find, take and scan one order line. `draw` copies the map, marks the walked squares with `*` using A* between consecutive stops, and writes the stop numbers. `show_order` prints the pick list sorted by the route, compares the route with walking in the order the lines were typed, and draws the map. `dict.fromkeys` keeps the typed order while removing repeated squares. `show_wave` plans every order alone and then in batches of four, and reports meters and minutes for both.

3.6 Running It

Run `python picker.py`. It shows order SO-025 in detail and then plans the whole wave.

```
Order SO-025: 6 lines, 6 stops
  1. shelf E09  1 x Biskuit kelapa
  2. shelf F08  1 x Gula pasir 1 kg
  3. shelf M06  1 x Mi instan kuah (5)
  4. shelf I07  2 x Minyak goreng 2 L
  5. shelf H09  1 x Mi instan goreng (5)
  6. shelf H10  1 x Kecap manis 520 ml
walk in the order typed: 62 steps = 74 m
optimized route        : 44 steps = 53 m, about 2.1 min

Morning wave: 40 orders, 139 lines
one trip per order     : 40 trips,   1954 m,  60.4 min
batches of 4 orders    : 10 trips,    787 m,  40.9 min
walking saved          : 60%
first batches: SO-031 SO-019 SO-037 SO-038; SO-029 SO-012 SO-026 SO-005; SO-009 SO-021 SO-
017 SO-040
```

The pick list is now in walking order, with the shelf names a picker can find. Walking in the order the lines were typed would take 62 steps, 74 meters; the planned route takes 44 steps, 53 meters, almost 30 percent less. The map shows why: the route goes up one aisle, across the middle cross aisle to the far rack, and back down the next aisle, without doubling back. **Figure 3.1** draws the two routes side by side.

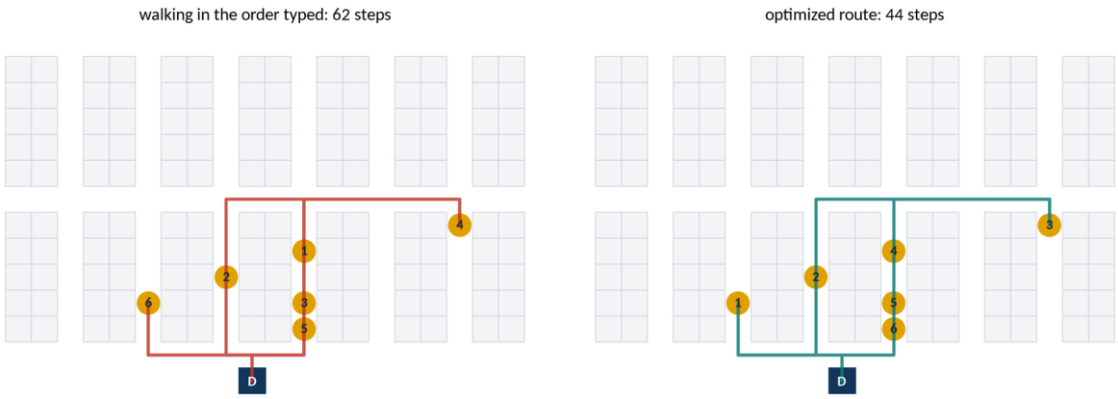

Figure 3.1 Order SO-025 walked in the order it was typed (left) and along the planned route (right); circles are the stops in visiting order, D is the packing table.

For the whole morning, 40 separate trips would walk 1,954 meters and take about an hour including the picking itself; ten trips with four orders each walk 787 meters, 60 percent less, and save about 20 minutes of a picker's morning. Over a year of mornings, that is roughly 120 hours for one picker in one small room.

3.7 Measuring It

Listing 3.4 measures each part of the program against a reference.

    time_exact(stock, depot, dist)

if __name__ == "__main__":
    main()
```

```
Search, 200 random start/goal pairs:
  method           avg path  optimal  avg expanded
  BFS                  13.5  200/200          87.7
  DFS                  40.6   46/200          84.3
  A*                   13.5  200/200          27.3
  weighted A* w=2      13.6  190/200          16.6

Routing the 40 orders one by one (total steps):
  order typed        1934  (+18.8% vs best)
  nearest neighbor   1712  (+5.2% vs best)
  NN + 2-opt         1628  (+0.0% vs best)
  best possible      1628  (+0.0% vs best)

Batching (orders per trolley trip):
  1 per trip: 40 trips,  1628 steps
  2 per trip: 20 trips,  1070 steps
  3 per trip: 14 trips,   828 steps
  4 per trip: 10 trips,   656 steps
  5 per trip:  8 trips,   556 steps
  6 per trip:  7 trips,   504 steps

Time to route one trip exactly vs with NN + 2-opt:
  6 stops: exact 66 steps in     5.5 ms, 2-opt 66 steps in   0.1 ms
  8 stops: exact 78 steps in   175.7 ms, 2-opt 78 steps in   0.1 ms
  9 stops: exact 80 steps in  1748.1 ms, 2-opt 80 steps in   0.4 ms
```

Searches. On 200 random pairs of squares, BFS and A* always find a shortest path, 13.5 steps on average, as the theory of Section 3.3 promises. DFS finds a shortest path only 46 times in 200 and averages 40.6 steps, three times too long. A* expands 27.3 squares on average against 87.7 for BFS: a third of the work for the same answer. Weighted A* with $w = 2$ expands only 16.6 squares but misses the shortest path in 10 of 200 cases, by a step or two. **Figure 3.2** shows the three plain searches on one long trip from the depot to the far corner.

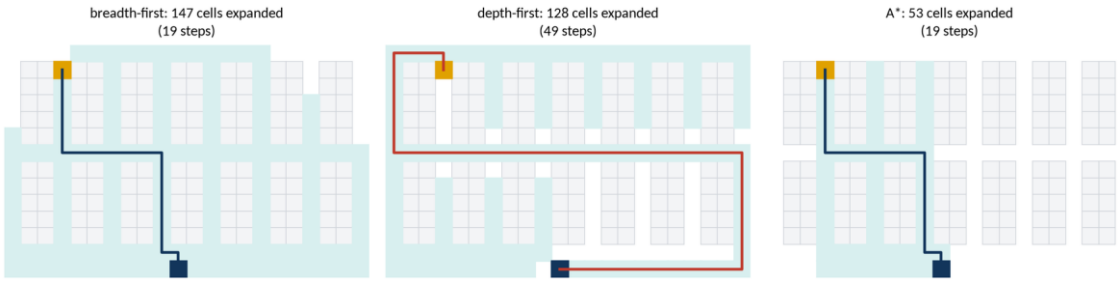

Figure 3.2 The squares each search expanded (light teal) on the way from the depot (navy) to a bay in the far corner (amber): BFS floods almost the whole hall, DFS wanders and returns a 49-step path, A* heads for the goal.

Routes. Routing each of the 40 orders in the typed order costs 1,934 steps, 18.8 percent more than the best possible routes, which the lab finds by trying every order (all our orders have at most six stops). Nearest neighbor alone is 5.2 percent above the best; with 2-opt the gap is zero for every order in this wave. The timing table shows why we do not simply try every order: nine stops already take more than a second, and each extra stop multiplies the time by the number of stops, as Equation (3.6) predicts, while 2-opt stays well under a hundredth of a second.

Batches. **Figure 3.3** plots the total walk against the number of orders per trip. Two orders per trip save a third of the walking, four save 60 percent, and beyond that the gains shrink, because the trolley must still visit every shelf once. In practice the size of the trolley and the risk of putting an item in the wrong box set the limit; four to six boxes is common.

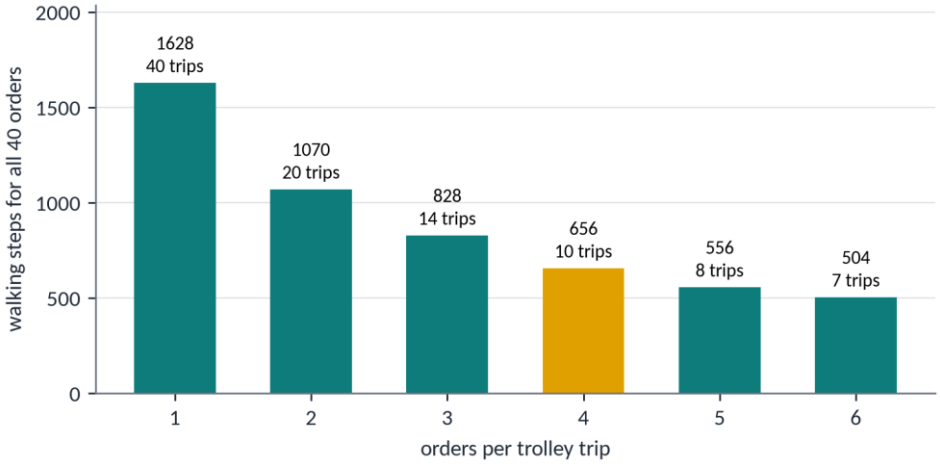

Figure 3.3 Total walking for the 40 orders when each trolley trip carries one to six orders; the program's default of four is highlighted.

3.8 Testing It

Listing 3.5 tests the searches, the access points and labels, the routes and the batches on the tiny room of Section 3.3.2, where every answer can be checked by hand.

Listing 3.5 `test_picker.py`: tests on the four-by-six room.

```
"""Tests for the picking-route optimizer. Run: python -m unittest -v"""
import unittest

from grid import access_point, astar, bfs, dfs, shelf_label
from route import (Distances, batch_orders, best_route, nearest_neighbor,
                   plan_route, route_length)

GRID = ["......",
        ".##.#.",
        ".##.#.",
        "......"]

class PickerTests(unittest.TestCase):
    def test_searches(self):
        start, goal = (3, 0), (0, 5)
        path, _ = bfs(GRID, start, goal)
        self.assertEqual(len(path) - 1, 8)              # 3 up and 5 right
        self.assertEqual(len(astar(GRID, start, goal)[0]) - 1, 8)
        path, _ = dfs(GRID, start, goal)
        self.assertEqual((path[0], path[-1]), (start, goal))
        for a, b in zip(path, path[1:]):                # one step at a time
            self.assertEqual(abs(a[0] - b[0]) + abs(a[1] - b[1]), 1)

    def test_access_and_label(self):
        self.assertEqual(access_point(GRID, (1, 1)), (1, 0))
        self.assertEqual(access_point(GRID, (2, 4)), (2, 3))
        self.assertEqual(shelf_label(GRID, (2, 4)), "C02")

    def test_routes(self):
        dist = Distances(GRID)
        depot, stops = (3, 0), {(0, 5), (2, 3), (1, 0), (3, 5)}
        best = route_length(depot, best_route(depot, stops, dist), dist)
        nn = route_length(depot, nearest_neighbor(depot, stops, dist), dist)
        planned = route_length(depot, plan_route(depot, stops, dist), dist)
        self.assertLessEqual(best, planned)
        self.assertLessEqual(planned, nn)
        self.assertEqual(best, 18)                      # checked by hand
```

Listing 3.5 (Continued) *test_picker.py: tests on the four-by-six room.*

```
    def test_batches(self):
        dist = Distances(GRID)
        stops = {"A": {(0, 5)}, "B": {(1, 5)}, "C": {(1, 0)}, "D": {(2, 0)},
                 "E": {(0, 3)}}
        batches = batch_orders(stops, stops, (3, 0), dist, size=2)
        self.assertEqual(sorted(o for b in batches for o in b), list("ABCDE"))
        self.assertTrue(all(len(b) <= 2 for b in batches))
        self.assertIn(["A", "B"], batches)              # far and together

if __name__ == "__main__":
    unittest.main()
```

The route test is worth checking by hand. From the depot (3,0) the best route visits (1,0) (2 steps), (0,5) (6 steps: one up and five right), (3,5) (3 steps down), (2,3) (3 steps: two left along the bottom and one up) and returns to (3,0) (4 steps), $2 + 6 + 3 + 3 + 4 = 18$ steps by Equation (3.5). The DFS test does not demand a shortest path, only a valid one: it starts and ends at the right squares and every move is one step.

3.9 Improving It

Put the best sellers near the packing table. The routes are only as good as the placement of the goods. Moving the most frequently ordered products to the bays closest to the depot, called *slotting*, often saves more walking than any routing rule. Exercise 4 does it in about thirty lines and halves the walking again.

One-way aisles and wide trolleys. In narrow aisles pickers cannot pass each other, so many warehouses make aisles one-way. In the graph this means directed edges: a step from (r, c) to $(r+1, c)$ may be allowed while the reverse is not. BFS and A* work unchanged on directed graphs.

Different costs. Climbing a ladder for a top shelf or passing a crowded packing area costs more than a step on open floor. Then the edges need different weights, and BFS must be replaced by Dijkstra's algorithm, which Chapter 8 builds.

Trolley capacity. Our batches are limited by the number of orders. A real trolley is also limited by volume and weight: five orders of bottled water do not fit. Adding the volume of each product to `stock.csv` and a capacity check to `batch_orders` is a small change.

Better route improvement. 2-opt was optimal on this wave. On larger trips, other moves (moving a single stop to another position, or reversing with three cuts, called 3-opt) or specialized warehouse rules such as the S-shape and largest-gap policies [2] close the remaining gaps.

3.10 Using It for Real

Draw your map. Measure your stockroom and draw it on squared paper, one square for each shelf bay width (about a meter). Type it into `warehouse.txt` with `.` for floor, `#` for shelf bays and `D` for the packing table. Mark walls and pillars as `#` too. Check the map by running `picker.py` on a few orders and walking the routes yourself.

Record where things are. Give each bay a label and stick it on the shelf; `shelf_label` produces names such as `E09`, but you can use any scheme. Keep `stock.csv` up to date whenever goods move; a routing program with wrong locations is worse than none.

Export the orders. Most marketplace seller centers and shop systems let you download the day's orders as CSV or Excel. Convert them to the three columns `order,sku,qty` with a spreadsheet or a few lines of pandas, as Chapter 2 did for statements.

Print the pick lists. Change `show_order` to write each batch's list and map to a text file, or print them directly. Pickers need the shelf name, the product name and the quantity, in route order, and the box number of the order when several orders share a trolley.

Measure before and after. Time a few typical mornings before you change anything, then again with routed and batched pick lists. The numbers of Section 3.6 are an estimate from a model; your own stopwatch is the proof.

Scale up. For a large warehouse with thousands of bays the same code works, but computing distances once per morning for every bay pair used that day and storing them, or switching to one of the routing libraries used in logistics, becomes worthwhile.

3.11 Common Mistakes, and How to Avoid Them

Using straight-line distance as the real distance. Shelves are in the way. Two bays back to back are close in a straight line but a whole rack apart on foot. Always use distances computed on the floor graph.

An inadmissible heuristic without knowing it. If h can overestimate, for example by counting a diagonal step as 2 on a map where diagonal moves are allowed, A* may return a path that is not shortest. Check Equation (3.3) whenever you change the moves or the costs.

Marking a square as seen too late. In BFS the parent must be recorded when a square is *put into* the queue, not when it is taken out. Otherwise the same square is put in many times and the search slows down dramatically.

Forgetting the trip back. The route length includes the walk back to the depot, as in Equation (3.5). Leaving it out favors routes that end far away.

Trying every order in production. $k!$ grows faster than any computer. Use exact search only to check heuristics on small cases, as the lab does.

Optimizing the wrong thing. Walking is not the only cost. If a route saves ten meters but sends two pickers into the same narrow aisle at the same time, it may be slower in practice. Watch the floor before trusting the numbers.

3.12 Chapter Summary

- A warehouse floor is a graph of squares; the distance between two places is the length of the shortest path in that graph.
- Breadth-first search explores ring by ring and finds shortest paths; depth-first search finds some path, often a long one; A* (Equation (3.1)) with the Manhattan distance (Equation (3.2)) finds shortest paths while expanding about a third as many squares, because the heuristic is admissible (Equation (3.3)) and consistent (Equation (3.4)).
- Ordering the stops of a route (Equation (3.5)) is a traveling salesman problem with $k!$ possible orders (Equation (3.6)); nearest neighbor plus 2-opt matched the best route on every order of our wave in a fraction of the time.
- Batching four orders per trolley trip cut the morning's walking by 60 percent, from 1,954 to 787 meters.
- Placement matters as much as routing: putting best sellers near the packing table halves the walking again.

3.13 Exercises

1. Compute the Manhattan distance from the depot (13,10) to the square (1,3) and explain why the true walking distance cannot be smaller. The lab's BFS reports 19 steps; what does that tell you about the path?
2. Run BFS by hand on the tiny room of Section 3.3.2 from (0,3) to (3,3). How many steps does the shortest path have, and how many different shortest paths are there?
3. Change the weight of weighted A* in `lab.py` to $w = 5$. What happens to the path length, the number of optimal paths and the number of expanded squares, compared with $w = 2$?
4. Write a program that moves the most frequently ordered products to the bays closest to the depot, and compare the morning wave before and after.
5. If finding and taking one line takes 20 seconds instead of 12, how many minutes does batching save on the morning wave, and what percentage of the total time is that?
6. In an open room of 6×6 squares without shelves, the depot is at (5,0) and an order has the stops (1,0), (2,2), (3,2) and (0,3). Build the nearest-neighbor route by hand (break ties by the smaller square, as the program does), compute its length, and then improve it with 2-opt.

3.14 Solutions to the Exercises

1. $|13 - 1| + |10 - 3| = 19$. Every step changes the row or the column by one, and we must change the row by 12 and the column by 7, so no path can have fewer than 19 steps, whatever the shelves are. BFS finds exactly 19, so there is a path without any detour: the shelves happen not to block the direct way (along the bottom cross aisle, then up aisle column 3). Here the Manhattan distance is *exact*, and A* expands far fewer squares than BFS: 53 against 147 on this trip.

2. From (0,3) the only way down is the aisle in column 3, which is open in rows 1 and 2, so the path is (0,3), (1,3), (2,3), (3,3): 3 steps, equal to the Manhattan distance. There is exactly one shortest path, because every other first step (left to (0,2) or right to (0,4)) moves away from column 3 and the squares (1,2) and (1,4) beside the aisle are shelves, so any detour costs at least two extra steps.

3. With $w = 5$ the lab prints an average path of 13.6 steps, 189 of 200 optimal, and 17.0 expanded squares. Compared with $w = 2$ (13.6 steps, 190 optimal, 16.6 expanded) nothing improves: a larger weight only makes the search greedier, and on this map $w = 2$ already heads straight for the goal. A small weight is the useful range.

4. The program `solutions/slotting.py` in the chapter's folder counts how often each product was ordered, sorts all 140 bays by their walking distance from the depot, and puts the best seller in the nearest bay, the second best in the next, and so on:

```
"""Exercise 4: put the best-selling products on the bays nearest the depot."""
import csv
import sys
from collections import Counter
from pathlib import Path

HERE = Path(__file__).parent.parent
sys.path.insert(0, str(HERE))
from grid import access_point, load_layout  # noqa: E402
from picker import show_wave  # noqa: E402
from route import Distances, load_orders, load_stock  # noqa: E402

grid, depot = load_layout(HERE / "data/warehouse.txt")
orders = load_orders(HERE / "data/orders.csv")
dist = Distances(grid)
sold = Counter(sku for lines in orders.values() for sku, _ in lines)
old = load_stock(HERE / "data/stock.csv", grid)
bays = sorted(((r, c) for r, row in enumerate(grid)       # every shelf bay,
               for c, ch in enumerate(row) if ch == "#"),  # nearest first
              key=lambda b: (dist(depot, access_point(grid, b)), b))
ranked = sorted(old, key=lambda s: (-sold[s], s))      # best sellers first
with open(HERE / "data/stock_abc.csv", "w", newline="", encoding="utf-8") as f:
    w = csv.writer(f)
    w.writerow(["sku", "name", "row", "col"])
    for sku, (r, c) in zip(ranked, bays):
        w.writerow([sku, old[sku][0], r, c])
print("before:")
show_wave(orders, old, grid, depot, dist)
print("\nafter slotting:")
show_wave(orders, load_stock(HERE / "data/stock_abc.csv", grid), grid, depot, dist)
```

Its output ends with

```
after slotting:

Morning wave: 40 orders, 139 lines
one trip per order     : 40 trips,    970 m,  44.0 min
batches of 4 orders    : 10 trips,    382 m,  34.2 min
walking saved          : 61%
```

Slotting alone halves the walking of single-order picking (1,954 to 970 meters), and combined with batching the morning walk drops from 1,954 to 382 meters. In a real warehouse, the frequency count would use several weeks of orders, not one morning.

5. Walking does not change: 1,954 meters take 1,954 seconds, 32.6 minutes, one trip per order, and 787 meters take 13.1 minutes in batches. Picking now takes $139 \times 20 = 2{,}780$ seconds, 46.3 minutes, in both cases. The totals are $32.6 + 46.3 = 78.9$ and $13.1 + 46.3 = 59.5$ minutes (rounded from the exact seconds), so batching saves about 19.5 minutes, about 25 percent of the total. The saved minutes are the same as before; only the percentage shrinks, because a larger share of the time is spent picking, which batching cannot reduce.

6. From the depot (5,0) the stops (1,0) and (3,2) are both 4 steps away; the tie goes to the smaller square, (1,0). From there (2,2) is 3 steps away, (3,2) and (0,3) are 4, so the picker goes to (2,2), then to (3,2) (1 step), then to (0,3) (4 steps), and back to the depot, 8 steps. By Equation (3.5) the length is $4 + 3 + 1 + 4 + 8 = 20$. The greedy rule left the farthest stop for last and paid for it with a long walk home. 2-opt repairs this with two reversals. Reversing the piece (2,2), (3,2), (0,3) gives (1,0), (0,3), (3,2), (2,2) with length $4 + 4 + 4 + 1 + 5 = 18$, and reversing then the piece (3,2), (2,2) gives (1,0), (0,3), (2,2), (3,2) with length $4 + 4 + 3 + 1 + 4 = 16$. No further reversal helps, and trying all $4! = 24$ orders confirms that 16 is the best: go up to the top first, then work your way back toward the depot.

Chapter 4

A Meal Planner on a Budget and a Nutrition Target

"What shall we cook today, so that it is healthy and the money lasts until the end of the month?" Millions of households ask this every morning, and so do the cooks of school kitchens, hospitals and boarding schools. In this chapter we build a program that answers it with numbers. It reads a table of Indonesian foods with their market prices and their nutrients, taken from the Indonesian food composition table of the Ministry of Health, and finds the cheapest day of food that provides enough energy, protein, fiber, calcium and iron for an adult woman. When the budget is too small, it finds the plan that falls short as little as possible, and it turns the answer into whole portions and a weekly shopping list. By the end of the chapter you will be able to write a planning problem as a *linear program*, solve a small one by hand and a large one with SciPy, explain why a greedy rule is not enough, read the *shadow price* that tells you which nutrient is expensive, handle a problem that has no solution, and switch to whole portions with *integer programming*.

4.1 Good Food on a Small Budget

In January 2026 Indonesia's free nutritious meal program, *Makan Bergizi Gratis* (MBG), reached almost 60 million recipients, served by more than 21,000 kitchen units across the country [1]. For Java and nearby regions the food budget is 10,000 rupiah per portion, adjusted upward only in regions where food is much more expensive [2]. Every one of those kitchens faces the question of this chapter every day: which combination of rice, tempe, eggs, fish, vegetables and fruit meets the nutrition standard without exceeding the money available? Dietitians in hospitals, cooks in *pesantren* and mothers at the traditional market face the same question on a smaller scale.

The question is older than computers. In 1945 the economist George Stigler asked what the cheapest diet was that still met the recommended nutrient allowances of the time; with 77 foods and 9 nutrients he could only guess cleverly, and his guess was later shown to be slightly too expensive [3]. Two years later George Dantzig invented the *simplex method* for linear programming, and one of its first large tests was Stigler's diet problem, solved exactly by a team of clerks with desk calculators in about 120 person-days of work [4]. Today the same kind of problem, with thousands of variables, is solved in milliseconds and is used to plan animal feed, hospital menus, army rations and school meals.

What such a program saves is concrete. On our data, a sensible-looking rule of thumb spends 32,408 rupiah a day to meet the targets, and linear programming meets exactly the same targets for 28,841 rupiah, 11 percent less, which for a family of four is more than 400,000 rupiah a month. More importantly, the program shows *which* nutrient is expensive and what a smaller budget gives up, so that people can decide with open eyes.

4.2 The Idea in Plain Words

Imagine a shopping basket and a checklist. Every food you put in the basket costs money and adds something to each line of the checklist: energy, protein, fiber, calcium and iron. The checklist has a

minimum for each line, and for energy also a maximum, because too much is not healthy either. You want to fill the checklist at the smallest total price.

The obvious way is to go food by food: "Tofu is cheap and has a lot of protein and calcium, take some; tempe is cheap too, take some…" and keep adding whatever seems best value until every line is ticked. That is a *greedy* rule. It is simple and often decent, but it never looks back: an early choice that seemed good may make a later expensive purchase necessary, and the rule never undoes it.

Linear programming looks at all foods and all lines of the checklist at the same time. It answers the question "how many grams of each food?" exactly, as the cheapest point that satisfies every line. It can also tell you something no shopper can see: how much more the cheapest basket would cost if one line of the checklist asked for one unit more. If one more gram of fiber costs a thousand rupiah and one more kilocalorie four rupiah, you know where the money goes.

Two practical details complete the picture. A plan that says "227 grams of rice and 48 grams of banana" is awkward in a kitchen, so we also solve the problem in whole portions, which is *integer programming*. And when the money is not enough to meet every line, we ask the program for the plan that misses the targets by as little as possible within the budget.

> **DEFINITION.** A *linear program* chooses numbers $x_1, \dots, x_n$ (here, grams of each food) to make a linear *objective* as small as possible (here, the cost), subject to linear *constraints*: sums of the form $a_1x_1 + \cdots + a_nx_n$ that must be at least or at most a given number.

4.3 The Math, Gently

4.3.1 The cost of what we can eat

Market prices are per kilogram *as bought*, but nutrient tables are per 100 grams of the *edible part*. A kilogram of chicken includes bones, and a kilogram of bananas includes peel. The table of food composition gives the edible share, the *BDD* (*berat dapat dimakan*, edible weight): 58 percent for chicken, 75 percent for bananas, 100 percent for rice and tempe. If a food costs p rupiah per kilogram and its edible share is e percent, one gram that we can actually eat costs

$$c = \frac{p}{1000} \cdot \frac{100}{e} \tag{4.1}$$

rupiah. Chicken at 42,600 rupiah per kilogram thus costs $42.6 \times 100/58 = 73.4$ rupiah per edible gram, 7,345 rupiah per 100 grams, while tofu at 12,000 rupiah costs 1,200 rupiah per 100 grams. That is the first line of the program's output.

4.3.2 The linear program

Let x_i be the grams of food i in a day's plan, c_i its cost per gram from Equation (4.1), and n_{ji} the amount of nutrient j in one gram of food i (the table value per 100 grams divided by 100). The total cost is

$$C(x) = \sum_{i=1}^{n} c_i \, x_i \tag{4.2}$$

and the amount of nutrient j in the plan is $\sum_i n_{ji}\, x_i$. With a minimum L_j for each nutrient, a maximum U_j where there is one, and a largest sensible amount u_i of each food per day, the planning problem is

$$\min_x \sum_i c_i\, x_i \quad \text{subject to} \quad L_j \le \sum_i n_{ji}\, x_i \le U_j, \quad 0 \le x_i \le u_i \tag{4.3}$$

Everything in Equation (4.3) is a sum of numbers times variables, nothing is squared or multiplied together, which is exactly what "linear" means. The limits u_i keep the plan edible: nobody wants a kilogram of spinach a day.

4.3.3 A small linear program by hand

Take only two foods, rice and tempe, and only two targets, at least 2,250 kilocalories and at least 60 grams of protein, with no upper limits. Measure the foods in units of 100 grams: a units of rice and b units of tempe. From the table, 100 grams of rice give 357 kcal and 8.4 g of protein for 1,655 rupiah, and 100 grams of tempe give 201 kcal and 20.8 g of protein for 2,000 rupiah. The problem is

$$\min\ 1655a + 2000b \quad \text{subject to} \quad 357a + 201b \ge 2250, \quad 8.4a + 20.8b \ge 60, \quad a, b \ge 0 \tag{4.4}$$

Figure 4.1 draws it. Each constraint is a straight line, and the allowed plans lie on the far side of both lines, the shaded region. The cost is also a straight line for every fixed amount of money; moving it toward the origin makes the plan cheaper. The cheapest allowed plan is where the cost line last touches the shaded region, and that is always a *corner*. This is the central fact of linear programming, and the reason the simplex method only has to walk from corner to corner.

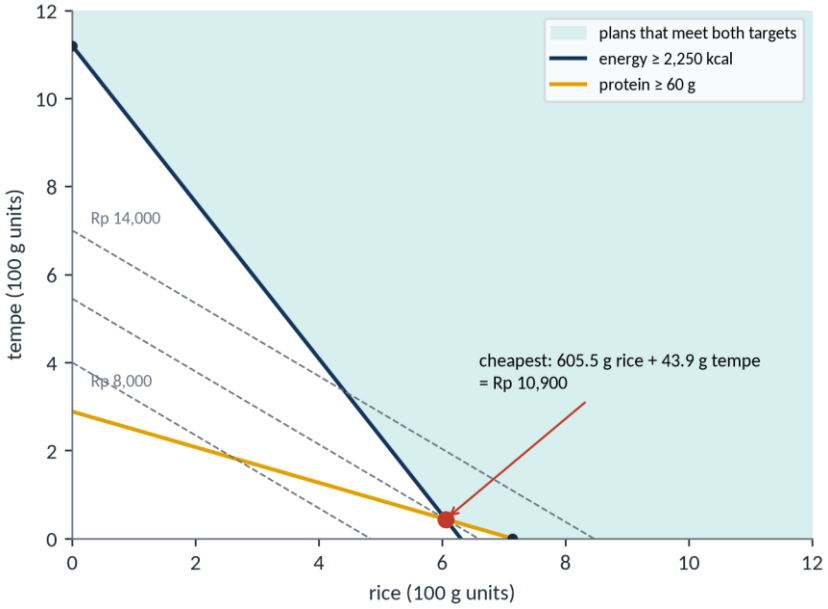

Figure 4.1 The two-food problem of Equation (4.4): plans in the shaded region meet both targets; the cheapest one is the corner where both constraints are exactly met.

So we only need to check the corners. The corner on the rice axis ($b = 0$) needs enough rice for the protein: $a = 60/8.4 = 7.14$, which gives $357 \times 7.14 = 2{,}550$ kcal, enough, at a cost of $1655 \times 7.14 = 11{,}821$ rupiah. The corner on the tempe axis ($a = 0$) needs enough tempe for the

energy: $b = 2250/201 = 11.19$, costing 22,388 rupiah. The corner where both lines cross solves the two equations together. From the protein equation, $a = (60 - 20.8b)/8.4$; putting that into the energy equation gives $42.5(60 - 20.8b) + 201b = 2250$, so $2550 - 884b + 201b = 2250$, $683b = 300$ and $b = 0.439$; then $a = (60 - 9.14)/8.4 = 6.055$. This plan, 605.5 grams of rice and 43.9 grams of tempe, costs $1655 \times 6.055 + 2000 \times 0.439 = 10{,}900$ rupiah, the cheapest of the three corners. Notice the lesson: the cheapest source of energy (rice) and the cheapest source of protein (tempe) are combined in exactly the proportion that satisfies both targets with nothing to spare.

4.3.4 The greedy rule

Our greedy rule adds food in steps of $\Delta = 25$ grams. For each food it measures how much of the *remaining* gap the step would close, as a share of each target, and divides by the price of the step. If g_j is the part of target j still missing, as a fraction of L_j, the score of food i is

$$\text{score}_i = \frac{1}{c_i \Delta} \sum_j \min\left(\frac{n_{ji}\,\Delta}{L_j},\ g_j \right) \tag{4.5}$$

and the food with the highest score gets the next 25 grams. The minimum inside the sum stops a food from getting credit for nutrients that are already sufficient. It is a reasonable rule, but it decides one step at a time and never reconsiders; Section 4.6 shows what that costs.

4.3.5 Shadow prices

When the linear program is solved, the solver also returns a number for each constraint, its *shadow price* or *marginal*. For a minimum L_j it is

$$\lambda_j = \frac{\partial C^*}{\partial L_j} \tag{4.6}$$

the increase of the cheapest cost C^* if the minimum were raised by one unit. The symbol ∂ reads "the change in, for a small change of". A constraint that is not tight (the plan has more than enough) has a shadow price of zero: asking for a little more costs nothing. A large shadow price marks the nutrient that drives the cost. Shadow prices come from the *dual* of the linear program, a second problem that the simplex method solves at the same time [4].

4.3.6 When the budget is too small

If the cheapest plan costs more than the budget B, no plan meets every target. Instead of giving up, we let each target j be missed by s_j percent, and we look for the plan that misses as little as possible in total:

$$\min_{x,s} \sum_j s_j \quad \text{subject to} \quad \sum_i n_{ji}\,x_i + \frac{s_j}{100} L_j \geq L_j, \quad \sum_i c_i\,x_i \leq B, \quad 0 \leq s_j \leq 100 \tag{4.7}$$

The new variables s_j are still linear, so this is again a linear program. Measuring the shortfall in percent makes kilocalories, grams and milligrams comparable.

4.3.7 Whole portions

A kitchen cooks eggs, not 37.4 grams of egg. If food i comes in portions of q_i grams, we write $x_i = q_i k_i$ and require

$$k_i \in \{0,1,2,\dots,m_i\} \tag{4.8}$$

where m_i is the most portions a person should eat in a day. A linear program in which some variables must be whole numbers is an *integer program*. Integer programs are much harder in general, because the answer is no longer at a corner, but solvers such as HiGHS [5] handle ones of our size instantly with *branch and bound*: they solve the ordinary linear program, and whenever a variable comes out as a fraction, say $k = 2.4$, they split the problem into one branch with $k \le 2$ and one with $k \ge 3$ and continue, discarding branches that cannot beat the best whole-number plan found so far. The whole-number plan can never be cheaper than the linear program, because it has fewer choices; usually it is only slightly more expensive.

4.4 The Algorithm as Pseudocode

Pseudocode 4.1 is the greedy rule of Equation (4.5). The linear and integer programs need no pseudocode of ours: we describe them with Equation (4.3), Equation (4.7) and Equation (4.8) and let a proven solver do the work.

Pseudocode 4.1 The greedy rule: repeatedly add the step of food that closes the largest share of the remaining gap per rupiah.

```
GREEDY-PLAN(foods, targets, Δ)
1  x = 0 grams of every food
2  loop
3      g_j = the missing share of each minimum L_j (0 if met)
4      if every g_j = 0: return x
5      best = none
6      for each food i with x_i + Δ ≤ u_i
7          score = Σ_j min(n_ji Δ / L_j, g_j) / (c_i Δ)
8          if score > score of best: best = i
9      if best is none: return x                // no food can still help
10     x_best = x_best + Δ
```

4.5 Building It Step by Step

Create a folder `Chapter004` and a virtual environment as in Chapter 1, Section 1.3. This chapter uses NumPy for arrays and SciPy for the solvers, whose optimization module includes the HiGHS solvers for linear and integer programs [6].

```
# Chapter 4: versions this chapter was tested with (Python 3.14.7)
numpy==2.5.3
scipy==1.18.1
```

4.5.1 The data: TKPI nutrients and market prices

The file `data/foods.csv` lists thirteen common, affordable Indonesian foods. Their nutrients per 100 grams of edible part, and their edible share, come from the Indonesian food composition table, *Tabel Komposisi Pangan Indonesia* (TKPI) 2017 of the Ministry of Health [7]; we read the values from the online copy at nilaigizi.com and checked them one by one. The prices of rice, eggs and chicken are the national averages of Bank Indonesia's strategic food price center (PIHPS) for

3 September 2026 [8]; the price of mackerel is the National Food Agency's national average of September 2025 [9]. The other prices are marked `estimate` in the file: they are typical traditional-market prices that you should replace with your own. **Table 4.1** shows the data the program uses.

Table 4.1 The thirteen foods: price as bought, edible share and nutrients per 100 g edible part (TKPI 2017), portion size and the most portions per day.

Food	Rp/kg	Edible %	Kcal	Protein g	Fiber g	Calcium mg	Iron mg	Portion g	Max
Beras giling (rice)	16,550	100	357	8.4	0.2	147	1.8	50	8
Telur ayam ras (egg)	29,650	89	154	12.4	0.0	86	3.0	55	2

The file also contains fat and carbohydrate, which the planner does not use yet; Exercise 5 adds a limit on fat. The file `data/targets.csv` holds the daily targets for a woman aged 19 to 29 from the Indonesian recommended dietary allowances, *Angka Kecukupan Gizi* (AKG) 2019 [10]: 2,250 kcal of energy (we allow up to 10 percent more, 2,475), 60 g of protein, 32 g of fiber, 1,000 mg of calcium and 18 mg of iron.

```
nutrient,unit,minimum,maximum
energy,kcal,2250,2475
protein,g,60,
fiber,g,32,
calcium,mg,1000,
iron,mg,18,
```

4.5.2 The model

Listing 4.1 contains the whole model: loading the data, the greedy rule and the three solvers.

Listing 4.1 `menu.py`: the data, the greedy rule, the linear program, the budget version and the whole-portion version.

```python
"""Cheapest daily food that meets nutrition targets: greedy, LP and integer LP."""
import csv

import numpy as np
from scipy.optimize import Bounds, LinearConstraint, linprog, milp

NUTRIENTS = ["energy", "protein", "fiber", "calcium", "iron"]

```

`load_foods` reads the CSV with `csv.DictReader`, turns every number into a `float`, and computes `cost_g` with Equation (4.1) and `max_g`, the u_i of Equation (4.3). `matrix` builds the table n_{ji} as a NumPy array with one row per nutrient and one column per food, so that `matrix(foods) @ grams`, a matrix-times-vector product, gives all five nutrient totals at once; `totals` and `cost` use it.

`greedy` follows **Pseudocode 4.1**; `need` is the vector of missing shares g_j and `score` is Equation (4.5). The array `low` holds the minimums L_j, with a zero replaced by a tiny positive number so that a target of zero never causes a division by zero.

`solve_lp` hands Equation (4.3) to SciPy's `linprog`. `linprog` only accepts constraints of the form "sum at most a number", so `lp_rows` writes each minimum $\sum n_{ji}x_i \geq L_j$ in the equivalent form $-\sum n_{ji}x_i \leq -L_j$, multiplying both sides by -1 and turning the inequality around. The bounds $0 \leq x_i \leq u_i$ are passed separately. The result `res` holds the plan `res.x`, the cost `res.fun`, a `status` (0 means solved) and, for each row, the shadow price in `res.ineqlin.marginals`.

`solve_budget` implements Equation (4.7) with SciPy's `milp`, which accepts constraints written as "lower ≤ sum ≤ upper" with `LinearConstraint`. Its variables are portions of each food followed by the five shortfalls; the first block of rows is the minimums with the shortfall added, the second the maximums, the last the budget. The objective adds up the shortfalls, plus the cost multiplied by a millionth, a tiny term that only matters between plans with equal shortfall and then prefers the cheaper one. The argument `whole` switches Equation (4.8) on or off through `integrality`. `solve_portions` is the cheapest whole-portion plan that meets every target.

4.5.3 The application

Listing 4.2 prints the price table, the greedy plan, the linear-programming plan with its shadow prices, the budget plans when needed, and a shopping list for a week.

Listing 4.2 `planner.py`: from data to a week's shopping list.

```
"""Meal planner on a budget: the cheapest day of food that meets the targets.

python planner.py                  targets in data/targets.csv, budget Rp 25,000
python planner.py --budget 20000
"""
import argparse
from pathlib import Path

from menu import (NUTRIENTS, cost, greedy, load_foods, load_targets,
                  solve_budget, solve_lp, solve_portions, totals)

        show(f"Best plan for Rp {args.budget:,.0f} in whole portions", foods,
             grams, targets)
        print("  still missing: " + ", ".join(
            f"{n} {s:.1f}%" for n, s in missing.items() if s > 1e-6))

    print("\nShopping list for 7 days (weight to buy, including peel and bones):")
    week = 0
    for x, g in zip(foods, grams):
        if g > 0.5:
            kg = 7 * g / (x["edible_pct"] / 100) / 1000
            week += kg * x["price_per_kg"]
            print(f"  {kg:5.2f} kg  {x['food']:<26} "
                  f"Rp {kg * x['price_per_kg']:>7,.0f}")
    print(f"  total{'':32} Rp {week:>7,.0f}")

if __name__ == "__main__":
    main()
```

`show` prints any plan with its cost and the five nutrients against their minimums. The loop over `zip(names, res.ineqlin.marginals)` prints only the constraints whose shadow price is not zero; `linprog` reports the marginals of "at most" rows as negative numbers, since raising the right-hand side lowers the cost, so we print their absolute value. The shopping list divides edible grams by the edible share, which gives the weight to buy, and multiplies by seven days.

4.6 Running It

Run `python planner.py`. The budget defaults to 25,000 rupiah per day.

```
Rupiah per 100 g you can eat:
   1,200  Tahu (tofu)
   1,655  Beras giling (rice)
   1,667  Kangkung (water spinach)
   1,690  Bayam (spinach)
   1,750  Wortel (carrot)
   1,829  Jambu biji (guava)
   2,000  Tempe
   2,400  Pisang ambon (banana)
   2,600  Kacang hijau (mung bean)
   3,000  Kacang merah (red bean)
   3,331  Telur ayam ras (egg)
   5,190  Ikan kembung (mackerel)
   7,345  Daging ayam (chicken)

Greedy plan: Rp 32,408 per day
    400 g  Beras giling (rice)
     50 g  Tempe
    125 g  Tahu (tofu)
    100 g  Kacang hijau (mung bean)
    100 g  Kacang merah (red bean)
    300 g  Kangkung (water spinach)
    300 g  Pisang ambon (banana)
    300 g  Jambu biji (guava)
  energy 2820/2250, protein 119/60, fiber 32/32, calcium 1972/1000, iron 42/18

Cheapest plan (linear programming): Rp 28,841 per day
    227 g  Beras giling (rice)
    150 g  Tempe
    100 g  Kacang hijau (mung bean)
    100 g  Kacang merah (red bean)
    300 g  Kangkung (water spinach)
    250 g  Pisang ambon (banana)
    300 g  Jambu biji (guava)
  energy 2250/2250, protein 111/60, fiber 32/32, calcium 1584/1000, iron 39/18
  what one more unit of each binding target would cost:
    energy >= 2250   Rp     4.1
    fiber >= 32      Rp  1032.5

Best plan for Rp 25,000 (LP): Rp 25,000 per day
    288 g  Beras giling (rice)
    150 g  Tempe
    100 g  Kacang hijau (mung bean)
    100 g  Kacang merah (red bean)
    300 g  Kangkung (water spinach)
     48 g  Pisang ambon (banana)
    300 g  Jambu biji (guava)
  energy 2250/2250, protein 114/60, fiber 28/32, calcium 1634/1000, iron 39/18
```

```
Best plan for Rp 25,000 in whole portions: Rp 24,928 per day
    300 g  Beras giling (rice)
    150 g  Tempe
    100 g  Kacang hijau (mung bean)
    100 g  Kacang merah (red bean)
    300 g  Kangkung (water spinach)
     50 g  Wortel (carrot)
    300 g  Jambu biji (guava)
  energy 2258/2250, protein 115/60, fiber 28/32, calcium 1664/1000, iron 40/18
  still missing: fiber 12.8%

Shopping list for 7 days (weight to buy, including peel and bones):
   2.10 kg  Beras giling (rice)        Rp  34,755
   1.05 kg  Tempe                      Rp  21,000
   0.70 kg  Kacang hijau (mung bean)   Rp  18,200
   0.70 kg  Kacang merah (red bean)    Rp  21,000
   3.50 kg  Kangkung (water spinach)   Rp  35,000
   0.44 kg  Wortel (carrot)            Rp   6,125
   2.56 kg  Jambu biji (guava)         Rp  38,415
  total                                 Rp 174,495
```

The first table ranks foods by the price of 100 grams we can eat: tofu, rice and leafy vegetables are cheapest, chicken is six times as expensive as tofu once the bones are paid for.

The greedy plan meets every target for 32,408 rupiah but overshoots badly: 2,820 kcal against a maximum of 2,475 (the greedy rule ignores maximums) and 119 grams of protein, twice the target. The linear program meets exactly the same targets for 28,841 rupiah, 11 percent less, and with energy exactly at 2,250. **Figure 4.2** compares what each nutrient receives in the linear-programming plan.

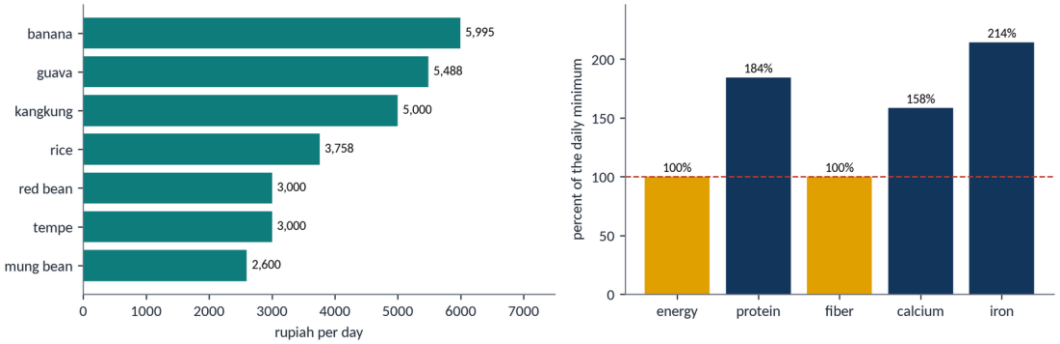

Figure 4.2 The cheapest plan that meets every target: where the money goes (left) and each nutrient as a percentage of its minimum (right); energy and fiber are exactly met, the others come for free.

The shadow prices explain the plan. Only two constraints are tight: energy, at 4.1 rupiah per extra kilocalorie, and fiber, at 1,032.5 rupiah per extra gram. Protein, calcium and iron are over-supplied as a by-product of the fiber-rich beans and vegetables, so asking for more of them costs nothing. Fiber is what makes this diet expensive: every food in the plan except rice and tempe is there mainly for its fiber, and the program chose guava, kangkung, mung beans and red beans, which give the most fiber per rupiah, up to their daily limits.

With 25,000 rupiah the targets cannot all be met, so the program solves Equation (4.7). The best it can do is to meet everything except fiber and to miss fiber by 11.6 percent, 28 grams instead of 32. The whole-portion version gives a cookable day for 24,928 rupiah: 300 grams of raw rice (six portions of 50 grams), three slices of tempe, a bowl of mung beans and one of red beans, a large bunch of kangkung, a carrot and three guavas, missing 12.8 percent of the fiber. The shopping list for a week costs 174,495 rupiah.

It is worth being clear about what this plan is. It is the cheapest *combination of ingredients* that reaches the numbers; it contains no eggs, fish or chicken because, at these prices, plant proteins deliver the same nutrients for less. A real menu also needs variety, taste and nutrients we did not include, such as vitamins A and C and the essential fats in fish. Section 4.9 shows how to add them as constraints; the program's job is to make the price of each wish visible.

4.7 Measuring It

Listing 4.3 asks three questions: how much do the methods differ, how does the cost depend on the fiber target, and what does a smaller budget give up?

Listing 4.3 `lab.py`: the methods compared, the fiber target varied and the budget varied.

```
"""How the cheapest plan reacts to the fiber target and to the budget."""
from pathlib import Path

  fiber >= 28 g: Rp   24,711
  fiber >= 30 g: Rp   26,776
  fiber >= 32 g: Rp   28,841
  fiber >= 34 g: Rp   31,534
  fiber >= 36 g: Rp   35,572

What a smaller budget gives up (percent of targets missing):
  Rp 15,000: fiber 53%
  Rp 17,500: fiber 41%
  Rp 20,000: fiber 30%
  Rp 22,500: fiber 20%
  Rp 25,000: fiber 12%
  Rp 27,500: fiber 4%
  Rp 30,000: nothing
```

Greedy costs 12.4 percent more than linear programming for the same targets; requiring whole portions costs only 2 percent more than the ideal fractional plan. **Figure 4.3** plots the second table. From 16 to 32 grams, every further 4 grams of fiber a day costs between about 2,600 and 4,100 rupiah more; beyond 32 grams the steps get steeper as the cheap sources run out (32 to 36 grams costs 6,700 rupiah more); and a separate linear program that maximizes fiber instead of minimizing cost shows that these foods, within their daily limits and the energy maximum, can deliver at most 37.2 g. The slope of this curve at 32 grams is exactly the shadow price of fiber, about a thousand rupiah per gram. The last table is the same curve seen from the budget side: with 15,000 rupiah a woman can still meet energy, protein, calcium and iron, but less than half of the fiber target.

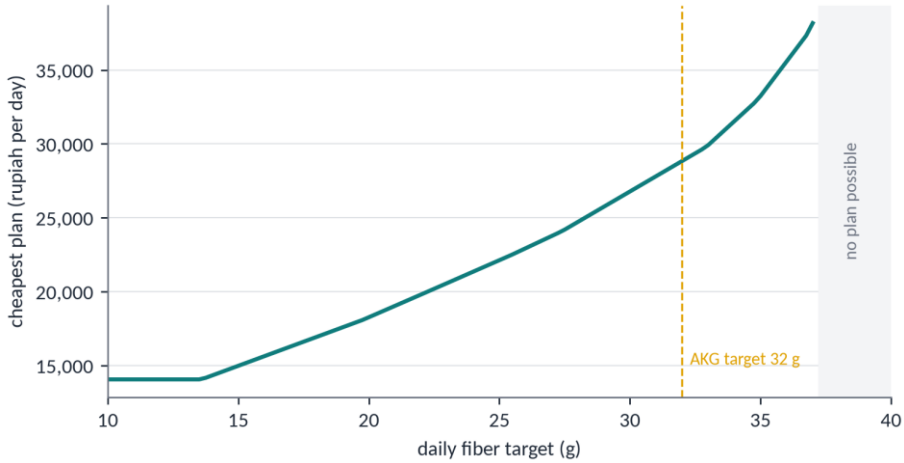

Figure 4.3 The cheapest plan meeting every target as the daily fiber target changes; the AKG target for a woman aged 19 to 29 is 32 g, and above about 37 g no plan exists with these foods and limits.

4.8 Testing It

Listing 4.4 checks the solver against the calculation of Section 4.3.3, then checks the greedy rule, whole portions and the budget version on the same two foods.

Listing 4.4 `test_menu.py`: tests based on the two-food example.

```

        self.assertAlmostEqual(sum(missing.values()), 0, places=6)
        grams, missing = solve_budget(f, TARGETS, budget=5000)
        self.assertLessEqual(cost(f, grams), 5000 + 1e-6)
        self.assertGreater(missing["energy"], 0)

if __name__ == "__main__":
    unittest.main()
```

The first test is the most important kind of test for an optimization program: a case small enough to solve by hand, whose answer (605.5 g of rice, 43.9 g of tempe, about 10,900 rupiah) we know independently of the code. The budget test checks both directions: with 50,000 rupiah nothing is missing, and with 5,000 rupiah the plan stays within the budget and energy falls short.

4.9 Improving It

Variety over a week. Plan seven days at once, with a variable $x_{i,d}$ for each food and day, the same daily constraints for each day, and weekly limits such as “tempe on at most four days” or “fish at least twice a week”. The model stays linear; it just gets seven times as many variables.

More nutrients. Vitamin A, vitamin C, zinc and fat are columns in TKPI too. Add them to `NUTRIENTS` and `targets.csv`. Every added constraint can only make the plan more expensive or keep its cost, and the shadow prices tell you which additions matter.

Minimums you care about. “At least one egg a day for the children” is the constraint $k_{\text{egg}} \geq 1$ in the integer program. Try it: the price of such a wish is the difference in cost, which the program computes instantly.

Cooking oil and seasoning. Frying adds oil, and therefore energy and fat. Add oil as a food whose amount is tied to the fried foods, for example $x_{\text{oil}} \geq 0.1\, x_{\text{tempe}}$, again a linear constraint.

Family planning. A family is several people with different AKG targets (a man aged 30 to 49, a child of 7 to 9, and so on). Sum the targets of all members for the family’s daily shopping, and use the individual targets to divide the portions.

4.10 Using It for Real

Use your prices. Replace the `price_per_kg` column with the prices at your market or supermarket, and update them every month; food prices in Indonesia move with the seasons. For rice, eggs, chicken, oil and sugar, the PIHPS website of Bank Indonesia and the National Food Agency’s price panel publish daily averages by province [8], [9].

Use your foods. Add the foods your family actually eats, with values from TKPI [7] for the raw ingredient. Choose the portion size you cook, and a maximum per day that you would really eat.

Use the right targets. AKG 2019 lists targets by age, sex, pregnancy and breastfeeding [10]. For a pregnant woman, for example, iron and protein targets are higher, and the program will show what that costs. For a person with a medical condition, targets must come from a doctor or a registered dietitian, not from a table.

For a school or catering kitchen. Multiply the portions by the number of meals, add the kitchen’s fixed costs, and compare with the budget per portion. For a meal program such as MBG, where one meal should cover roughly a third of the daily needs, divide the targets by three and set the budget to the money per portion.

Check the result. The optimizer is honest but literal: it will happily serve three guavas every day if guava is the cheapest fiber. Read the plan as a cook would, add the constraints that make it a menu, and look at how much each one costs.

4.11 Common Mistakes, and How to Avoid Them

Mixing "as bought" and "edible" amounts. Prices are per kilogram bought, nutrients per 100 g eaten. Forgetting Equation (4.1) makes chicken and bananas look cheaper than they are.

Per 100 grams versus per gram. TKPI values are per 100 grams; the model uses grams. A missing division by 100 makes every food a hundred times more nutritious.

The direction of an inequality. `linprog` wants "at most" constraints. A minimum must be multiplied by -1, on both sides. Forgetting one sign turns a minimum into a maximum, and the program will cheerfully return a plan of zero food.

No upper limits. Without u_i the cheapest plan may contain 900 grams of kangkung. Mathematically fine, practically inedible.

Rounding a linear program instead of solving the integer program. Rounding 1.4 portions down to 1 may break a target, and rounding up may break the budget. Let the integer solver choose.

Ignoring an infeasible result. When the solver reports that no plan exists, the data are telling you something: a target is too high for these foods and limits, or the budget too small. Find out which, as Equation (4.7) does, instead of loosening constraints at random.

4.12 Chapter Summary

- Planning food on a budget is a linear program (Equation (4.3)): minimize the cost (Equation (4.2)) of the grams of each food, subject to nutrient minimums and maximums and sensible limits per food; costs must be per edible gram (Equation (4.1)).
- The cheapest plan lies at a corner of the region of allowed plans, as the two-food example (Equation (4.4)) shows by hand.
- A greedy rule (Equation (4.5)) cost 12 percent more than the linear program on the same targets.
- Shadow prices (Equation (4.6)) show which targets drive the cost; on our data, fiber at about a thousand rupiah per gram.
- When the budget is too small, minimizing the total percentage shortfall (Equation (4.7)) gives the best compromise; whole portions (Equation (4.8)) turn the plan into a menu at a cost of about 2 percent.

4.13 Exercises

1. Using Equation (4.1), compute the cost of 100 edible grams of mackerel at 41,522 rupiah per kilogram with an edible share of 80 percent, and of eggs at 29,650 rupiah with 89 percent.
2. In the two-food problem Equation (4.4), change the protein target to 80 g. Find the three corners by hand and the cheapest plan.
3. Why is the shadow price of protein zero in the plan of Section 4.6? Would it stay zero if the protein target were 120 g?

4. Run `python planner.py --budget 30000` and explain the output.
5. AKG 2019 also gives 65 g of fat a day for a woman aged 19 to 29. Using the fat column of `foods.csv` (per 100 g: rice 1.7, tempe 8.8, mung bean 1.5, red bean 1.1, kangkung 0.7, banana 0.8, guava 0.3 g), compute the fat in the linear-programming plan of Section 4.6. Would a maximum of 65 g of fat change the plan or its cost?
6. Require at least one egg a day in the whole-portion plan. How much does that wish cost?

4.14 Solutions to the Exercises

1. Mackerel: $41{,}522/1000 \times 100/80 = 51.9$ rupiah per edible gram, 5,190 rupiah per 100 g. Eggs: $29{,}650/1000 \times 100/89 = 33.3$ rupiah, 3,331 rupiah per 100 g. Both match the first table of the program. A fifth of a mackerel and a tenth of an egg are paid for but not eaten.

2. The protein line is now $8.4a + 20.8b = 80$. Rice-only corner: $a = 80/8.4 = 9.52$, energy 3,400, cost 15,762. Tempe-only corner: $b = 2250/201 = 11.19$ (protein 233 g, enough), cost 22,388. Crossing point: $a = (80 - 20.8b)/8.4$, so $42.5(80 - 20.8b) + 201b = 2250$, that is $3400 - 884b + 201b = 2250$, $683b = 1150$, $b = 1.684$, and $a = (80 - 35.02)/8.4 = 5.355$. Cost $1655 \times 5.355 + 2000 \times 1.684 = 8{,}862 + 3{,}368 = 12{,}230$ rupiah: still the crossing point, now with more tempe and less rice.

3. The plan contains 111 g of protein, far more than 60, because beans and tempe, chosen for fiber, are rich in protein. A constraint with slack has a shadow price of zero: raising the target to 61 or even 110 g changes nothing. At 120 g the constraint would be tight and would get a positive shadow price, since some extra protein source would have to be bought.

4. The cheapest plan costs 28,841 rupiah, which is within 30,000, so the program does not need Equation (4.7). It prints the greedy plan, the linear-programming plan and its shadow prices as before, then solves the whole-portion program `solve_portions`, which meets every target for 29,425 rupiah (the lab's third line), and prints a shopping list based on that plan.

5. Rice $227 \times 1.7/100 = 3.9$, tempe $150 \times 8.8/100 = 13.2$, mung beans 1.5, red beans 1.1, kangkung $300 \times 0.7/100 = 2.1$, banana $250 \times 0.8/100 = 2.0$ and guava $300 \times 0.3/100 = 0.9$ grams: about 24.7 g of fat in total, far below 65 g. A maximum of 65 g would have slack, so its shadow price would be zero and neither the plan nor its cost would change. Such a check is still worth making, because it confirms that the cheap plan is not a fatty one. To add fat to the model for real, put `"fat"` into `NUTRIENTS` and a line `fat,g,0,65` into `targets.csv`, the greedy rule already copes with a minimum of zero, because `low` replaces it by a tiny positive number before dividing.

6. In `solve_portions`, replace `Bounds(0, …)` by lower bounds that are 0 for every food except the egg, which gets 1. The cheapest whole-portion plan then costs 31,105 rupiah instead of 29,425. Compared with the plan without the egg, it adds one egg, one more slice of tempe, a piece of tofu and a carrot, and drops one portion of rice and one banana: $1{,}832 + 1{,}000 + 600 + 875 - 828 - 1{,}800 = 1{,}680$ rupiah more per day. The wish costs a little less than the egg itself, because the egg's energy lets the plan drop some rice; but the egg brings no fiber, the nutrient that drives the cost, so the rest of the plan has to be rearranged to keep the fiber at 32 g.

Chapter 5

A Timetable Scheduler for a School or a Clinic: Constraint Satisfaction

Every school year begins with a puzzle that someone has to solve by hand: which class has which subject, with which teacher, in which period of which day, so that no teacher is in two classrooms at once, every subject gets its hours, and the part-time teacher who is only free on Mondays is only scheduled on Mondays. Clinics face the same puzzle with doctors, polyclinics and shifts. In this chapter we build a scheduler that solves it. It treats the timetable as a *constraint satisfaction problem*, fills it with backtracking search made fast by two classic ideas, the *minimum-remaining-values* rule and *forward checking*, and then improves the valid timetable with *local search* until teachers have no idle hours and doubles are back to back. By the end of the chapter you will be able to state a scheduling problem as variables, domains and constraints, tell hard constraints from soft ones, trace backtracking with MRV and forward checking by hand, measure how much each idea saves, write an independent checker for a timetable, and adapt the program to a clinic.

5.1 The Week Nobody Wants to Plan

Indonesia had 319,701 schools in the 2025/2026 school year, from kindergartens to vocational high schools, according to Statistics Indonesia [1], and more than 10,000 community health centers, *puskesmas*: 10,337 at the end of 2025 according to the Ministry of Health's health profile [2]. Every one of them needs a weekly timetable or a duty roster, and in most of them it is still made by hand, by a vice principal for curriculum or a head nurse, with a spreadsheet, colored paper and a great deal of patience. Building the timetable of a mid-sized school by hand takes days, and every late change, a teacher who falls ill or a class that must move, can undo hours of work.

The difficulty is not in any single rule; each is simple. It is in their number and in how they interact. Computer scientists proved in 1976 that the general timetabling problem is *NP-complete* [3], which means, roughly, that no known method solves every instance quickly, and that it is very unlikely that one exists. Yet real timetables are solved every day, by people and by software, because real instances have structure that a good search method can exploit. That is what this chapter does.

The rewards are practical. A program produces a valid timetable in a fraction of a second, so the planner can try alternatives ("what if Bu Sari only works three days?") instead of defending the first version that happened to work. It checks every rule mechanically, so no teacher is ever double-booked by accident. And it can polish a valid timetable for things people care about, such as fewer idle hours for teachers and no mathematics in the hot last period.

5.2 The Idea in Plain Words

Think of the timetable as an empty grid for each class: days across, periods down. Each cell must receive one subject. A subject carries its teacher with it: in class 7A, mathematics means Bu Sari. Some rules are *hard*: a teacher cannot be in two classes in the same period; each subject must get

exactly its weekly hours; a subject may have at most two hours in a class on one day; Pak Joko teaches elsewhere on Mondays; sport is only held in the cool morning periods. A timetable that breaks a hard rule is useless. Other rules are *soft*: teachers prefer no idle hours between lessons, two hours of the same subject on one day are better back to back, and mathematics and science are better not in the last two periods. A timetable may break soft rules, but the fewer the better.

A person filling the grid by hand does two sensible things without thinking about them. First, they start with the hardest cells: the Monday cells of the classes that Pak Joko teaches, or the morning cells that sport needs, because those have the fewest options. Second, whenever they write a subject into a cell, they immediately cross out the options that have just become impossible elsewhere: if Bu Sari teaches 7A in the first period on Monday, she cannot teach 7B then, so they cross mathematics out of 7B's first Monday cell. If some cell loses its last option, they know at once that the last decision was wrong and undo it, instead of discovering the problem an hour later. The first habit is the *minimum-remaining-values* (MRV) rule; the second is *forward checking*. Search that makes a choice, continues, and undoes the choice when it leads to a dead end is *backtracking*.

Once the grid is full and valid, the soft rules come in. Swapping the contents of two cells of the same class keeps every subject's hours; if the swap breaks no hard rule and reduces the idle hours or the late mathematics, we keep it. Repeating such swaps until none helps is *local search*.

> **DEFINITION.** A *constraint satisfaction problem* (CSP) consists of a set of *variables*, a *domain* of possible values for each variable, and a set of *constraints* that say which combinations of values are allowed. A *solution* gives every variable a value from its domain so that every constraint is satisfied.

5.3 The Math, Gently

5.3.1 The timetable as a CSP

Let G be the set of classes and S the set of time slots, each slot a pair (day, period). Our variables are the cells

$$X = \{ x_{g,s} : g \in G,\ s \in S \} \tag{5.1}$$

one for each class and slot, and the value of $x_{g,s}$ is the subject taught in that cell. The domain $D_{g,s}$ holds the subjects of class g that are allowed in slot s by the rules about single cells, the *unary* constraints: a teacher's unavailability and the rule that sport is only in periods 1 to 3. Writing $\text{teacher}(g, j)$ for the teacher of subject j in class g, $h_{g,j}$ for its weekly hours, and $[\dots]$ for 1 when the statement inside is true and 0 otherwise, the three remaining hard constraints are:

$$\text{teacher}(g, x_{g,s}) \neq \text{teacher}(g', x_{g',s}) \quad \text{for all } g \neq g' \text{ and every slot } s \tag{5.2}$$

$$\sum_{s \in S} [x_{g,s} = j] = h_{g,j} \quad \text{for every class } g \text{ and subject } j \tag{5.3}$$

$$\sum_{p} [x_{g,(d,p)} = j] \leq 2 \quad \text{for every class } g, \text{ subject } j \text{ and day } d \tag{5.4}$$

Equation (5.2) forbids double booking, Equation (5.3) gives every subject its hours, and Equation (5.4) spreads the hours over the week.

5.3.2 How big is the search space?

Our sample school has 4 classes and 28 slots per class (six periods from Monday to Thursday, four on Friday), 112 cells in all, and each class has 10 subjects. Filling each cell with any of 10 subjects gives 10^{112} grids. Even counting only the grids that give every subject its exact hours, one class alone can be arranged in

$$\frac{28!}{5!\ 4!\ 4!\ 3!\ 3!\ 2!\ 2!\ 2!\ 2!\ 1!} \approx 7.7 \times 10^{21} \tag{5.5}$$

ways: 28 lessons in a row, divided by the orders of the 5 Indonesian lessons among themselves, the 4 mathematics lessons, and so on, which are indistinguishable. For four classes that is about $(7.7 \times 10^{21})^4 \approx 3 \times 10^{87}$ combinations, more than the number of atoms in the Earth. Trying them one by one is out of the question; the search must avoid almost all of them without looking at them.

5.3.3 Backtracking, MRV and forward checking

Backtracking fills one cell at a time. After each choice it checks the constraints against the cells filled so far; if a constraint is broken it tries the next value, and if no value is left it returns to the previous cell and changes that one. The order of the cells matters enormously. The MRV rule, also called *fail first*, always chooses the unfilled cell with the fewest values left in its domain:

$$x^{*} = \arg\min_{x \text{ unfilled}} |D_x| \tag{5.6}$$

where $|D_x|$ is the number of values in the domain and argmin means "the x that makes this smallest". If a cell has only one possible subject, it should be filled now; if it has none, the search should find out now [4].

Forward checking, introduced together with a study of fail-first ordering by Haralick and Elliott [5], makes the domains shrink as the search goes. After a cell receives a subject, every unfilled cell that shares a class or a slot with it, its *peers*, loses the values that are no longer consistent. If a peer's domain becomes empty, the choice is undone at once. We add one more cheap check that follows from Equation (5.3): for each subject j of class g, the hours still needed must fit into the cells that still allow it,

$$h_{g,j} - \text{placed}_{g,j} \le \left|\{\, s : x_{g,s} \text{ unfilled},\ j \in D_{g,s} \,\}\right| \tag{5.7}$$

because a subject that still needs three hours but can only go into two remaining cells can never be completed. Forward checking and MRV work together: forward checking keeps the domains honest, so MRV sees which cells really are the most constrained.

5.3.4 A small example by hand

Take the tiny school used in the tests. Two classes, X and Y, have three periods on Monday and three on Tuesday. Each has mathematics (3 hours, both taught by Bu Ani) and Indonesian (3 hours, Pak Budi in X and Bu Cici in Y), and Bu Cici arrives late on Monday, so she cannot teach in

the first period. Unary constraints give every cell the domain {MAT, BIN}, except $x_{Y,(\text{Mon},1)}$, whose domain is only {MAT}.

MRV picks $x_{Y,(\text{Mon},1)}$ first, the only cell with one value, and gives it MAT. Forward checking now visits the peers. In the same slot, $x_{X,(\text{Mon},1)}$ loses MAT, because Bu Ani is busy with Y (Equation (5.2)); its domain becomes {BIN}. The other cells of Y keep both values. MRV now picks $x_{X,(\text{Mon},1)}$, the only cell with one value left, and gives it BIN. From there all remaining cells have two values; MRV takes them in order, and every time Bu Ani is placed in one class, the same slot in the other class loses MAT. The search fills all twelve cells without ever undoing a choice. Without MRV, the search would start at $x_{X,(\text{Mon},1)}$ and try MAT first; the choice looks fine until the search reaches $x_{Y,(\text{Mon},1)}$, whose only value MAT is now impossible, and it must go back.

5.3.5 Soft constraints and local search

For a complete timetable T we measure the soft rules with a *penalty*

$$P(T) = \text{gaps}(T) + \text{late}(T) + \text{split}(T) \tag{5.8}$$

where gaps counts, for every teacher and day, the idle periods between the teacher's first and last lesson; late counts the mathematics and science lessons in periods 5 and 6; and split counts the days on which a class has two hours of a subject that are not back to back. For a teacher whose lessons on a day are in periods $p_1 < p_2 < \cdots < p_k$, the idle periods are

$$\text{gaps} = (p_k - p_1 + 1) - k \tag{5.9}$$

the length of the working span minus the lessons in it. Lessons in periods 1, 3 and 6 give $(6 - 1 + 1) - 3 = 3$ idle periods.

Local search starts from a valid timetable and considers every *swap* of two cells of the same class. A swap never changes a subject's hours, so Equation (5.3) stays true; it is accepted only if the other hard constraints still hold and P decreases. When no swap decreases P, the timetable is a *local minimum*: not necessarily the best possible, but one that no single swap can improve. This simple method is the ancestor of the min-conflicts heuristic of Minton and colleagues, which repairs whole schedules by local moves [6].

5.4 The Algorithms as Pseudocode

Pseudocode 5.1 is the complete search with MRV and forward checking.

Pseudocode 5.1 Backtracking search with the minimum-remaining-values rule and forward checking.

```
BACKTRACK(value, domains)
1  if every cell has a value: return true
2  x = the unfilled cell with the smallest domain            // MRV
3  for each subject j in domains[x]
4      if j is consistent with value
5          value[x] = j
6          for each unfilled peer y of x                     // forward checking
7              remove from domains[y] every subject no longer consistent
8          if no domain is empty and every subject still has room
9              if BACKTRACK(value, domains): return true
10         restore the domains of the peers; remove value[x]
11 return false                                              // backtrack
```

Pseudocode 5.2 is the local search of Section 5.3.5.

Pseudocode 5.2 Local search: keep any swap of two cells of one class that keeps the hard rules and lowers the penalty.

```
IMPROVE(T)
1  repeat
2      improved = false
3      for each class g and each pair of slots s1, s2
4          swap the subjects of cells (g, s1) and (g, s2)
5          if every hard constraint holds and P(T) decreased: improved = true
6          else swap them back
7  until improved is false
8  return T
```

5.5 Building It Step by Step

Create a folder `Chapter005` and a virtual environment as in Chapter 1, Section 1.3. The programs use only the Python standard library.

5.5.1 The data

A school, or a clinic, is described by three small CSV files, so that the planner can edit them in a spreadsheet. `slots.csv` lists the days and how many periods each has; `lessons.csv` lists, for every class, its subjects, their teachers and their weekly hours; `unavailable.csv` lists when a teacher, or a subject, cannot be scheduled, with the reason. Our sample is a small junior high school, SMP, with four classes, 7A, 7B, 8A and 8B, twelve teachers and ten subjects: Indonesian (BIN, 5 hours), mathematics (MAT, 4), science (IPA, 4), social studies (IPS, 3), English (ING, 3), sport (PJOK, 2), religion (AGM, 2), civics (PPK, 2), informatics (INF, 2) and arts (SBD, 1), 28 hours in all, which exactly fills the 28 slots of each class.

```
day,periods
Mon,6
Tue,6
Wed,6
Thu,6
Fri,4
```

```
who,day,period,reason
Pak Joko,Mon,*,teaches at another school on Mondays
Bu Dewi,Fri,*,leads the Friday science club
Pak Yusuf,Tue,1,picks up his children
Pak Yusuf,Tue,2,picks up his children
PJOK,*,4,sport only in the cool morning (periods 1-3)
PJOK,*,5,sport only in the cool morning (periods 1-3)
PJOK,*,6,sport only in the cool morning (periods 1-3)
```

The first lines of `lessons.csv` are

```
group,subject,teacher,hours
7A,BIN,Bu Rina,5
7A,MAT,Bu Sari,4
7A,IPA,Bu Dewi,4
```

The column `who` of `unavailable.csv` names either a teacher or a subject, and `*` means “every day” or “every period”. Bu Sari teaches mathematics in three classes, twelve hours; Pak Joko teaches mathematics in 8B and informatics in all four classes, also twelve hours, but not on Mondays.

5.5.2 The CSP and the search

Listing 5.1 reads the three files, builds the domains, and contains the search and an independent checker.

Listing 5.1 `csp.py`: the timetable as a CSP, backtracking with MRV and forward checking, and a checker.

```
"""A timetable as a constraint satisfaction problem, solved by backtracking.

Variables: every (class, time slot) cell of the timetable.
Values:    the subject taught in that cell (its teacher comes with it).
"""
import csv
import time
from pathlib import Path

class Timetable:
    def __init__(self, folder):
        folder = Path(folder)

    return found
```

`Timetable.__init__` builds the list of slots from `slots.csv`, the dictionaries `hours` and `teacher` keyed by (class, subject), and the set `blocked` of (teacher or subject, slot) pairs from `unavailable.csv`, expanding each `*`. The domains then contain, for every cell, the subjects of that

class whose teacher and whose subject are not blocked in that slot: all unary constraints are applied once, before the search starts. The last check makes sure the hours of every class exactly fill its slots; otherwise no solution can exist and it is better to say so immediately.

`ok` tests the non-unary constraints for one candidate: it walks through the filled cells, returns `False` as soon as the same teacher appears in another class in the same slot (Equation (5.2)), and otherwise counts how many hours of the subject are already placed in the class and on the same day, for Equation (5.3) and Equation (5.4).

`solve` implements **Pseudocode 5.1** as the inner function `search`, which calls itself. The switches `mrv` and `forward` turn the two ideas on or off so that we can measure them, and `limit` stops a hopeless search after a given number of assignments. `peers` is computed once: for every cell, the other cells of the same class or the same slot. Forward checking replaces each unfilled peer's domain by the values that `ok` still accepts, keeping the old list in `saved` so that line 10 of the pseudocode can put it back; `enough_room` is Equation (5.7). The dictionary `stats` counts assignments, the number of times a value was placed in a cell, and backtracks, the number of times one was taken out again.

`violations` checks a finished timetable against every hard rule directly, without using the search code. It is a second opinion: if the search had a bug, the checker would catch it.

5.5.3 Soft constraints and local search

Listing 5.2 measures Equation (5.8) and implements **Pseudocode 5.2**.

Listing 5.2 `soft.py`: the soft penalty and the swap-based local search.

```
"""Soft constraints: what makes a valid timetable a good one, and local search."""
from itertools import combinations

HEAVY = {"MAT", "IPA"}                          # better not in the last periods

def penalty(tt, value, detail=False):
    """Add up the soft-constraint violations of a complete timetable."""
    bad = {"teacher gaps": 0, "heavy late": 0, "split double": 0}
    days = [d for d, p in tt.slots if p == 1]
    by_teacher = {}
    for (g, (day, p)), subj in value.items():
        by_teacher.setdefault((tt.teacher[g, subj], day), []).append(p)
        if subj in HEAVY and p >= 5:
            bad["heavy late"] += 1
    for periods in by_teacher.values():         # idle periods in between
        bad["teacher gaps"] += max(periods) - min(periods) + 1 - len(periods)
    for g, subj in tt.hours:
        for day in days:
            ps = sorted(p for (g2, (d, p)), s in value.items()
                        if g2 == g and d == day and s == subj)
            if len(ps) == 2 and ps[1] - ps[0] != 1:
                bad["split double"] += 1        # two hours, not back to back
    return bad if detail else sum(bad.values())

def improve(tt, value):
    """Swap two cells of the same class while the swap keeps every hard rule
    and lowers the penalty. Stops when no swap helps."""
    value = dict(value)
    best = penalty(tt, value)
    improved = True
    while improved:
        improved = False
        for g in tt.groups:
            for s1, s2 in combinations(tt.slots, 2):
                a, b = (g, s1), (g, s2)
                if value[a] == value[b]:
                    continue
                if value[b] not in tt.domains[a] or value[a] not in tt.domains[b]:
                    continue                    # a teacher or subject rule
                value[a], value[b] = value[b], value[a]
                rest_a = {c: v for c, v in value.items() if c != a}
                rest_b = {c: v for c, v in value.items() if c != b}
                if (tt.ok(a, value[a], rest_a) and tt.ok(b, value[b], rest_b)
                        and penalty(tt, value) < best):
```

Listing 5.2 (Continued) *soft.py: the soft penalty and the swap-based local search.*

```
                    best = penalty(tt, value)
                    improved = True
                else:                           # undo
                    value[a], value[b] = value[b], value[a]
    return value
```

`penalty` groups the lessons by teacher and day and applies Equation (5.9) to each group, counts heavy subjects in periods 5 and 6, and looks for subjects with two non-adjacent hours on a day. With `detail=True` it returns the three parts separately. `improve` tries every pair of slots of every class, using `combinations` from the standard library, skips pairs whose subjects are equal or whose new places are forbidden by the domains, performs the swap, and keeps it only if `ok` accepts both cells against the rest of the timetable and the penalty went down.

5.5.4 The application

Listing 5.3 is the program the planner runs.

Listing 5.3 `timetable.py`: solve, improve, check, print and save the timetable.

```
"""Timetable scheduler: a valid timetable by constraint search, then a better one.

python timetable.py                     the sample school in data/school
python timetable.py data/clinic         any folder with the same three files
"""
import csv
import sys
from pathlib import Path

from csp import Timetable, solve, violations
from soft import improve, penalty

HERE = Path(__file__).parent

def grid(tt, value, group):
    days = [d for d, p in tt.slots if p == 1]
    rows = max(p for _, p in tt.slots)
    lines = ["      " + "".join(f"{d:<7}" for d in days)]
    for p in range(1, rows + 1):
        cells = [value.get((group, (d, p)), "-") for d in days]
        lines.append(f"  {p}   " + "".join(f"{c:<7}" for c in cells))
    return "\n".join(lines)

def main():
    folder = Path(sys.argv[1]) if len(sys.argv) > 1 else HERE / "data/school"
    tt = Timetable(folder)
    print(f"{len(tt.groups)} groups, {len(tt.slots)} slots each, "
          f"{len(tt.cells)} cells to fill")
    value, stats = solve(tt)
    if value is None:
        print("No timetable satisfies every hard constraint:", stats)
        return
    print(f"valid timetable after {stats['assignments']} assignments, "
          f"{stats['backtracks']} backtracks, {stats['seconds']:.2f} s")
    print("soft penalty before:", penalty(tt, value, detail=True))
    value = improve(tt, value)
    print("soft penalty after :", penalty(tt, value, detail=True))
    print("hard rules broken  :", len(violations(tt, value)))
    for g in tt.groups[:1]:
        print(f"\nTimetable of {g}:")
        print(grid(tt, value, g))
    out = HERE / "out"
    out.mkdir(exist_ok=True)
    with open(out / "timetable.csv", "w", newline="", encoding="utf-8") as f:
```

Listing 5.3 (Continued) *timetable.py: solve, improve, check, print and save the timetable.*

```
        w = csv.writer(f)
        w.writerow(["group", "day", "period", "subject", "teacher"])
        for (g, (d, p)), s in sorted(value.items()):
            w.writerow([g, d, p, s, tt.teacher[g, s]])
    print("\nwrote out/timetable.csv")

if __name__ == "__main__":
    main()
```

It takes the data folder as an optional argument, so the same program schedules the sample school, your school, or a clinic. `grid` prints one class's week as a small table, with `-` for slots that do not exist (Friday periods 5 and 6). The complete timetable, with teachers, goes to `out/timetable.csv`, which opens in any spreadsheet and can be filtered by class or by teacher.

5.6 Running It

Run `python timetable.py`.

```
4 groups, 28 slots each, 112 cells to fill
valid timetable after 112 assignments, 0 backtracks, 0.10 s
soft penalty before: {'teacher gaps': 26, 'heavy late': 10, 'split double': 14}
soft penalty after : {'teacher gaps': 0, 'heavy late': 6, 'split double': 0}
hard rules broken  : 0

Timetable of 7A:
     Mon    Tue    Wed    Thu    Fri
  1  IPS    IPS    MAT    IPA    PJOK
  2  PJOK   MAT    ING    IPS    PPK
  3  MAT    INF    ING    SBD    INF
  4  BIN    IPA    AGM    MAT    BIN
  5  BIN    BIN    PPK    AGM    -
  6  IPA    BIN    IPA    ING    -

wrote out/timetable.csv
```

With MRV and forward checking the search fills all 112 cells without a single backtrack, in about a tenth of a second. The first valid timetable is valid but not pleasant: teachers have 26 idle periods in total, heavy subjects appear 10 times in the last periods, and 14 times a subject has two hours on one day that are not back to back. Local search removes every idle period and every split double and brings the late heavy lessons down to 6, while the independent checker confirms that no hard rule is broken. **Figure 5.1** shows the finished timetables of all four classes.

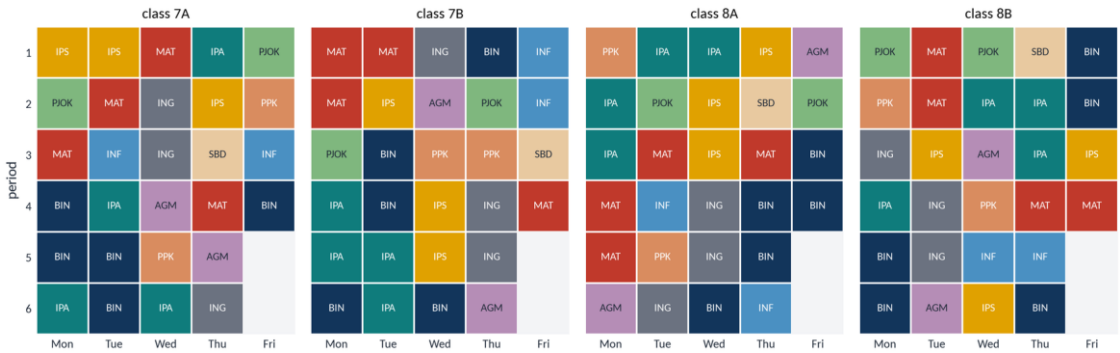

Figure 5.1 The improved timetables of the four classes; each color is a subject, and the grey cells are the Friday periods that do not exist.

Read class 7A's week in the output. Sport is in the first or second period, as the unary rule demands. Informatics never appears on Monday, because Pak Joko is elsewhere. Every day has at most two hours of any subject, and where there are two (Indonesian on Monday and Tuesday, English on Wednesday) they are back to back. The six remaining late heavy lessons are the price of a completely full timetable: each class has eight hours of mathematics and science and only so many morning periods, which are also wanted by sport and by the other teachers.

5.7 Measuring It

Listing 5.4 measures the four combinations of MRV and forward checking on the school and on a variant with stricter availability: Bu Sari only works Monday to Wednesday, Pak Yusuf is at training on Wednesdays, and Bu Lestari has committee work on Mondays.

Listing 5.4 `lab.py`: the search settings compared on two schools, and the effect of local search.

```

  MRV off, forward checking on : solved     125 assignments     13 backtracks   0.08 s
  MRV on , forward checking on : solved     112 assignments      0 backtracks   0.05 s
  soft penalty 50 -> 6
school_tight: 112 cells
  MRV off, forward checking off: solved     117 assignments      5 backtracks   0.01 s
  MRV on , forward checking off: gave up  20410 assignments  20410 backtracks   2.68 s
  MRV off, forward checking on : solved     115 assignments      3 backtracks   0.05 s
  MRV on , forward checking on : solved     112 assignments      0 backtracks   0.05 s
  soft penalty 44 -> 7
```

Figure 5.2 plots the number of assignments on a logarithmic scale. On the ordinary school, plain backtracking gives up after 20,000 assignments; MRV alone needs 202, forward checking alone 125, and both together 112, which is the minimum possible: one assignment per cell and no backtrack at all.

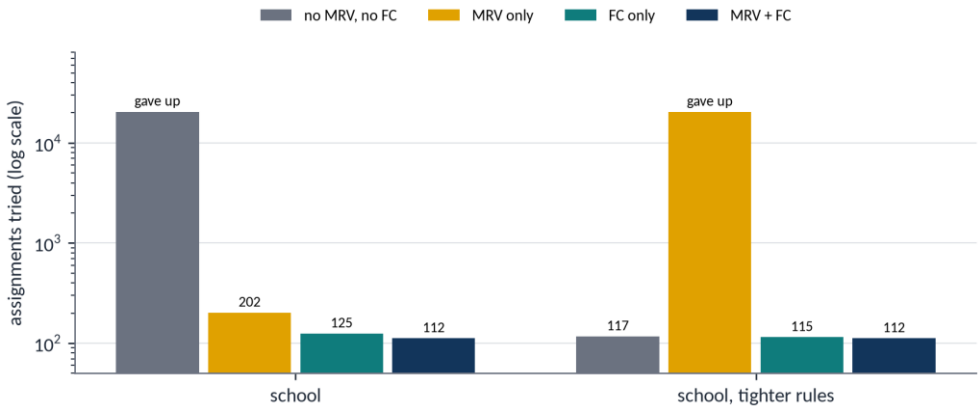

Figure 5.2 Assignments needed by the four search settings on the two schools, on a logarithmic scale; "gave up" marks runs stopped at the limit of 20,000.

The tighter school holds a surprise. There, plain backtracking succeeds almost at once, and MRV *alone* gives up. This is not a bug: MRV without forward checking works with the original domains, which never shrink, so it keeps choosing the cells that looked hardest at the start, not the ones that are hardest now, and chronological backtracking can then spend its effort in the wrong corner of the search. A heuristic is a good bet, not a guarantee. The combination of MRV with forward checking is the robust choice: it solved both schools without backtracking, because each idea covers the other's blind spot.

Figure 5.3 shows the effect of local search on the ordinary school: the total penalty falls from 50 to 6, and on the tighter school from 44 to 7.

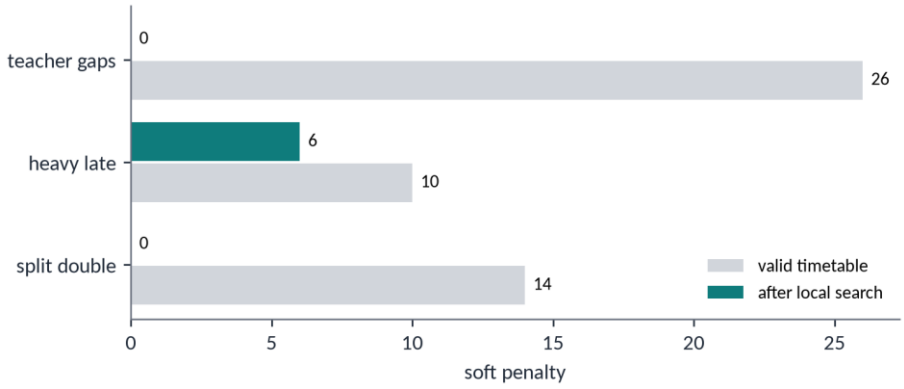

Figure 5.3 The three soft penalties of the first valid timetable and after local search.

5.8 Testing It

Listing 5.5 runs the tiny school of Section 5.3.4, written into a temporary folder, through every search setting and checks the results with `violations`.

        self.assertLessEqual(penalty(tt, better), penalty(tt, value))

if __name__ == "__main__":
    unittest.main()
```

`test_domains` checks the example's starting point: 12 cells, and only mathematics possible for Y in the first Monday period. `test_impossible` makes Bu Ani unavailable on Tuesday; then her six mathematics hours must fit into Monday's three periods, which is impossible, and the solver must say so by returning `None` rather than a wrong timetable. `test_improve_keeps_rules` checks the promise of local search: the penalty never rises and no hard rule is ever broken.

```

```

5.9 Improving It

Rooms. Science practicals need the laboratory and informatics needs the computer room. A room is one more resource, like a teacher: add a room column to `lessons.csv` and a constraint like Equation (5.2) for rooms.

Double lessons as a hard rule. Some schools require that sport is always one double period. That is a constraint on two cells together; the simplest way is to make "PJOK double" a single lesson that occupies two consecutive periods.

Better local search. Our swaps accept only improvements and stop at the first local minimum. *Simulated annealing* occasionally accepts a slightly worse swap, with a probability that shrinks over time, and often escapes to a better timetable. Min-conflicts search [6] can even start from an invalid timetable and repair it.

Weights for soft rules. Not all soft rules are equally important. Multiply each part of Equation (5.8) by a weight chosen by the school, for example 3 for teacher gaps and 1 for late mathematics.

Fairness. Count, per teacher, the lessons in the last period or on Friday afternoon, and add the spread between the most and the least loaded teacher to the penalty, so that unpopular slots are shared.

5.10 Using It for Real

For a school. Export the classes, subjects, teachers and weekly hours from your school's records into `lessons.csv`. Check the totals: the hours of each class must equal the number of slots, or you must add a subject such as "free" or "homeroom". Collect every teacher's unavailability in `unavailable.csv` before the first run, with the reason, because the program can only respect the rules it is told.

Iterate. Run the scheduler, print the timetables, show them to the teachers, and turn their complaints into new rows of `unavailable.csv` or new soft rules. Because a run takes a second, ten rounds of feedback cost minutes, not days.

For a clinic or puskesmas. The same program schedules doctors and midwives to polyclinics and shifts: a polyclinic is a "class", a shift is a "period", a doctor is a "teacher", and each person's sessions per week are the "hours". Hours that a polyclinic is closed are a "subject" of their own, with a teacher that exists only there. Exercise 4 builds a small clinic.

Keep the checker. Whatever you change in the search, run `violations` on the result, as `timetable.py` does. A timetable with a double-booked teacher costs far more trust than it saves time.

Publish it. `out/timetable.csv` can be pivoted in a spreadsheet into one sheet per class and one per teacher, or turned into a web page with the tools of Part 10.

5.11 Common Mistakes, and How to Avoid Them

Mixing hard and soft rules. If "no mathematics in the last period" is made a hard rule, the problem may have no solution at all, and the program will only say "no". Keep hard only what truly must hold, and let the penalty handle preferences.

Hours that do not add up. If a class has 27 hours for 28 slots, or 29, no complete timetable exists. Check the totals first, as `Timetable.__init__` does.

Forgetting to undo. Forward checking changes the domains; when a choice is taken back, the domains must be restored exactly. A missing restore makes the search skip valid timetables and report failure wrongly.

Trusting a heuristic blindly. Section 5.7 showed that MRV alone can do worse than no heuristic. Measure on your own data, and keep a limit so that a hopeless search stops.

Accepting a swap that breaks a hard rule. Local search must re-check every hard constraint for both swapped cells, including teacher availability and the daily limit, not only the penalty.

Treating the output as final. A schedule is a social document. Teachers will ask for changes; plan for several rounds, and keep the data files, not the output, as the thing you edit.

5.12 Chapter Summary

- A timetable is a CSP: one variable per class and slot (Equation (5.1)), domains restricted by unary rules, and hard constraints for teachers (Equation (5.2)), weekly hours (Equation (5.3)) and daily limits (Equation (5.4)).
- The search space is astronomically large (Equation (5.5)), so the search must prune rather than enumerate.
- Backtracking with MRV (Equation (5.6)) and forward checking, plus the room check (Equation (5.7)), filled the 112 cells of our school without a single backtrack; plain backtracking gave up.
- Heuristics are bets: MRV alone failed on the tighter school, while MRV with forward checking solved both.
- Local search with swaps reduced the soft penalty (Equation (5.8)) from 50 to 6, and an independent checker confirmed that no hard rule was broken.

5.13 Exercises

1. Compute the number of idle periods, by Equation (5.9), for a teacher who teaches in periods 2, 3 and 6 on one day, and for one who teaches in periods 1, 2, 3 and 4.
2. Continue the hand trace of Section 5.3.4: after $x_{Y,(\text{Mon},1)} = \text{MAT}$ and $x_{X,(\text{Mon},1)} = \text{BIN}$, MRV takes the next cell in order, $x_{X,(\text{Mon},2)}$, and tries MAT. Which domains does forward checking change?
3. Explain in your own words why plain backtracking, which gave up on the ordinary school, succeeded immediately on the tighter one.

4. Build a small clinic with three polyclinics (general, dental and maternal-child health), two shifts a day from Monday to Saturday, and five staff, one of whom works in two polyclinics. Run `timetable.py` on it.
5. The swap in `improve` changes two cells of the same class. Why can a swap never break Equation (5.3), and which hard rules must still be checked?
6. How many assignments would a search need at the very least for a school with 6 classes and 30 slots per class? What does it mean when `solve` reports exactly that number?

5.14 Solutions to the Exercises

1. Periods 2, 3 and 6: $(6 - 2 + 1) - 3 = 2$ idle periods (4 and 5). Periods 1 to 4: $(4 - 1 + 1) - 4 = 0$.

2. Bu Ani now teaches X in Monday period 2, so the peer in the same slot, $x_{Y,(\text{Mon},2)}$, loses MAT by Equation (5.2) and keeps only BIN. In class X, mathematics now has one hour on Monday; the other Monday cell of X, $x_{X,(\text{Mon},3)}$, may still take MAT, because Equation (5.4) allows two, so its domain is unchanged. MRV then picks $x_{Y,(\text{Mon},2)}$, the only cell with one value, and gives it BIN.

3. Without MRV the search fills the cells in a fixed order, class by class and slot by slot. Whether that order is lucky depends on the data: in the tighter school the unavailable teachers remove so many options that the first choices in that order happen to be forced into the right places early, and only five backtracks are needed. In the ordinary school the same order makes early choices that clash with rules discovered much later, and chronological backtracking can only undo the most recent choice, so it is trapped. The lesson of Section 5.7 is the same in both directions: a fixed order or a heuristic can be lucky or unlucky; forward checking makes the search notice dead ends early, whatever the order.

4. The folder `data/clinic` of the chapter's code contains such a clinic. `slots.csv` has Monday to Saturday with 2 periods (morning and afternoon shift); `lessons.csv` is

```
group,subject,teacher,hours
Umum,Andi,dr. Andi,5
Umum,Bela,dr. Bela,4
Umum,Eko,dr. Eko,3
Gigi,Citra,drg. Citra,8
Gigi,closed,nobody (Gigi),4
KIA,Dina,Bidan Dina,6
KIA,Eko,dr. Eko,3
KIA,closed,nobody (KIA),3
```

and `unavailable.csv` says that dr. Bela does not work on Saturdays, drg. Citra is off on Friday afternoons and dr. Eko works at the hospital on Mondays. Every polyclinic has 12 sessions a week, and the closed sessions are "subjects" with a teacher that exists only in that polyclinic, so they never clash. dr. Eko works in two polyclinics and can never be in both at once. `python timetable.py data/clinic` prints

```
3 groups, 12 slots each, 36 cells to fill
valid timetable after 36 assignments, 0 backtracks, 0.00 s
soft penalty before: {'teacher gaps': 0, 'heavy late': 0, 'split double': 0}
soft penalty after : {'teacher gaps': 0, 'heavy late': 0, 'split double': 0}
hard rules broken  : 0

Timetable of Gigi:
     Mon    Tue    Wed    Thu    Fri    Sat
  1  Citra  Citra  Citra  Citra  closed closed
  2  Citra  Citra  Citra  Citra  closed closed

wrote out/timetable.csv
```

The timetable is valid, but the dental clinic is open Monday to Thursday and closed on Friday and Saturday. For patients a spread over the week would be better: that is a soft rule for the clinic, for example a penalty for every day on which a polyclinic is closed all day, added to `penalty`.

5. A swap exchanges the subjects of two cells of the same class, so the number of cells of each subject in that class stays the same: Equation (5.3) is untouched. The other rules can break: the teacher of each moved subject may be busy in another class in the new slot (Equation (5.2)), may be unavailable then (the domain check), or the subject may get a third hour on the new day (Equation (5.4)). `improve` checks all three, with `tt.domains` and `tt.ok`.

6. Every cell must receive a value at least once, so $6 \times 30 = 180$ assignments is the minimum. If `solve` reports exactly the number of cells, with 0 backtracks, the search never made a choice it had to undo: MRV and forward checking guided it straight to a solution, as in Section 5.6.

Chapter 6

A Customer-Service Chatbot for a Small Business: Intents, Rules and a Human in the Loop

"Kak, jam berapa buka?" "How much for a bed cover?" "Is my laundry ready?" A small business answers the same few questions dozens of times a day, in chat, often late at night, and usually in two languages. In this chapter we build a chatbot for Profitina Laundry that answers them. It recognizes what the customer wants, its *intent*, with a small classifier trained on example sentences in English and Indonesian; it lets hand-written rules decide the cases where a mistake would be costly; it collects the details of a pickup request one question at a time, a technique called *slot filling*; it looks up real orders in the laundry's data; and, most importantly, it knows when to stop and hand the conversation to a person. By the end of the chapter you will be able to design the intents of a business chatbot, turn text into numbers with character n-grams and TF-IDF, explain how logistic regression turns scores into probabilities, combine rules with a classifier, fill slots with regular expressions, measure the bot on messages it has never seen, and decide when a machine should step aside.

6.1 Answering the Same Question for the Hundredth Time

Indonesia has about 65.5 million micro, small and medium enterprises, which employ some 119 million people, according to the Ministry of MSMEs in July 2025 [1]. For most of them, customers arrive by chat: WhatsApp, Instagram, a marketplace inbox. Answering quickly wins orders; answering at 22.00 about opening hours is exhausting. That is why chat automation has become a mass-market product. In June 2026 Meta made its AI business agent for WhatsApp, Messenger and Instagram available worldwide and reported that more than one million businesses were already using it, and that there were more than one billion active threads between people and businesses on its apps every day [2]. A central feature of such agents is the one we build here too: the business decides when a person takes over.

A laundry is a good example of what a small chatbot can and cannot do. Perhaps four questions in five are routine: opening hours, prices, where the outlets are, how to pay, whether an order is ready, and requests for pickup. Each has a clear answer that can be looked up. The fifth question is different: a damaged jacket, a missing sock, an angry customer. No program should try to talk its way out of those; the right answer is a quick, polite handover to a person who can apologize and decide.

The chatbot of this chapter is built from the ideas of the previous chapters. The intent classifier learns from labeled examples, like the categorizer of Chapter 2. The rules for complaints and order numbers are keyword and pattern rules, as in Chapter 2's first version. The pickup form is a small constraint problem, like Chapter 5's timetable, solved by asking. Everything runs offline on a laptop and uses the real sample data of Profitina Laundry: its twelve services with prices, its three outlets and almost three thousand orders.

6.2 The Idea in Plain Words

Imagine a new employee at the counter on her first day. She has a sheet of paper that lists the kinds of questions customers ask, each with a few examples: “jam berapa buka”, “what time do you open”, “are you open on Sunday” are all *hours*. When a customer writes, she compares the message with the examples and picks the kind that looks most similar. That is *intent classification*. If nothing looks similar enough, she says politely that she did not understand and suggests what she can help with; if it happens twice, she calls the supervisor.

Some messages she does not classify at all, because the boss told her rules that always apply: if a message contains an order number such as B2815, look it up; if a customer says the word *rusak* (damaged), *hilang* (missing) or asks for the admin, call the supervisor at once. Rules are checked first, because for these cases a clear rule is safer than a guess.

When a customer asks for a pickup, she needs four facts: the service, the amount, the address and the time. She fills in a form. Whatever the customer has already said, even in the first message, goes straight into the form; for each missing field she asks one question, and when the form is complete she confirms the booking with the price. Those fields are the *slots* of the *pickup* intent.

Finally, she answers in the customer’s language. A message full of “kak”, “berapa” and “bisa” gets an Indonesian answer; one with “how”, “is” and “my” gets an English one. **Figure 6.1** shows the whole flow.

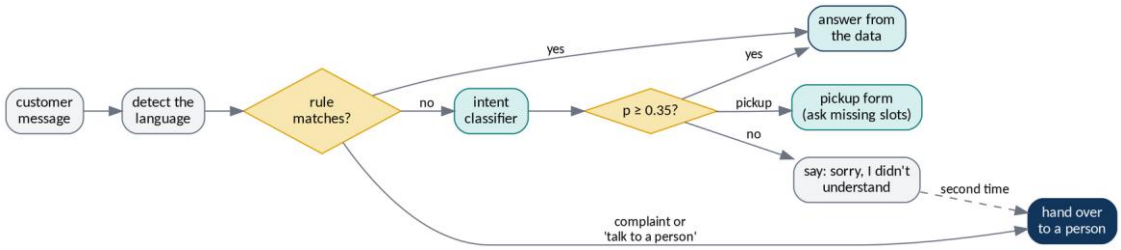

Figure 6.1 How the chatbot handles a message: detect the language, apply the rules, classify the intent, then answer, fill the form, or hand the conversation to a person.

> **DEFINITION.** An *intent* is what the customer wants to achieve with a message (ask the price, book a pickup, complain). A *slot* is a piece of information an intent needs (the service, the address). A *handoff* passes the conversation, with its history, to a human.

6.3 The Math, Gently

6.3.1 From text to numbers: character n-grams

Customers write “brp”, “berapa”, “berapaa” and “brapa”. Whole words would treat these as unrelated. Short pieces of letters, *character n-grams*, are more forgiving: “berapa” and “berapaa” share almost all their pieces. Before splitting, our program *normalizes* the text: lower case, punctuation removed, and a few common chat spellings replaced by the standard word (“gak” and “ga” become “tidak”, “brp” becomes “berapa”). Then each word is padded with a space on both sides and cut into all pieces of 2, 3 and 4 characters. The word “halo” gives twelve pieces:

```
' h'  'ha'  'al'  'lo'  'o '  ' ha'  'hal'  'alo'  'lo '  ' hal'  'halo'  'alo '
```

The 110 training examples produce 1,711 different pieces; each message becomes a list of 1,711 numbers, one per piece.

6.3.2 TF-IDF weights

Not all pieces are equally informative. The piece "a" occurs in almost every Indonesian message and says little; the piece "jemp" occurs only in pickup requests and says a lot. *TF-IDF* weights a piece t in a message d by how often it occurs there (term frequency) and how rare it is across the N training messages (inverse document frequency). With $\mathrm{tf}(t,d)$ the count in the message and $\mathrm{df}(t)$ the number of training messages containing t, our program uses

$$w(t,d) = (1 + \ln \mathrm{tf}(t,d)) \cdot \left(\ln \frac{1+N}{1+\mathrm{df}(t)} + 1 \right) \tag{6.1}$$

for pieces that occur in the message, and 0 for the others. The logarithm ln grows slowly, so a piece repeated three times does not count three times as much. Finally each message's list of weights is scaled to length 1, so that long and short messages are comparable [3].

6.3.3 Logistic regression: from scores to probabilities

For each intent k the classifier has learned a weight for every piece, a list $\mathbf{v}_k$, and a number b_k. The *score* of intent k for a message with weights $\mathbf{x}$ is the sum of the products, $z_k = \mathbf{v}_k \cdot \mathbf{x} + b_k$. Scores can be any numbers; to turn them into probabilities that are positive and add up to 1, *multinomial logistic regression* uses the *softmax* function:

$$P(k \mid \mathbf{x}) = \frac{e^{z_k}}{\sum_j e^{z_j}} \tag{6.2}$$

where $e \approx 2.718$ and the sum runs over all eleven intents. Training chooses the weights so that the correct intents of the training examples get high probability; the setting `C=10` controls how strongly large weights are discouraged [4].

Let us check one case by hand. For "bisa jemput cucian?" the three largest scores are 3.55 for *pickup*, 0.47 for *services* and 0.45 for *status*. Then $e^{3.55} = 34.81$, $e^{0.47} = 1.60$ and $e^{0.45} = 1.57$, and the other eight intents add 5.05, so the sum is 43.03. By Equation (6.2), $P(\text{pickup}) = 34.81/43.03 = 0.81$ and $P(\text{services}) = 1.60/43.03 = 0.037$. A difference of about 3 in the scores becomes a factor of more than 20 in the probabilities: the softmax rewards a clear winner.

6.3.4 Rules first, then the classifier, then a person

The bot decides in a fixed order. If a rule's pattern matches, the rule's intent is used with confidence 1. Otherwise the classifier's best intent $\hat{k}$ with probability $p_{\max}$ is accepted only if

$$p_{\max} \geq \theta \tag{6.3}$$

with the threshold $\theta = 0.35$. With eleven intents, a random guess would give each about $1/11 = 0.09$, so 0.35 means that one intent clearly stands out. A message that fails the threshold gets a polite "I didn't understand"; a second failure in a row hands the conversation to a person. Complaints and requests for a person are handed over at once. Section 6.7 shows how the threshold was chosen.

6.3.5 Which language?

The language test is a simple vote. With I the number of words of the message found in a list of common Indonesian words and E the number found in a list of common English words, the bot answers in

$$\text{language} = \begin{cases} \text{English} & \text{if } E > I \\ \text{Indonesian} & \text{otherwise} \end{cases} \tag{6.4}$$

A tie goes to Indonesian, because the business is in Surabaya. One-word messages such as “ok” do not change the language of the conversation.

6.3.6 What to count

A chatbot can fail in two different ways, and they must be counted separately. Of T test messages, let A be the number the bot answers (a rule fired or the classifier passed the threshold), and W the number of those answers that are wrong. The *answer rate* and the *error rate among answers* are

$$\text{answer rate} = \frac{A}{T}, \qquad \text{error rate} = \frac{W}{A} \tag{6.5}$$

The remaining $T - A$ messages get a follow-up question or go to a person. Raising θ lowers both rates at once: fewer answers, but fewer of them wrong. A business chooses the point where the error rate is acceptable, because a wrong answer is sent to a customer with the business’s name on it, while a question only costs a few seconds. For example, if a bot answers 34 of 44 messages with no mistakes, its answer rate is $34/44 = 77$ percent and its error rate $0/34 = 0$; if it answers all 44 with 6 mistakes, the answer rate is 100 percent but the error rate is $6/44 = 14$ percent, about one customer in seven misinformed.

6.4 The Algorithm as Pseudocode

Pseudocode 6.1 is the heart of the bot: what happens to one message.

Pseudocode 6.1 Handling one customer message: rules, classifier, threshold, form filling and handoff.

```
REPLY(session, message)
1  add message to the session's history
2  if the session was handed to a person: return "staff will reply shortly"
3  if the message has more than one word: session.lang = LANGUAGE(message)
4  (intent, p, how) = first matching rule, else the classifier's best intent
5  sure = (how is "rule") or p ≥ θ
6  if a form is open and not (sure and intent is complaint, human or thanks)
7      return FILL-FORM(session, message)
8  if not sure
9      session.fallbacks = session.fallbacks + 1
10     if session.fallbacks ≥ 2: return HANDOFF(session)
11     return "sorry, I didn't understand; I can help with ..."
12 session.fallbacks = 0
13 if intent is complaint or human: return HANDOFF(session)
14 if intent is pickup: open the pickup form; return FILL-FORM(session, message)
15 return the answer for intent (looked up in the data where needed)
```

`FILL-FORM` extracts whatever slot values the message contains, keeps those not yet known, and asks for the first missing slot; when none is missing it confirms the booking and closes the form.

6.5 Building It Step by Step

Create a folder `Chapter006` and a virtual environment as in Chapter 1, Section 1.3, and install scikit-learn, which also brings NumPy and SciPy:

```
# Chapter 6: versions this chapter was tested with (Python 3.14.7)
numpy==2.5.3
scipy==1.18.1
scikit-learn==1.9.1
```

6.5.1 The data

The folder `data` contains four kinds of files. `Service.csv`, `Outlet.csv` and `Bill.csv` come from the Profitina Laundry sample database: the twelve services with their prices, the three outlets with their addresses, and 2,953 orders with their dates, status and outlet. `intents.csv` has 110 training examples, ten for each of eleven intents, five in English and five in Indonesian; `test.csv` has 44 different messages, four per intent, written separately to test the bot honestly. `demo.txt` holds four conversations that we replay below.

```
intent,text
greet,hello
greet,halo kak
hours,what time do you open
hours,jam berapa buka
pickup,can you pick up my laundry
pickup,tolong ambil cucian di rumah besok
status,cek status pesanan
complaint,baju saya rusak
human,sambungkan ke cs
```

6.5.2 Understanding a message

Listing 6.1 contains everything that turns a message into structured information: the language, the rules, the classifier and the slot values.

Listing 6.1 `nlu.py`: language detection, normalization, rules, the intent classifier and slot extraction.

```

    """Every service the message names, in the order of SERVICE_WORDS."""
    t = text.lower()
    found = []
    for pattern, sid in SERVICE_WORDS:
        if re.search(pattern, t):
            found.append(sid)
            t = re.sub(pattern, " ", t)        # 'bed cover' is not also 'cover'
    return found

def extract(text):
    """Pull slot values out of one message."""
    t = text.lower()
    found = {}
    services = services_in(text)
    if services:
        found["service"] = services[0]
    m = re.search(r"(\d+(?:[.,]\d+)?)\s*(kg|kilo|pcs|potong|buah|pasang|pairs?"
                  r"|items?|pieces?)\b", t)
    if m:
        found["amount"] = float(m.group(1).replace(",", "."))
    m = re.search(r"\b(jl\.?|jalan)\s.*", t)     # from 'Jl.' to the end
    if m:
        found["address"] = text[m.start():].strip(" .!?")
    day = re.search(r"\b(besok|tomorrow|hari ini|today|lusa|sore ini|"
                    r"this (?:morning|afternoon|evening))\b", t)
    clock = re.search(r"\b(?:jam|pukul|at)\s*\d{1,2}(?:[.:]\d{2})?|"
                      r"\b\d{1,2}[.:]\d{2}\b", t)
    if day or clock:
        found["time"] = " ".join(m.group(0) for m in (day, clock) if m)
    return found
```

`language` implements Equation (6.4) with two sets of common words; `sum(w in ID_WORDS for w in words)` counts how many words are in the Indonesian set, because `True` counts as 1. `normalize` replaces chat spellings with the dictionary `SLANG`. `RULES` is a list of (pattern, intent) pairs. The first pattern, `\bB\d{4}\b`, is a *regular expression* that matches a capital B followed by exactly four digits, as a whole word: `\b` marks a word boundary and `\d{4}` four digits [5]. The other two match lists of words separated by `|`, which means "or".

`train_classifier` builds a two-step pipeline, as in Chapter 2: `TfidfVectorizer` with `analyzer="char_wb"` and `ngram_range=(2, 4)` produces the pieces of Section 6.3.1 and the weights of Equation (6.1) (`sublinear_tf=True` selects the logarithm), and `LogisticRegression` learns the weights of Equation (6.2) [4].

`services_in` finds every service a message mentions, using the patterns in `SERVICE_WORDS`, which run from specific to general: "setrika saja" (ironing only) must be tested before "cuci" (wash), and "bed cover" before anything else that might match "cover". After a match, the matched words are blanked out so that they cannot match again. `extract` fills the four slots. The amount pattern accepts a number with a unit such as `kg`, `buah` or `pairs`; the address is everything from "Jl." or

"Jalan" to the end of the message; the time combines a day word ("besok", "tomorrow") and a clock time ("jam 9", "10.30") when either is present.

6.5.3 The dialog

Listing 6.2 holds the business knowledge and the conversation logic.

Listing 6.2 `bot.py`: the business data, the answers in two languages, and the dialog with forms and handoff.

```

The three data files are read once into dictionaries keyed by id, so `BILLS["B2815"]` is an order. `rupiah` writes amounts the Indonesian way, with dots between thousands: it formats with commas and swaps them. `TEXT` holds every fixed answer in both languages; keeping all wording in one place makes it easy for the owner to change the tone without touching the logic.

A *session* is a small dictionary that remembers one conversation: its language, the open form and its slots, the number of consecutive fallbacks, whether it has been handed over, and a log of every message. `Bot.reply` follows **Pseudocode 6.1** line by line. `_handoff` marks the session, stores a *ticket* with the reason and the whole conversation, and tells the customer when a person will answer. `_fill` is the form: it merges the new slot values into the session, asks for the first missing one in the order of `SLOTS`, and when all four are known computes the price and confirms. `_status` looks up an order and phrases its three possible states; `_price` quotes one or more services and, when exactly one service and an amount are given, the total.

6.5.4 The application

Listing 6.3 lets you chat with the bot in the terminal, or replay the demo conversations, and saves the handoff tickets for the staff.

Listing 6.3 `chatbot.py`: chatting in the terminal, replaying demo conversations and saving handoff tickets.

```
"""Chat with the Profitina Laundry bot in the terminal.

python chatbot.py            type messages; an empty line ends the chat
python chatbot.py --demo     replay the conversations in data/demo.txt
"""
import csv
import sys
from pathlib import Path

from bot import Bot

HERE = Path(__file__).parent

def save_tickets(bot):
    out = HERE / "out"
    out.mkdir(exist_ok=True)
    with open(out / "handoff.csv", "w", newline="", encoding="utf-8") as f:
        w = csv.DictWriter(f, fieldnames=["reason", "lang", "conversation"])
        w.writeheader()
        w.writerows(bot.tickets)
    print(f"\n{len(bot.tickets)} conversation(s) handed to staff: out/handoff.csv")

def demo(bot):
    text = (HERE / "data/demo.txt").read_text(encoding="utf-8")
    blocks = [b for b in text.split("\n\n") if b.strip()]
    for n, block in enumerate(blocks, 1):
        print(f"--- conversation {n} ---")
        session = bot.new_session()
        for line in block.splitlines():
            if line.startswith("#") or not line.strip():
                continue
            print("customer:", line)
            answer = bot.reply(session, line)
            print("bot     :", answer.replace("\n", "\n          "))

def chat(bot):
    session = bot.new_session()
    while (line := input("you: ").strip()):
        print("bot:", bot.reply(session, line))
```

Listing 6.3 (Continued) *chatbot.py: chatting in the terminal, replaying demo conversations and saving handoff tickets.*

```
if __name__ == "__main__":
    bot = Bot()
    demo(bot) if "--demo" in sys.argv else chat(bot)
    save_tickets(bot)
```

The loop in `chat` uses the *walrus operator* `:=`, which assigns and tests in one expression: it keeps reading lines until an empty one. The tickets go to `out/handoff.csv`, one line per conversation that needs a person, with the reason and the full history, so that the staff member who takes over does not have to ask the customer to repeat everything.

6.6 Running It

Run `python chatbot.py --demo`.

```
--- conversation 1 ---
customer: halo kak
bot     : Halo! Ini asisten Profitina Laundry. Saya bisa membantu soal harga, jam buka,
antar jemput, dan status pesanan.
customer: berapa harga cuci kiloan 5 kg?
bot     : Wash, dry & fold (per kg): Rp 8.000; 5 x = Rp 40.000
customer: bisa jemput cucian?
bot     : Layanan apa yang Kakak inginkan (mis. cuci lipat, setrika saja, bed cover,
sepatu)?
customer: cuci setrika 6 kg
bot     : Alamat penjemputannya di mana (nama jalan dan nomor)?
customer: di Jl. Kenari Raya No. 5
bot     : Kapan kami datang (mis. besok jam 9)?
customer: besok jam 9 pagi
bot     : Penjemputan tercatat: Wash, dry & fold (per kg), 6 x Rp 8.000 = sekitar Rp
48.000, di Jl. Kenari Raya No. 5, besok jam 9. Sampai jumpa!
customer: makasih
bot     : Sama-sama, Kak! Semoga harinya menyenangkan.
--- conversation 2 ---
customer: Hi, is my laundry B2815 ready?
bot     : Order B2815 is ready for collection at Profitina Laundry Keputih since 2026-09-
17.
customer: And what time do you close?
bot     : All our outlets are open every day, 07.00-21.00, public holidays included.
customer: thanks!
bot     : You're welcome! Have a nice day.
--- conversation 3 ---
customer: Good morning, how much to clean a bed cover and 2 pairs of shoes?
bot     : Bed cover, any size (per item): Rp 35.000
          Shoes deep clean (per pair): Rp 45.000
customer: My jacket came back damaged and I am really disappointed
bot     : I'm passing this to our staff now. A person will reply here within 15 minutes
(07.00-21.00).
--- conversation 4 ---
customer: zxcv qwerty
bot     : Maaf, saya belum paham. Kakak bisa bertanya soal harga, jam buka, antar jemput,
atau nomor nota (mis. B2815).
customer: bla bla
bot     : Saya teruskan ke staf kami sekarang. Petugas akan membalas di sini dalam 15 menit
(pukul 07.00-21.00).

2 conversation(s) handed to staff: out/handoff.csv
```

The first conversation is in Indonesian from start to finish. The price question names the service and the amount, so the bot quotes the total. “bisa jemput cucian?” opens the pickup form; since the message does not name a service, the bot asks for it, and “cuci setrika 6 kg” fills two slots at once, service and amount. The address and the time follow, and the confirmation computes 6 × Rp 8.000 = Rp 48.000. (The service names come from the laundry’s database, which stores them in English.)

The second conversation is in English. The order number triggers the rule, and the bot reads order B2815 from the database: finished on 17 September 2026 at the Keputih outlet and not yet collected. The third shows two services in one question, answered with both prices, and then a complaint: the word “damaged” matches a rule, and the conversation goes straight to a person. The fourth shows the fallback: two messages the bot cannot understand, and after the second one it hands over rather than guessing. Both handed-over conversations are in `out/handoff.csv`.

6.7 Measuring It

A chatbot must be tested on messages written *after* it was trained, by people who did not look at the training examples. **Listing 6.4** runs the 44 test messages through the rules and the classifier.

Listing 6.4 `lab.py`: intent accuracy on the test messages and the effect of the threshold.

```
"""How well does the bot understand messages it was not trained on?"""
import csv
from pathlib import Path

from bot import Bot

HERE = Path(__file__).parent

def main():
    with open(HERE / "data/test.csv", encoding="utf-8") as f:
        tests = list(csv.DictReader(f))
    bot = Bot()
    rows = [(t["intent"], *bot.intent(t["text"]), t["text"]) for t in tests]
    n = len(rows)
    right = sum(truth == guess for truth, guess, *_ in rows)
    print(f"{n} test messages, intent right for {right} ({right / n:.0%})")
    by_rule = [r for r in rows if r[3] == "rule"]
    print(f"decided by a rule: {len(by_rule)}, "
          f"right {sum(r[0] == r[1] for r in by_rule)}")

    print("\nthreshold  answered  wrong  asked again")
    for th in [0.2, 0.3, 0.35, 0.4, 0.5]:
        answered = [r for r in rows if r[3] == "rule" or r[2] >= th]
        wrong = sum(r[0] != r[1] for r in answered)
        print(f"   {th:.2f}      {len(answered):3d}     {wrong:3d}     "
              f"{n - len(answered):3d}")

    print("\nmistakes and low-confidence answers at threshold 0.35:")
    for truth, guess, conf, how, text in rows:
        if truth != guess or (how == "model" and conf < 0.35):
            print(f"  {text:<42} true {truth:<9} said {guess:<9} {conf:.2f}")

if __name__ == "__main__":
    main()
```

```
44 test messages, intent right for 38 (86%)
decided by a rule: 5, right 5

threshold  answered  wrong  asked again
   0.20       44       6        0
   0.30       36       0        8
   0.35       34       0       10
   0.40       29       0       15
   0.50       23       0       21

mistakes and low-confidence answers at threshold 0.35:
  is the laundry open on public holidays     true hours     said hours     0.32
  where are you located                      true location  said hours     0.27
  laundrynya di jalan apa                    true location  said location  0.30
  what are your prices                       true prices    said location  0.23
  do you iron clothes only                   true services  said complaint 0.26
  can you wash a kebaya                      true services  said payment   0.27
  bisa ambil cucian sore ini                 true pickup    said status    0.24
  do you take credit cards                   true payment   said services  0.24
  my shirt has a stain now                   true complaint said complaint 0.30
  baju saya jadi kusut dan kotor             true complaint said complaint 0.34
```

The best intent is right for 38 of the 44 messages, 86 percent, and the five messages decided by rules are all right. The threshold table is the important part, and **Figure 6.2** draws it. Without a threshold (0.20 lets everything through) the bot would answer all 44 messages and give 6 wrong answers: telling a customer who asks “what are your prices” where the outlets are, or treating “do

you iron clothes only" as a complaint. With $\theta = 0.30$ or higher, every wrong answer is caught: all six mistakes had a probability below 0.30. At 0.35 the bot answers 34 messages, all correctly, and asks again about 10: by Equation (6.5) an answer rate of 77 percent with an error rate of zero. Higher thresholds only ask more.

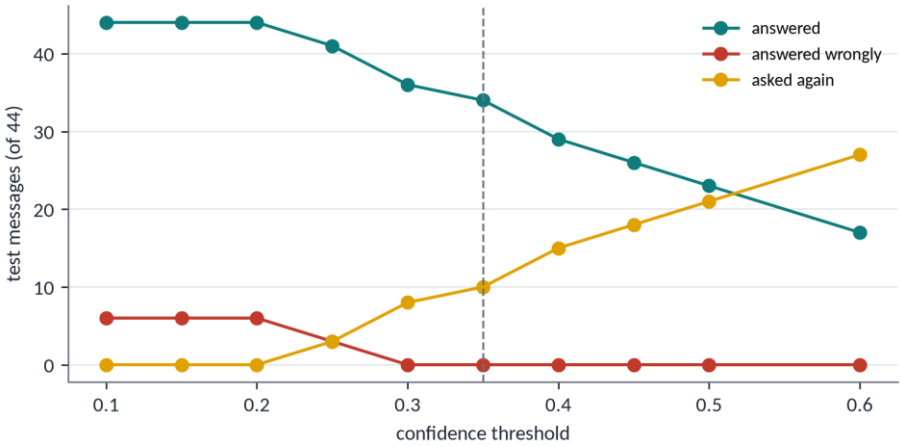

Figure 6.2 Answers, wrong answers and follow-up questions on the 44 test messages as the confidence threshold rises; from 0.30 on no wrong answer gets through.

The list of mistakes and low-confidence answers is a to-do list for the owner. "Where are you located" and "what are your prices" are ordinary questions that the training examples phrase differently; "can you wash a kebaya" was confused with payment. Each of them can be fixed by adding two or three examples to `intents.csv`, which is how real chatbots improve: by reading the conversations they failed.

6.8 Testing It

Listing 6.5 checks the parts that must never break: language detection, slang, slot extraction, the rules, order lookup, a complete pickup form and the handoff.

Listing 6.5 `test_bot.py`: tests for understanding, the pickup form, order status and handoff.

```
"""Tests for the laundry chatbot. Run: python -m unittest -v"""
import unittest

from bot import Bot
from nlu import extract, language, normalize

BOT = Bot()                                    # train once for all tests

class BotTests(unittest.TestCase):
    def test_language_and_slang(self):
        self.assertEqual(language("berapa harga cuci kiloan"), "id")
        self.assertEqual(language("how much is it"), "en")
        self.assertEqual(normalize("Brp kak, gak mahal?"), "berapa kak tidak mahal")

    def test_extract(self):
        self.assertEqual(extract("cuci setrika 6 kg")["amount"], 6)
        self.assertEqual(extract("bed cover 2 buah")["service"], "S0008")
        self.assertEqual(extract("di Jl. Kenari Raya No. 5.")["address"],
                         "Jl. Kenari Raya No. 5")
        self.assertEqual(extract("besok jam 9")["time"], "besok jam 9")

    def test_rules_win(self):
        self.assertEqual(BOT.intent("status B2815?")[2], "rule")
        self.assertEqual(BOT.intent("baju saya rusak")[0], "complaint")

    def test_status(self):
        s = BOT.new_session()
        self.assertIn("B2815", BOT.reply(s, "is order B2815 ready?"))
        self.assertIn("tidak ditemukan", BOT.reply(s, "cek nota B9999 kak"))

    def test_pickup_form(self):
        s = BOT.new_session()
        BOT.reply(s, "bisa jemput cucian?")
        self.assertEqual(s["form"], "pickup")
        BOT.reply(s, "cuci lipat 4 kg")
        BOT.reply(s, "Jalan Mawar 3")
        answer = BOT.reply(s, "besok jam 10")
        self.assertIsNone(s["form"])
        self.assertIn("Rp 32.000", answer)             # 4 kg x Rp 8.000
```

Listing 6.5 (Continued) *test_bot.py: tests for understanding, the pickup form, order status and handoff.*

```
    def test_handoff_after_two_fallbacks(self):
        s = BOT.new_session()
        before = len(BOT.tickets)
        BOT.reply(s, "zxcv qwerty")
        BOT.reply(s, "bla bla")
        self.assertTrue(s["handed_off"])
        self.assertEqual(len(BOT.tickets), before + 1)

if __name__ == "__main__":
    unittest.main()
```

The pickup test plays a whole form: after “bisa jemput cucian?” the form is open; “cuci lipat 4 kg” gives service and amount, “Jalan Mawar 3” the address, and “besok jam 10” the time; then the form is closed and the confirmation contains Rp 32.000, which is 4 × Rp 8.000. The handoff test checks that two unintelligible messages create exactly one new ticket.

```

----------------------------------------------------------------------
Ran 6 tests in 0.029s

OK
```

6.9 Improving It

More examples from real chats. The fastest improvement is data. Export a month of real chats (without names and phone numbers), label the customer messages with intents, and add them to `intents.csv`. Rerun `lab.py` each time to see the effect.

Remember the customer. With a phone number the bot could greet returning customers by name and look up their latest order without asking for the number. That requires the customer database and, therefore, care about personal data.

Cancel and correct. A customer who writes “eh, jangan besok, lusa saja” (not tomorrow, the day after) wants to change a slot. A *correction* intent that overwrites a slot, and a *cancel* intent that closes the form, make the dialog more natural.

Confirm before booking. Real bookings should end with “Is this correct? (ya/tidak)” before being saved. That is one more state in the form.

A language model. Part 9 of this book connects chatbots to large language models, which understand far more varied phrasing. The structure of this chapter stays useful even then: rules for what must never go wrong, data lookups for facts, and a person for everything sensitive.

6.10 Using It for Real

Put it where the customers are. The function `Bot.reply(session, text)` is the whole interface. To connect it to WhatsApp, a business registers for the WhatsApp Business Platform (Cloud API); Meta then sends each incoming message to a web address of the business as a small JSON document, and the business answers by calling Meta’s API with the reply text [6]. A web framework such as Flask or FastAPI (Chapters 91 and 92) receives the message, keeps one session per phone number, calls `reply`, and sends the answer back. The same function serves a web chat widget or a Telegram bot.

Keep the human in the loop. Decide who receives the handoff tickets and how fast they must answer, and say it honestly in the handoff message. A bot that promises “a person will reply within 15 minutes” must be backed by a person who does.

Use your own data. Replace the three business files with your services, outlets and orders, rewrite `TEXT` in your own voice, and write intents and examples for the questions your customers actually ask. Start with ten intents at most.

Sessions and business hours. A session should end after some quiet time, for example 30 minutes, so that a customer who returns tomorrow starts fresh. Outside opening hours, the

handoff message must say honestly when a person will read it ("tomorrow from 07.00"), and urgent matters, such as a lost item, can be flagged for the first person on duty.

Protect personal data. Chat logs contain names, addresses and phone numbers. Under Indonesia's Personal Data Protection Law (UU PDP) [7], keep them only as long as needed, restrict who can read them, and do not send them to services you have not assessed.

Measure after launch. Count every week how many conversations were handed over, and why. A rising number of fallbacks means customers ask something new: add an intent. A rising number of complaints is not a chatbot problem; show it to the owner.

6.11 Common Mistakes, and How to Avoid Them

Letting the bot guess. Without a threshold, the classifier always returns *some* intent, and a customer asking about prices is told the opening hours. Use Equation (6.3) and a polite fallback.

No way out. A bot that keeps saying "I didn't understand" drives customers away. Hand over after two failures, and at once for complaints and explicit requests for a person.

Testing on the training examples. The bot answers its own examples perfectly. Keep a separate test set written by someone else, as `test.csv` is.

Rules in the wrong order. Rules are checked in order; a general pattern placed before a specific one wins. That is why `SERVICE_WORDS` goes from specific to general, and why complaint rules come before the classifier.

Losing the form. If every message is classified afresh, the answer to "what is the address?" may be classified as *location* and answered with the outlet list. While a form is open, messages go to the form unless they are clearly a complaint, a request for a person or a goodbye, as in line 6 of **Pseudocode 6.1**.

One language only. Indonesian customers switch languages and write informally. Test with real spellings ("gak", "brp", "kak") and in both languages.

6.12 Chapter Summary

- A business chatbot recognizes intents with a classifier trained on example sentences, here character n-grams weighted by TF-IDF (Equation (6.1)) and multinomial logistic regression (Equation (6.2)).
- Rules come first for cases where a mistake is costly (order numbers, complaints, requests for a person); the classifier handles the rest.
- A confidence threshold (Equation (6.3)) turns uncertainty into a follow-up question; on 44 unseen messages, $\theta = 0.35$ let no wrong answer through while answering 34.
- Slot filling collects the details of a request one question at a time, keeping what the customer already said.
- A good chatbot knows its limits: it answers in the customer's language (Equation (6.4)) and hands complaints and repeated misunderstandings to a person, with the full conversation.

6.13 Exercises

1. List the character pieces of length 2 to 4 that the classifier makes from the word "buka".

2. Three intents have scores 2.0, 1.0 and 0.0 and there are no others. Compute their probabilities with Equation (6.2). Would the best intent pass the threshold of 0.35?
3. Which language does Equation (6.4) choose for "kak is my laundry ready?" and for "ok"? Explain with the word lists in `nlu.py`.
4. Write a rule so that any message containing "refund" or "uang kembali" (money back) is handed to a person, and test it.
5. Add two training examples so that "where are you located" is recognized as *location*, and rerun `lab.py`.
6. Why does the bot not simply lower the threshold to 0.20 to answer more messages? Use the numbers of Section 6.7.

6.14 Solutions to the Exercises

1. With the padding spaces, " buka " gives the 2-pieces ' b', 'bu', 'uk', 'ka', 'a'; the 3-pieces ' bu', 'buk', 'uka', 'ka'; and the 4-pieces ' buk', 'buka', 'uka': twelve in all, the same count as for "halo" because both words have four letters.

2. $e^2 = 7.389$, $e^1 = 2.718$, $e^0 = 1$; the sum is 11.107. The probabilities are $7.389/11.107 = 0.665$, $2.718/11.107 = 0.245$ and $1/11.107 = 0.090$, which add up to 1. The best intent has 0.665 and passes the threshold of 0.35.

3. "kak is my laundry ready?" contains *kak* (Indonesian list) and *is* and *my* (English list), so $I = 1$ and $E = 2$: English. It is a reasonable choice, since most of the sentence is English. "ok" has one word, so line 3 of **Pseudocode 6.1** keeps the language the conversation already has; if it is the first message, the session starts in Indonesian.

4. The complaint rule already contains `refund`. For "uang kembali", add it to the complaint pattern, for example `r"\b(rusak|hilang|luntur|kecewa|refund|uang kembali|damaged|missing|ruined)\b"`. Then `BOT.intent("saya minta uang kembali")` returns `("complaint", 1.0, "rule")`, and `reply` hands the conversation over. A test: `self.assertEqual(BOT.intent("minta uang kembali")[0], "complaint")`.

5. Adding the test sentence itself would be cheating, so add related phrasings instead, for example the two lines `location,where are you` and `location,what is your location`. `lab.py` then reports 39 of 44 right (89 percent), and "where are you located" is recognized. But the table also shows a new problem: at the threshold of 0.35 one wrong answer now gets through, because "what are your prices" is now taken for *location* with probability 0.48; the new examples taught the classifier that "what is your …" means location. Adding one more prices example, `prices,what are the prices`, repairs it: 40 of 44 right and no wrong answer from 0.30 on. Two lessons follow. Every new example shifts the weights of *all* intents, so always rerun the whole test. And each time we look at the test set to decide what to add, it becomes a little less of an honest test; for a final measurement, collect a fresh set of messages.

6. At 0.20 the bot answers all 44 test messages but 6 of the answers are wrong; at 0.35 it answers 34, all correctly, and asks 10 customers to rephrase or passes them on. A wrong answer misleads a customer who then acts on it (goes to the wrong outlet, expects a wrong price), while a follow-up question costs a few seconds. For a business, 10 polite questions are much cheaper than 6 wrong answers.

Chapter 7

A Rule-Based Expert System: The Laundry-Stain Advisor

An experienced laundry worker can look at a stain, ask the customer two or three questions, and say at once how to treat it and, just as important, what must never be done to it. That knowledge is valuable, it lives in a few people's heads, and it walks out of the door when they go home. In this chapter we capture it in a program: an *expert system* for the counter of a laundry, which asks about the color of a stain, where it probably came from, whether it feels greasy, what the fabric is and how old the stain is, and then recommends a treatment, gives warnings, and explains its reasoning. By the end of the chapter you will be able to write knowledge as IF-THEN rules in a small rule language, build an inference engine that reasons forward from facts and backward from goals, attach *certainty factors* to rules and combine them the way the famous MYCIN system did, make the program explain *why* it asks a question and *how* it reached a conclusion, and evaluate a knowledge base on recorded cases.

7.1 Knowledge Behind the Counter

Picture the counter of Profitina Laundry on a Monday morning. A customer puts down a white cotton shirt with a brown mark on the collar. "Coffee, I think. From last week." A new employee might throw it in the machine with hot water and chlorine bleach; an old hand knows better. Coffee comes out with cool water and detergent, an old coffee stain may need an oxygen-bleach soak, and hot water is the enemy of other stains, such as blood, because heat sets protein into the fibers. For silk or wool, the old hand would not treat the stain at all, but would send the garment to professional dry cleaning.

In the 1970s and 1980s, programs that captured such expertise were the great commercial success of artificial intelligence. MYCIN, built at Stanford, diagnosed bacterial blood infections and recommended antibiotics about as well as the specialists it was tested against [1]. XCON configured computer orders for Digital Equipment Corporation. These *expert systems* had a simple architecture: a *knowledge base* of rules written with the help of human experts, and an *inference engine* that applied the rules to the facts of a case. The engine knew nothing about medicine or computers; all the expertise was in the rules, so the same engine, a *shell*, could be reused for a completely different field.

Expert systems fell out of fashion because writing and maintaining thousands of rules by hand is slow and expensive, a problem known as the *knowledge acquisition bottleneck*, and machine learning, from Part 2 on, learns rules from data instead. But rule-based reasoning never disappeared. It checks tax returns and insurance claims, drives the "if this, then that" of business software and home automation, and increasingly guards the output of language models (Chapter 90). Its great strength is one that learned models still struggle with: every conclusion can be *explained* by pointing to the rules that produced it.

7.2 The Idea in Plain Words

Our advisor knows about ten kinds of stain (blood, coffee or tea, turmeric, sambal, oil, grass, mud, ink, rust and lipstick) and five fabrics. It reasons in three layers, shown in **Figure 7.1**. From the observations, it concludes *what the stain is*. From the fabric, it concludes *how delicate* the garment is. From both, and the stain's age, it concludes a *method* and *warnings*.

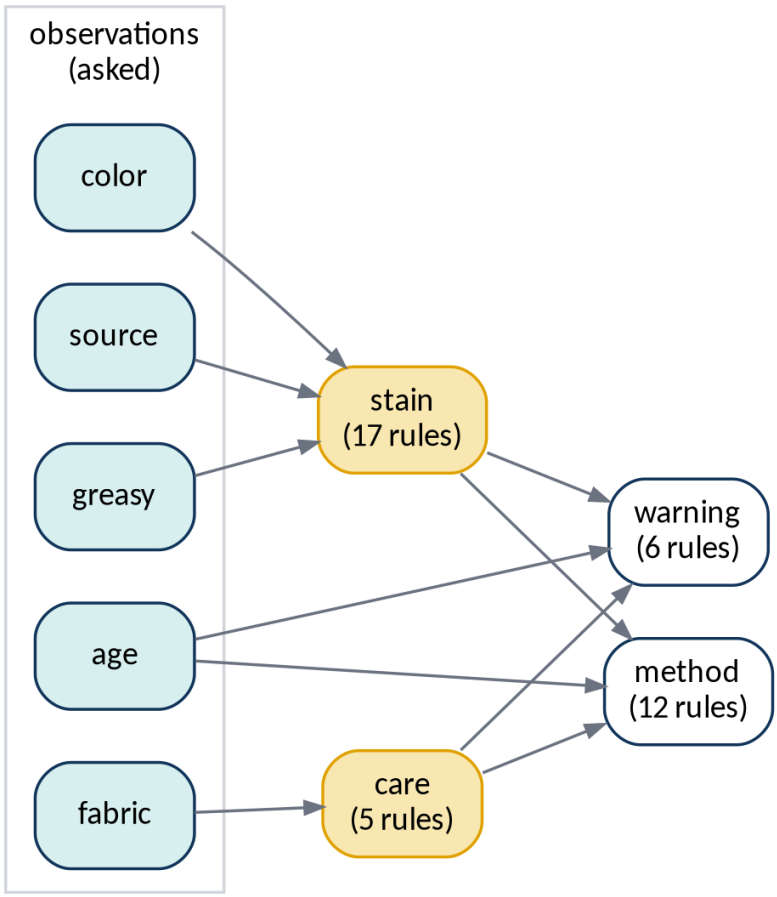

Figure 7.1 The structure of the knowledge base: five observations, asked of the user, lead to two intermediate conclusions (the stain and the care the fabric needs), which lead to methods and warnings.

Each piece of knowledge is a *rule*: "IF the color is brown AND the stain came from a drink AND it is not greasy, THEN it is coffee or tea". Rules can be used in two directions.

Forward chaining starts from the facts and applies every rule whose conditions are met, adding its conclusion as a new fact, and repeats until nothing new appears. It is like a becak driver who notices everything along the road and draws every conclusion he can: "wet road, dark clouds, so rain soon; rain soon, so the market will be empty; empty market, so go to the station instead".

Both directions are classic methods of automated reasoning, treated in depth by Russell and Norvig [2]. *Backward chaining* starts from a question, a *goal*, such as "what method?", and looks for rules that conclude it; their conditions become new goals; and when a goal cannot be concluded by any rule, the program asks the user. It is how a doctor works: to decide on a treatment she needs a diagnosis, to decide on the diagnosis she needs the patient's temperature, so she asks for it. Backward chaining asks *only the questions it needs*, in a natural order, which makes it the right choice for a conversation at a counter.

Real observations are rarely certain. The customer "thinks" it was coffee; the color is "sort of brown". So every rule carries a *certainty factor* (CF), a number up to 1 that says how strongly its

conditions support its conclusion, and the user may add a certainty to an answer. The engine then computes how certain each conclusion is.

7.3 The Math, Gently

7.3.1 Rules and certainty factors

A rule has the form

$$\text{IF } E_1 \wedge E_2 \wedge \cdots \wedge E_k \text{ THEN } H \quad \text{with } \mathrm{CF}_{\text{rule}} \tag{7.1}$$

where each E_i is a condition such as "color is brown", the symbol $\wedge$ means AND, H is the conclusion, and $\mathrm{CF}_{\text{rule}}$ is a number between 0 and 1. The certainty factors of MYCIN range from -1 (definitely false) through 0 (no evidence either way) to $+1$ (definitely true) [3]; our rules only give positive evidence, but the combination formula below handles negative evidence too.

Conditions joined by AND. A chain is as strong as its weakest link. The certainty of all conditions together is the smallest of their certainties:

$$\mathrm{CF}(E_1 \wedge \cdots \wedge E_k) = \min_i \mathrm{CF}(E_i) \tag{7.2}$$

Applying a rule. If the conditions hold with certainty $\mathrm{CF}(E)$, the rule adds evidence for its conclusion of

$$\mathrm{CF}(H) = \mathrm{CF}(E) \times \mathrm{CF}_{\text{rule}} \quad \text{if } \mathrm{CF}(E) \geq 0.2 \tag{7.3}$$

and nothing at all if $\mathrm{CF}(E) < 0.2$. The threshold of 0.2 is MYCIN's: very weak evidence is ignored rather than allowed to trigger a long chain of weak conclusions. For the coffee shirt, with all answers certain, rule s3 gives $\mathrm{CF}(\text{coffee-tea}) = 1.0 \times 0.8 = 0.8$.

Two rules, one conclusion. When two rules support the same conclusion, their evidence should add up, but the total must never exceed 1. MYCIN combined two certainty factors a and b like this:

$$\mathrm{combine}(a,b) = \begin{cases} a + b\,(1-a) & a, b \geq 0 \\ a + b\,(1+a) & a, b < 0 \\ \dfrac{a+b}{1-\min(|a|,|b|)} & \text{otherwise} \end{cases} \tag{7.4}$$

Read the first line in words: the second piece of evidence closes a fraction b of the *remaining* doubt $1 - a$. So the combination is always at least as large as either piece, never larger than 1, and the order in which the rules fire does not matter, because $a + b(1-a) = b + a(1-b)$. **Figure 7.2** draws the first line for three values of a.

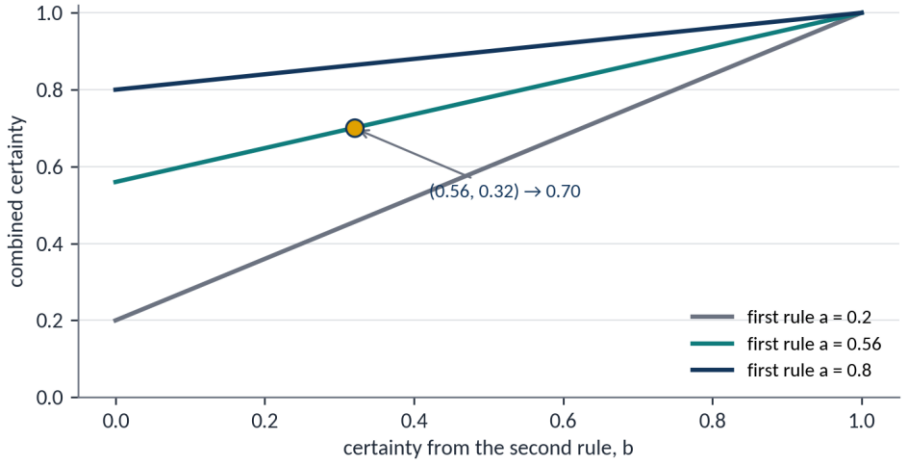

Figure 7.2 MYCIN's combination of two positive certainty factors: whatever the first value, a second piece of evidence only moves the total toward 1, never past it; the marked point is the turmeric example of Section 7.6.

7.3.2 A worked example

A yellow stain on a silk blouse, from food, greasy, fresh; the customer is only fairly sure of the color, so the answer is "yellow" with certainty 0.8. Two rules conclude turmeric:

- s4: IF color is yellow AND source is food THEN stain is turmeric, CF 0.7. By Equation (7.2), the conditions have certainty $\min(0.8,1.0) = 0.8$, and by Equation (7.3) the rule contributes $0.8 \times 0.7 = 0.56$.
- s5: IF color is yellow AND greasy is yes THEN stain is turmeric, CF 0.4. It contributes $\min(0.8,1.0) \times 0.4 = 0.32$.

By Equation (7.4),

$$\begin{aligned}\text{combine}(0.56,0.32) &= 0.56 + 0.32 \times (1 - 0.56) = 0.56 + 0.1408 \\ &= 0.7008\end{aligned} \qquad (7.5)$$

so the stain is turmeric with certainty about 0.70. Silk makes the care "delicate" with certainty 1.0 (rule f1), so rule t12 recommends professional dry cleaning with $\min(1.0) \times 0.9 = 0.9$, rule w4 warns against chlorine with 1.0, and rule w5 warns against hot water with $0.70 \times 0.6 = 0.42$. We will see exactly these numbers in the program's output.

7.3.3 Forward and backward chaining compared

Table 7.1 summarizes the two strategies of Section 7.2. Both use the same rules and the same certainty arithmetic; they differ in which rules they try and when.

Table 7.1 Forward and backward chaining over the same knowledge base.

	Forward chaining	Backward chaining
Starts from	the known facts	a goal (a question to answer)
Tries	every rule whose conditions are met	only rules that conclude the current goal
Asks the user	nothing: all facts must be given	only for facts it needs and cannot conclude
Good for	monitoring, batch processing of recorded cases	consultations, diagnosis
In this chapter	`Engine.forward`, used by the lab	`Engine.backward`, used by the advisor

7.3.4 Forward chaining by hand

Forward chaining on a recorded case shows the order in which conclusions appear. Take case 4 of Section 7.7: a yellow, greasy stain from food on a fresh cotton shirt, all five observations certain. The engine sweeps through the rules from the top of the knowledge base.

- s4 fires: yellow and food give turmeric with $1.0 \times 0.7 = 0.7$.
- s5 fires: yellow and greasy add $1.0 \times 0.4 = 0.4$, and Equation (7.4) makes turmeric $0.7 + 0.4 \times 0.3 = 0.82$.
- f3 fires: cotton makes the care sturdy with 1.0.
- t4 fires: turmeric (0.82) and sturdy (1.0) give the soap-and-sunlight method with $\min(0.82,1.0) \times 0.8 = 0.656$.
- w5 fires: turmeric gives the warning against hot water with $0.82 \times 0.6 = 0.492$.

A second sweep fires nothing new, so the engine stops after five firings, which is the count the lab prints for this case. Notice one subtle point: t4 used the *combined* certainty 0.82 only because s5 appears before t4 in the file. Had t4 come first, it would have fired with 0.7 alone and, since each rule fires only once, never been updated. Section 7.10 returns to this order dependence.

7.3.5 Certainty factors are not probabilities

It is tempting to read "coffee-tea with certainty 0.80" as "an 80 % chance that the stain is coffee or tea". It is not, and the difference matters. Probabilities of the alternatives for one question must add up to 1: if the stain is coffee with probability 0.8, all the other stains together have probability 0.2. Certainty factors obey no such rule. In case 11 of Section 7.7 the lipstick rules gave 0.93 and, had the sambal rules also fired, sambal could have received 0.8 at the same time, a total far above 1. Each CF measures only how much the evidence *supports* one conclusion, independently of the others.

The combination formula also differs from probability. Two independent pieces of evidence that each make a conclusion twice as likely would, by the laws of probability, make it four times as likely, and how much the resulting probability rises depends on how likely the conclusion was to begin with, its *prior*. Equation (7.4) has no prior at all: combine(0.56,0.32) is 0.70 whether the stain is a rare one or the most common stain in the shop. Shortliffe and Buchanan designed certainty factors this way on purpose, because the doctors they worked with could not supply the many probabilities a full probabilistic model needs, but could say how strongly one finding pointed to one disease [3]. Later analysis showed that the CF formulas are exactly correct only under strong independence assumptions that real evidence rarely satisfies, which is one reason why probabilistic methods took over. For a small advisor whose rules come from a laundry worker's experience, certainty factors remain a reasonable and, above all, explainable choice.

7.4 The Algorithm as Pseudocode

Pseudocode 7.1 is the backward-chaining procedure. It is recursive: to establish a goal it establishes the conditions of the rules that conclude it, and at the bottom of the recursion it asks.

Pseudocode 7.1 Backward chaining with certainty factors: conditions are established on demand, and the user is asked only when no rule can conclude a fact.

```
BACKWARD(goal)
1  if goal already has values: return
2  rules = the rules whose conclusion is about goal
3  if rules is empty
4      ask the user for goal (value and certainty); store it; return
5  for each rule in rules
6      for each condition (a is v) of rule, left to right
7          BACKWARD(a)
8          if CF(a is v) < 0.2: skip to the next rule    // cannot fire
9      if every condition held
10         add CF(E) × CF(rule) to the rule's conclusion, combining
```

Line 8 is what keeps the questioning short: as soon as one condition of a rule fails, the remaining conditions of that rule are not pursued, so their questions are never asked on its behalf.

7.5 Building the Advisor Step by Step

7.5.1 The knowledge base

The knowledge lives in a plain text file, written in a tiny rule language that a laundry expert could read and edit without knowing Python. **Listing 7.1** is the whole knowledge base: 40 rules.

Listing 7.1 `kb.txt`: the knowledge base of the stain advisor, 17 rules to identify the stain, 5 about fabrics, 12 methods and 6 warnings.

```
# Laundry-stain advisor: knowledge base.
# RULE name: IF attribute is value [AND ...] THEN attribute is value CF number

# --- 1. What is the stain? ------------------------------------------------
RULE s1: IF color is red AND source is injury
    THEN stain is blood CF 0.9
RULE s2: IF color is brown AND source is injury
    THEN stain is blood CF 0.7
RULE s3: IF color is brown AND source is drink AND greasy is no
    THEN stain is coffee-tea CF 0.8
RULE s4: IF color is yellow AND source is food
    THEN stain is turmeric CF 0.7
RULE s5: IF color is yellow AND greasy is yes
    THEN stain is turmeric CF 0.4
RULE s6: IF color is red AND source is food AND greasy is yes
    THEN stain is sambal CF 0.8
RULE s7: IF color is red AND source is food AND greasy is no
    THEN stain is sambal CF 0.4
RULE s8: IF greasy is yes AND color is grey
    THEN stain is oil CF 0.8
RULE s9: IF greasy is yes AND source is food AND color is brown
    THEN stain is oil CF 0.6
RULE s10: IF color is green AND source is outdoor
    THEN stain is grass CF 0.9
RULE s11: IF color is brown AND source is outdoor AND greasy is no
    THEN stain is mud CF 0.7
RULE s12: IF color is blue AND source is office
    THEN stain is ink CF 0.9
RULE s13: IF color is black AND source is office
    THEN stain is ink CF 0.7
RULE s14: IF color is orange AND source is metal
    THEN stain is rust CF 0.9
RULE s15: IF color is brown AND source is metal
    THEN stain is rust CF 0.7
RULE s16: IF color is red AND source is makeup
    THEN stain is lipstick CF 0.9
RULE s17: IF color is red AND greasy is yes
    THEN stain is lipstick CF 0.3
```

Listing 7.1 (Continued) *kb.txt: the knowledge base of the stain advisor, 17 rules to identify the stain, 5 about fabrics, 12 methods and 6 warnings.*

```
# --- 2. How delicate is the fabric? ----------------------------------------
RULE f1: IF fabric is silk
    THEN care is delicate CF 1.0
RULE f2: IF fabric is wool
    THEN care is delicate CF 1.0
RULE f3: IF fabric is cotton
    THEN care is sturdy CF 1.0
RULE f4: IF fabric is polyester
    THEN care is sturdy CF 1.0
RULE f5: IF fabric is denim
    THEN care is sturdy CF 1.0

# --- 3. What should be done? -----------------------------------------------
RULE t1: IF stain is blood AND care is sturdy
    THEN method is cold-enzyme CF 0.9
RULE t2: IF stain is coffee-tea AND care is sturdy
    THEN method is rinse-detergent CF 0.8
RULE t3: IF stain is coffee-tea AND age is old AND care is sturdy
    THEN method is oxygen-soak CF 0.7
RULE t4: IF stain is turmeric AND care is sturdy
    THEN method is soap-sunlight CF 0.8
RULE t5: IF stain is sambal AND care is sturdy
    THEN method is degrease-then-soap CF 0.8
RULE t6: IF stain is oil AND care is sturdy
    THEN method is degrease-hot CF 0.8
RULE t7: IF stain is lipstick AND care is sturdy
    THEN method is degrease-then-soap CF 0.7
RULE t8: IF stain is grass AND care is sturdy
    THEN method is cold-enzyme CF 0.8
RULE t9: IF stain is mud AND care is sturdy
    THEN method is dry-brush-wash CF 0.8
RULE t10: IF stain is ink AND care is sturdy
    THEN method is alcohol-dab CF 0.8
RULE t11: IF stain is rust AND care is sturdy
    THEN method is acid-rust CF 0.8
RULE t12: IF care is delicate
    THEN method is professional-dry-clean CF 0.9
```

Listing 7.1 (Continued) *kb.txt: the knowledge base of the stain advisor, 17 rules to identify the stain, 5 about fabrics, 12 methods and 6 warnings.*

```
# --- 4. What must not be done? ---------------------------------------------
RULE w1: IF stain is blood
    THEN warning is no-hot-water CF 1.0
RULE w2: IF stain is grass
    THEN warning is no-hot-water CF 0.8
RULE w3: IF stain is rust
    THEN warning is no-chlorine CF 1.0
RULE w4: IF care is delicate
    THEN warning is no-chlorine CF 1.0
RULE w5: IF stain is turmeric
    THEN warning is no-hot-water CF 0.6
RULE w6: IF age is old
    THEN warning is test-hidden-spot CF 0.8
```

Each rule has a name, conditions joined by AND, a conclusion and a certainty factor; the THEN part continues on an indented second line, which keeps every line short. Lines starting with `#` are comments. The advice about treatments follows common laundry practice and the stain-removal guide of the American Cleaning Institute, which, for example, warns that hot water sets blood and that chlorine bleach can intensify rust stains [4].

Two more data files complete the knowledge. `questions.json` holds, for each of the five observations, the question in English and Indonesian and the allowed answers in both languages; `advice.json` holds, for each method and warning, the advice text in both languages. They are in the chapter's code folder; keeping all text out of the program is what makes the advisor bilingual.

7.5.2 The inference engine

Listing 7.2 is the shell: it knows nothing about laundry.

Listing 7.2 `engine.py`: the rule parser, MYCIN's combination, forward chaining, backward chaining and the "how" explanation.

```
"""A small expert-system shell: rules with certainty factors, forward and
backward chaining, and explanations of 'why' and 'how'."""
import re
from dataclasses import dataclass

                lines.append(f"{rule.name}: {prem} (certainty {strength:.2f}) "
                             f"-> {attr} is {value} with {added:.2f}")
        return lines
```

Rules as data. `Rule` is a *dataclass*: the decorator `@dataclass` writes the constructor and a readable printed form for us from the annotated fields [5]. A rule's premises are a list of `(attribute, value)` pairs.

Parsing. `load_rules` first joins all non-comment lines into one long string, which makes the indented continuation lines disappear, and then finds every rule with the regular expression `RULE_RE`, reusing the skills of Chapter 6. The non-greedy `(.+?)` captures the conditions up to the word THEN; `PREMISE_RE.findall` then splits them into pairs. Values may contain hyphens, as in `coffee-tea`, hence `[\w-]+`.

Certainty arithmetic. `combine` is Equation (7.4), line for line. `premise_strength` is Equation (7.2), and `fire` is Equation (7.3): it refuses to fire below `THRESHOLD`, otherwise it adds the evidence with `add`, which combines it with any evidence already present for the same conclusion, and records the firing in `self.fired` for later explanation. Facts are stored as a dictionary of dictionaries, `facts[attribute][value] = cf`, so that an attribute can have several candidate values with different certainties, such as two possible stains.

Forward chaining. `forward` sweeps through the rules repeatedly, firing each rule at most once, until a full sweep fires nothing new. Each rule is fired only once because firing it twice would count the same evidence twice in Equation (7.4).

Backward chaining. `backward` follows **Pseudocode 7.1**. It marks the goal as "being established" by storing an empty dictionary before it recurses, which prevents it from asking about the same

attribute twice. The `for … else` construction of Python is exactly what line 9 of the pseudocode needs: the `else` block of a `for` loop runs only if the loop was not left with `break`, that is, only if no condition failed. The parameter `why` carries the chain of rules that led to the current question, so the user interface can answer "why?".

Explanations. `best` returns the most certain value of an attribute, and `how` lists, for a conclusion, every fired rule that supported it, with the strength of its conditions and the certainty it added.

7.5.3 The consultation

Listing 7.3 is the program the laundry worker uses.

Listing 7.3 `advisor.py`: the question-and-answer consultation with "why" explanations, advice in English or Indonesian, and a "how" explanation at the end.

```
"""Laundry-stain advisor: asks questions, reasons backwards, explains.

usage: python advisor.py [en|id]     answer with a value, optionally followed
by a certainty from 0 to 1 ("brown 0.6"); type 'why' to see the reason.

    print(f"\n{t['stain']}: {stain} ({t['cf']} {cf:.2f})" if stain
          else f"\n{t['stain']}: {t['none']}")
    for goal in ("method", "warning"):
        for value, c in sorted(engine.facts.get(goal, {}).items(),
                               key=lambda kv: -kv[1]):
            if c >= 0.2:
                print(f"{t[goal]} ({c:.2f}): {advice[value][lang]}")
    print(f"\n{t['how']}")
    for line in engine.how("stain", stain) if stain else []:
        print("  " + line)

if __name__ == "__main__":
    main()
```

`make_ask` builds the function that `Engine.backward` calls whenever it needs an observation. It is a *closure*: the inner function `ask` remembers `questions` and `lang` from the call that created it, so the engine never has to know about languages. The inner dictionary `to_value` maps what the user types in the chosen language (“kuning”) to the value the rules use (“yellow”). If the user types `why`, the function prints the rule that is currently being tried, which is the last element of `why`, and asks again. An answer may be followed by a certainty, “brown 0.6”, which is clamped to the range 0 to 1.

`main` asks the engine to establish two goals, the method and the warnings, then prints the most likely stain, every method and warning with certainty at least 0.2, most certain first, and the “how” explanation of the stain.

7.6 Running It

The coffee shirt from Section 7.1, with the user asking “why” at the second question:

```
(.venv) $ python advisor.py
```

```
What color is the stain? (red/brown/yellow/green/blue/black/grey/orange) brown
Where did it probably come from? (food/drink/injury/outdoor/office/metal/makeup/unknown)
why
   I am trying rule s2: if color is brown and source is injury, then stain is blood.
Where did it probably come from? (food/drink/injury/outdoor/office/metal/makeup/unknown)
drink
Does it feel greasy or look shiny? (yes/no) no
What is the fabric? (cotton/polyester/denim/silk/wool) cotton
Is the stain fresh (today) or old? (fresh/old) old

Stain: coffee-tea (certainty 0.80)
Method (0.64): Rinse with cool water, rub in liquid detergent, wait 10 minutes, wash as
usual.
Method (0.56): Soak 1 to 2 hours in oxygen bleach (not chlorine), then wash.
Warning (0.80): Old stain: test the treatment on a hidden spot first.

How was the stain identified?
  s3: color is brown and source is drink and greasy is no (certainty 1.00) -> stain is
coffee-tea with 0.80
```

Several things are worth noticing. The questions came in a natural order, and each was asked once. When the user typed "why", the advisor explained that it was trying rule s2, blood from an injury, because a brown stain from an injury is often old blood; the first rule, s1, had already failed because the color was not red. The stain was identified as coffee or tea with certainty 0.80, by rule s3 alone, as the "how" explanation shows. Two methods were recommended: the simple rinse with $0.8 \times 0.8 = 0.64$ from rule t2, and, because the stain is old, the oxygen-bleach soak with $0.8 \times 0.7 = 0.56$ from rule t3. **Figure 7.3** draws the complete chain of reasoning of this consultation.

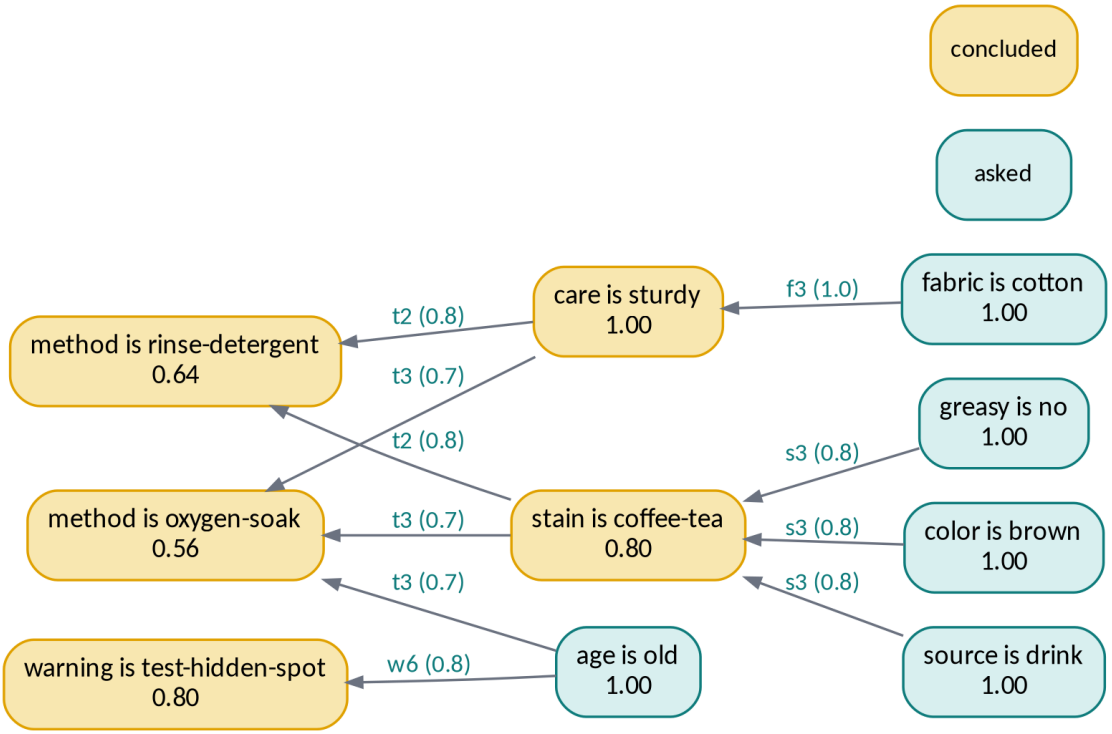

Figure 7.3 The reasoning of the coffee consultation: the user's answers (teal), the conclusions drawn from them (amber) with their certainty, and the rules, with their certainty factors, on the arrows.

Now the silk blouse of Section 7.3.2, in Indonesian, with the color given with certainty 0.8:

```
(.venv) $ python advisor.py id
```

```
Apa warna nodanya? (merah/cokelat/kuning/hijau/biru/hitam/abu-abu/oranye) kuning 0.8
Kira-kira dari mana asalnya? (makanan/minuman/luka/luar/kantor/logam/riasan/entah) makanan
Apakah terasa berminyak atau tampak mengilap? (ya/tidak) ya
Apa bahan kainnya? (katun/poliester/denim/sutra/wol) sutra
Nodanya masih baru (hari ini) atau sudah lama? (baru/lama) baru

Noda: turmeric (kepastian 0.70)
Cara (0.90): Jangan ditangani sendiri: kirim ke dry cleaning profesional dan sebutkan jenis
nodanya.
Peringatan (1.00): Jangan pakai pemutih klorin.
Peringatan (0.42): Jangan pakai air panas: panas membuat noda ini menempel permanen.

Bagaimana nodanya dikenali?
  s4: color is yellow and source is food (certainty 0.80) -> stain is turmeric with 0.56
  s5: color is yellow and greasy is yes (certainty 0.80) -> stain is turmeric with 0.32
```

The output reproduces the hand calculation of Equation (7.5): rules s4 and s5 contributed 0.56 and 0.32, combined to 0.70, and because the fabric is silk the advisor refused home treatment and warned against chlorine (1.00) and hot water (0.42). The stain names and rule explanations stay in the program's own English terms, while the advice for the customer is in Indonesian.

7.7 Evaluating the Knowledge Base

A knowledge base is a hypothesis about how experts reason, and like any hypothesis it must be tested against real cases. `cases.csv` records 14 stains with their observations and the stain an experienced worker identified. **Listing 7.4** runs forward chaining on each case and compares.

Listing 7.4 `advisor_lab.py`: forward chaining over 14 recorded cases, comparing the identified stain with the expected one.

```
"""Run the knowledge base forward on 14 recorded cases and check the stain."""
import csv
from pathlib import Path

from engine import Engine, load_rules

HERE = Path(__file__).parent

def main():
    rules = load_rules(HERE / "kb.txt")
    print(f"{len(rules)} rules loaded")
    print(f"{'case':>4}  {'expected':<11}{'found':<11}{'cf':>5}  "
          f"{'method':<23}{'fired':>6}")
    right = 0
    with open(HERE / "cases.csv", encoding="utf8") as f:
        for row in csv.DictReader(f):
            engine = Engine(rules)
            for attr in ("color", "source", "greasy", "fabric", "age"):
                engine.add(attr, row[attr], 1.0)
            engine.forward()
            stain, cf = engine.best("stain")
            method, _ = engine.best("method")
            ok = stain == row["expected"]
            right += ok
            print(f"{row['case']:>4}  {row['expected']:<11}{stain or '-':<11}"
                  f"{cf:>5.2f}  {method or '-':<23}{len(engine.fired):>6}"
                  f"{'' if ok else '  <- wrong'}")
    print(f"correct: {right} of 14")

if __name__ == "__main__":
    main()
```

`csv.DictReader` reads each line of the file as a dictionary keyed by the header, so `row["color"]` is the color of the case. Every observation is added as a certain fact, the engine chains forward, and the best stain and method are printed with the number of rules that fired.

```
40 rules loaded
case  expected   found         cf  method                 fired
   1  blood      blood       0.90  cold-enzyme                4
   2  blood      blood       0.70  cold-enzyme                5
   3  coffee-tea coffee-tea  0.80  rinse-detergent            5
   4  turmeric   turmeric    0.82  soap-sunlight              5
   5  sambal     sambal      0.80  degrease-then-soap         5
   6  oil        oil         0.80  degrease-hot               4
   7  grass      grass       0.90  cold-enzyme                4
   8  mud        mud         0.70  dry-brush-wash             3
   9  ink        ink         0.90  alcohol-dab                3
  10  rust       rust        0.90  acid-rust                  5
  11  lipstick   lipstick    0.93  professional-dry-clean     5
  12  oil        oil         0.60  professional-dry-clean     5
  13  blood      -           0.00  -                          1  <- wrong
  14  ink        -           0.00  -                          2  <- wrong
correct: 12 of 14
```

Twelve of the fourteen stains were identified correctly. Case 11 shows combination at work: the lipstick rules s16 and s17 both fired, combine(0.9,0.3) = 0.93. Case 12, oil on wool, was identified correctly, and the method is dry cleaning because wool is delicate. The two failures are instructive: in cases 13 and 14 the customer did not know where the stain came from, and the knowledge base has *no rule at all* for a red or black stain of unknown source. The engine did not guess wrong; it had nothing to say. That is the knowledge acquisition bottleneck in miniature, and

fixing it means going back to the expert with a question, which is exactly what Exercise 4 asks you to do.

7.8 Testing It

Listing 7.5 tests the shell independently of the laundry knowledge where possible: the combination formula with the numbers of Equation (7.5), rule parsing, a forward-chaining case, the promise that backward chaining asks each question only once, and the threshold of Equation (7.3).

Listing 7.5 `test_engine.py`: tests for combination, parsing, forward chaining, backward questioning and the certainty threshold.

```
"""Tests for the expert-system shell. Run: python -m unittest -v"""
import unittest
from pathlib import Path

from engine import Engine, combine, load_rules

RULES = load_rules(Path(__file__).parent / "kb.txt")

class EngineTests(unittest.TestCase):
    def test_combine(self):
        self.assertAlmostEqual(combine(0.56, 0.32), 0.7008)
        self.assertAlmostEqual(combine(-0.5, -0.5), -0.75)
        self.assertAlmostEqual(combine(0.8, -0.5), 0.6)

    def test_rules_loaded(self):
        self.assertEqual(len(RULES), 40)
        self.assertEqual(RULES[0].premises, [("color", "red"),
                                             ("source", "injury")])

    def test_forward_blood(self):
        e = Engine(RULES)
        for attr, value in (("color", "red"), ("source", "injury"),
                            ("greasy", "no"), ("fabric", "cotton"),
                            ("age", "fresh")):
            e.add(attr, value, 1.0)
        e.forward()
        self.assertEqual(e.best("stain"), ("blood", 0.9))
        self.assertEqual(e.best("method")[0], "cold-enzyme")
        self.assertIn("no-hot-water", e.facts["warning"])

    def test_backward_asks_each_question_once(self):
        answers = {"color": "green", "source": "outdoor", "greasy": "no",
                   "fabric": "cotton", "age": "fresh"}
        asked = []

        def ask(attr, why):
            asked.append(attr)
            return answers[attr], 1.0

        e = Engine(RULES)
        e.backward("method", ask)
        self.assertEqual(sorted(asked), sorted(set(asked)))   # no repeats
        self.assertEqual(e.best("stain")[0], "grass")
```

Listing 7.5 (Continued) *test_engine.py: tests for combination, parsing, forward chaining, backward questioning and the certainty threshold.*

```
    def test_weak_evidence_does_not_fire(self):
        e = Engine(RULES)
        e.add("color", "red", 0.1)             # below the 0.2 threshold
        e.add("source", "injury", 1.0)
        e.forward()
        self.assertEqual(e.best("stain"), (None, 0.0))

if __name__ == "__main__":
    unittest.main()
```

`assertAlmostEqual` compares floating-point numbers up to seven decimal places, which is the right way to test results like 0.7008 that may not be represented exactly in binary. The check `sorted(asked) == sorted(set(asked))` is true only if no attribute appears twice in the list.

```
test_backward_asks_each_question_once

... ok

----------------------------------------------------------------------
Ran 5 tests in 0.001s

OK
```

7.9 Improving It

Fill the gaps. Add rules for stains of unknown source with lower certainty factors, so that cases 13 and 14 are covered, and add stains the advisor does not know yet, such as wax, chewing gum or sweat.

Negative evidence. Some observations speak *against* a conclusion: a greasy stain is unlikely to be blood. Rules with negative certainty factors, combined with the second and third lines of Equation (7.4), express this.

Ask about certainty. Instead of letting the user type “brown 0.6”, offer words (“certain”, “probably”, “maybe”) and map them to numbers, which people find much easier to use.

Show the whole “why”. The `why` parameter holds the whole chain of rules, not just the last one. Printing the chain (“I need the stain to choose a method; I am trying rule s2 to decide whether the stain is blood”) gives a much better explanation.

Connect it to the counter. In a laundry’s order system, the advisor’s conclusion could be stored with the order, so that the washing staff sees the treatment and the warnings on the work ticket. Chapter 100 builds an assistant for Profitina Laundry that combines this kind of rule knowledge with a language model.

7.10 Common Mistakes, and How to Avoid Them

Firing a rule twice. In forward chaining, a rule that fires on every sweep adds the same evidence again and again, and Equation (7.4) pushes the certainty toward 1. Fire each rule at most once, as `forward` does.

Firing too early. With fire-once forward chaining, a rule that fires before all the evidence for its conditions has arrived keeps the weaker certainty forever, as Section 7.3.4 showed. Order the rules so that conclusions are drawn before the rules that use them (our file puts stains first, then care, then methods), or recompute conclusions whenever the certainty of a condition changes.

Asking the same question twice. Backward chaining reaches the same attribute through several rules. Store that the attribute is being established before recursing, as `backward` does with `self.facts[goal] = {}`.

Treating certainty factors as probabilities. CFs are not probabilities: they do not add up to 1 across alternatives, and Equation (7.4) is not the rule for combining probabilities. They are a practical measure of confidence invented for MYCIN. Chapter 15's naive Bayes classifier shows the probabilistic alternative.

Writing knowledge into the code. If the rules are Python `if` statements, only a programmer can change them, and nobody can list them for an expert to check. Keep rules as data, as in `kb.txt`.

Testing only the happy path. A knowledge base that is never run on real cases always looks complete. Record cases, including hard ones, and run them after every change, as the lab does.

Giving advice beyond the knowledge. The advisor is honest when it says "not recognized". A version that always produced *some* answer would be more dangerous, not more useful.

7.11 Chapter Summary

- An expert system separates a knowledge base of IF-THEN rules (Equation (7.1)) from an inference engine that applies them; the same engine can serve any field.
- Forward chaining derives everything that follows from the facts; backward chaining (**Pseudocode 7.1**) works from a goal and asks only the questions it needs.
- Certainty factors: conditions joined by AND take the minimum (Equation (7.2)), a rule multiplies by its CF above a threshold of 0.2 (Equation (7.3)), and evidence for the same conclusion is combined with MYCIN's formula (Equation (7.4)), as in the turmeric example (Equation (7.5)).
- The advisor explains *why* it asks and *how* it concluded, in English or Indonesian.
- On 14 recorded cases it identified 12 stains correctly; the two failures revealed missing knowledge, not faulty reasoning.

7.12 Exercises

1. Using Equation (7.2) and Equation (7.3), compute what rule s9 contributes for a brown, greasy stain from food, when the user gives "brown" with certainty 0.5.
2. Compute combine(0.9,0.3) and combine(0.3,0.9) and check that they are equal. Then compute combine$(0.6, -0.4)$.
3. Which questions does the advisor ask, and in which order, for a green grass stain on denim? Try it and compare with **Pseudocode 7.1**.
4. Add rules so that cases 13 and 14 are identified (a red stain of unknown source is probably blood; a black one is probably ink), with modest certainty factors. Rerun `advisor_lab.py`.
5. Add a negative rule: IF greasy is yes THEN stain is blood CF -0.6. Which change to `load_rules` is needed so that negative numbers are read, and what happens to a red, greasy stain from an injury?
6. Make the "why" answer print the whole chain of rules in `why`, not only the last one.

7. Write three new cases for `cases.csv`, one of which you expect the knowledge base to get wrong, and explain the result.

7.13 Solutions to the Exercises

1. Rule s9 has conditions greasy is yes (1.0), source is food (1.0) and color is brown (0.5). By Equation (7.2) their strength is $\min(1.0,1.0,0.5) = 0.5$, which is above the threshold, so by Equation (7.3) the rule contributes $0.5 \times 0.6 = 0.3$ to "stain is oil".

2. $\text{combine}(0.9,0.3) = 0.9 + 0.3 \times 0.1 = 0.93$ and $\text{combine}(0.3,0.9) = 0.3 + 0.9 \times 0.7 = 0.93$: equal, as the symmetry $a + b(1-a) = b + a(1-b)$ promises. With mixed signs, $\text{combine}(0.6,-0.4) = (0.6 - 0.4)/(1 - 0.4) = 0.2/0.6 \approx 0.33$.

3. Recording the calls to `ask` gives this order: color (asked on behalf of rule s1), greasy (rule s8, the first stain rule whose first condition is not about color), source (rule s10), fabric (rule f1) and age (rule w6). Rules s1 to s7 all start with a color condition that fails for green, so their later conditions are never pursued, exactly as line 8 of **Pseudocode 7.1** prescribes. Each question is asked once; the result is grass with certainty 0.90, the cold enzyme method with $0.9 \times 0.8 = 0.72$, and the warning against hot water, also 0.72.

4. Add, for example,

```
RULE s18: IF color is red AND source is unknown AND greasy is no
    THEN stain is blood CF 0.5
RULE s19: IF color is black AND source is unknown
    THEN stain is ink CF 0.4
```

and change the count in `test_rules_loaded` to 42. Both cases are then identified, with certainties 0.50 and 0.40, and the lab reports 14 of 14. The low certainty factors are deliberate: without knowing the source, a counter worker would also only guess.

5. The pattern `CF ([\d.]+)` does not accept a minus sign; change it to `CF (-?[\d.]+)`. The threshold test in `fire` must then compare the *strength of the conditions*, which stays positive, with 0.2 (it already does), and the negative contribution is combined with the positive evidence from s1 by the third line of Equation (7.4): $(0.9 - 0.6)/(1 - 0.6) = 0.75$. Blood remains the answer, but with less certainty.

6. Replace the body of the `why` branch by a loop over the whole tuple:

```
            for rule in why:
                prem = " and ".join(f"{a} is {v}" for a, v in rule.premises)
                print(f"   rule {rule.name}: if {prem}, then "
                      f"{rule.conclusion[0]} is {rule.conclusion[1]}")
```

For the coffee consultation this prints first rule t1 (the method needs the stain) and then rule s2 (the stain rule being tried).

7. For example: a grey greasy stain on a polyester shirt from a bicycle chain (source metal): the knowledge base has no rule for grey and metal, and s8 needs only "greasy" and "grey", so it concludes oil (0.80), which is right. A brown stain from a drink that is greasy (coffee with milk and sugar) is a good candidate for a failure: s3 requires "greasy is no", so no coffee rule fires, and s9 needs the source to be food, so nothing at all is concluded. The failure shows that the rules encode a simplified picture of real stains, and that recorded cases are the way to find where it is too simple.

Chapter 8

A Route Planner for Surabaya: Dijkstra and A* on a City Graph

In Chapter 3 every step between warehouse aisles cost the same. On real roads it does not: the stretch from Keputih to Rungkut is several kilometers long, a toll road is fast but not always short, and the shortest route is often not the fastest one. In this chapter we build a small route planner for Surabaya. Its map is a graph of 26 well-known places, from Tanjung Perak in the north to Juanda airport in the south, including the three Profitina Laundry outlets, joined by 36 roads, each with a length and a travel time. We find routes with Dijkstra's algorithm, the classic method for graphs with unequal costs, and speed it up with A* and a heuristic based on the curvature of the Earth. By the end of the chapter you will be able to build a weighted graph from data files, compute distances between map coordinates with the haversine formula, explain why Dijkstra's algorithm is correct, choose a heuristic that keeps A* optimal even after rounding, find both the shortest and the fastest route, and measure how much work a heuristic saves.

8.1 Every Delivery Is a Search Problem

Profitina Laundry has three outlets in Surabaya: Rungkut in the southeast, Keputih near the ITS campus in the east, and Wiyung in the west. Every afternoon a van carries clean laundry between them and to customers across the city. Which way should the driver go? A driver who has worked in Surabaya for twenty years knows; a new driver, or a program that plans a day of pickups, has to compute it.

Route planning is one of the most successful applications of classic AI. Every navigation app on every phone solves it millions of times a day, on graphs with millions of junctions. The algorithms are the same as in this chapter; they are simply combined with clever pre-processing and live traffic data. Edsger Dijkstra published his algorithm in a three-page paper in 1959 and later said he had designed it in about twenty minutes, sitting on a café terrace in Amsterdam [1]. A*, from Chapter 3, followed in 1968 [2].

Our map is small enough to draw on one page, **Figure 8.1**, yet big enough to be interesting: it has a toll road along its western side, arterial roads through the center, and local streets, and the shortest route between two laundry outlets is quite different from the fastest.

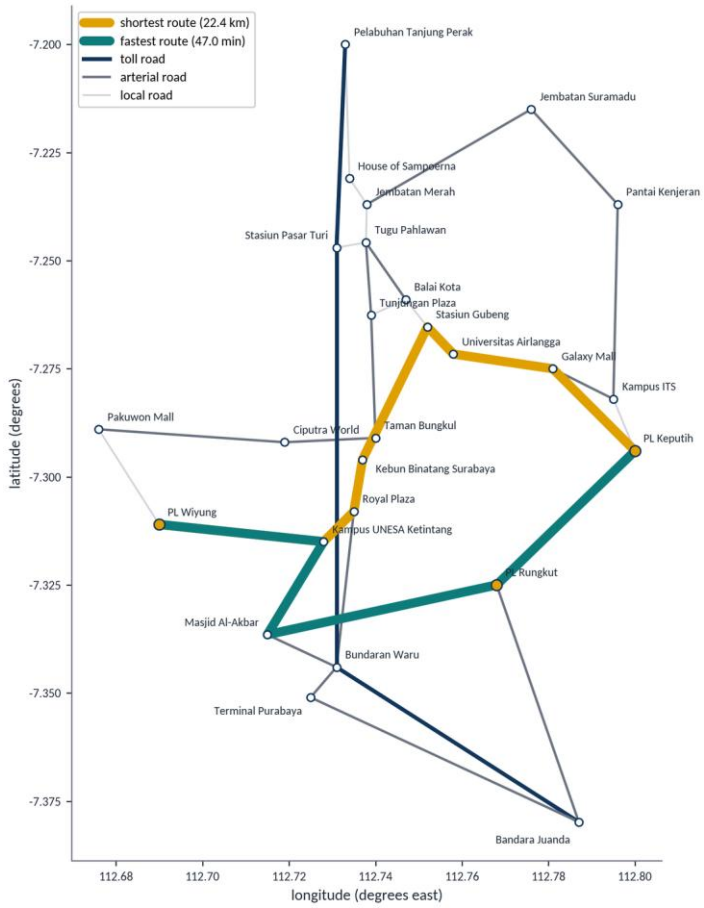

Figure 8.1 The road graph of this chapter: 26 places (laundry outlets in amber) and 36 roads, with the shortest (amber) and fastest (teal) routes from Profitina Laundry Keputih to Profitina Laundry Wiyung found by the planner.

8.2 The Idea in Plain Words

A *weighted graph* is a set of places joined by roads, where every road carries a number, its *weight*: kilometers, or minutes. The cost of a route is the sum of the weights of its roads, and we want the route with the smallest cost.

Dijkstra's idea is best pictured as a group of becak drivers spreading out from the start at the same time, all pedaling at the same pace, one kilometer per minute, say. Whenever a group reaches a junction, it splits and follows every road leaving it. The first driver to reach any place has, necessarily, come by the shortest route, because every other route would have brought a driver there later. So the algorithm keeps a list of places with the best cost found so far, repeatedly takes the place with the *smallest* such cost, declares it *settled* (its cost is now final), and looks at the roads leaving it: if a road offers a cheaper way to a neighbor than the one known so far, the neighbor's cost is lowered. That lowering is called *relaxing* the road.

Breadth-first search, from Chapter 3, is the special case in which every road costs 1. Dijkstra's algorithm allows any costs that are not negative.

A* adds the heuristic of Chapters 3 and 4: instead of the place with the smallest cost so far, it settles the place with the smallest cost so far *plus an estimate of the cost still to go*. Our estimate is the straight-line distance to the goal, which we can compute from the map coordinates. The drivers still spread out, but they now pedal harder toward the goal, and fewer places are visited before it is reached.

8.3 The Math, Gently

8.3.1 Distances on the Earth

Each place has a latitude φ (north or south of the equator, in degrees) and a longitude λ (east or west of Greenwich). Surabaya lies at about 7.25° south and 112.75° east. Because the Earth is round, the distance between two points is measured along a *great circle*, and the *haversine formula* computes it reliably even for short distances [3]:

$$d = 2R\arcsin\sqrt{\sin^2\frac{\varphi_2-\varphi_1}{2} + \cos\varphi_1\cos\varphi_2\sin^2\frac{\lambda_2-\lambda_1}{2}} \tag{8.1}$$

where $R = 6371$ km is the Earth's mean radius and the angles are converted to radians before the sines and cosines are taken. A quick check: two points one degree of latitude apart on the same meridian give $d = 2R\arcsin(\sin 0.5°) = R \times \pi/180 \approx 111.2$ km, the familiar length of a degree of latitude.

8.3.2 Road lengths and travel times

A road is longer than the straight line between its ends, because it bends around buildings and rivers. We do not have measured road lengths, so our map models them: the length of a road is the straight-line distance times a *detour factor* of 1.3, rounded *up* to a tenth of a kilometer, and its travel time follows from a typical speed for its kind of road:

$$\ell(u,v) = \lceil 10 \times 1.3\, d(u,v) \rceil / 10, \qquad t(u,v) = \frac{\ell(u,v)}{s_{\text{kind}}} \times 60 \tag{8.2}$$

with ℓ in kilometers, t in minutes and the speed s equal to 70 km/h on a toll road, 30 km/h on an arterial road and 20 km/h on a local street. These are modeling choices, not measurements: real speeds in Surabaya change with the hour and the weather, and a production planner would use measured lengths from a map database and live traffic. Why round *up*? We will see in Section 8.3.5 that it is needed to keep A* honest.

8.3.3 Relaxation and Dijkstra's algorithm

Let $w(u,v)$ be the weight of the road from u to v, and let $g(v)$ be the cheapest cost to v found so far, with $g(\text{start}) = 0$ and $g(v) = \infty$ for every other place at the beginning. *Relaxing* the road from u to v means

$$g(v) \leftarrow \min(g(v),\ g(u) + w(u,v)) \tag{8.3}$$

in words: if going through u is cheaper than the best way known to v, remember the cheaper way. Dijkstra's algorithm repeatedly settles the unsettled place u with the smallest $g(u)$ and relaxes every road leaving it.

Why is the cost of a settled place final? Suppose u is about to be settled with cost $g(u)$, but there is a cheaper route to u. That route starts at the (settled) start and at some point leaves the set of settled places for the first time, at some unsettled place x. Because the part of the route up to x runs through settled places, whose roads have all been relaxed, $g(x)$ is at most the cost of that part. The rest of the route, from x to u, has a cost of at least 0, because no road has negative weight. So

$$g(x) \le \text{cost of the cheaper route} < g(u) \tag{8.4}$$

which contradicts the choice of u as the unsettled place with the *smallest* g. Hence no cheaper route exists, and $g(u)$ is final [4]. The proof uses the absence of negative weights in exactly one place; with negative weights, a road discovered later could make an already settled place cheaper, and the algorithm would be wrong. Road lengths and travel times are never negative, so Dijkstra's algorithm is safe for maps.

Table 8.1 shows the first places Dijkstra's algorithm settles on the way from ITS to Juanda airport, measured in kilometers, as printed by a trace of the program. The places are settled in order of increasing distance from ITS, whatever direction they lie in: Galaxy Mall, Airlangga University and Kenjeran beach are all settled before the Rungkut outlet, although they lie in the wrong direction.

Table 8.1 The order in which Dijkstra's algorithm settles places from ITS toward Juanda, with the A* estimate for the places A* considers; Dijkstra settles 21 places, A* only those with the smallest f: ITS, Keputih, Rungkut and Juanda.

Order	Place settled	g (km from ITS)	Estimate h to Juanda (km)	f=g+h
1	Kampus ITS	0.0	14.2	14.2
2	Profitina Laundry Keputih	1.9	12.5	14.4
3	Galaxy Mall	2.3	15.2	17.5
4	Universitas Airlangga	5.7		
5	Pantai Kenjeran	6.6	20.7	27.3
6	Stasiun Gubeng	7.0		
7	Balai Kota	8.2		
8	Profitina Laundry Rungkut	8.4	8.4	16.8
…	…	…		
21	Bandara Juanda	16.8	0.0	16.8

8.3.4 A* with a straight-line heuristic

A* settles the place with the smallest $f(v) = g(v) + h(v)$, where $h(v)$ estimates the remaining cost to the goal. For kilometers we use

$$h_{\text{km}}(v) = 1.3 \times d(v,\text{goal}) \tag{8.5}$$

the straight-line distance of Equation (8.1) stretched by the same detour factor as the roads. The last two columns of **Table 8.1** show it at work. After ITS, A* compares Keputih ($f = 1.9 + 12.5 = 14.4$), Galaxy Mall (17.5) and Kenjeran (27.3) and settles Keputih; from there it reaches Rungkut with $f = 8.4 + 8.4 = 16.8$, which is still smaller than Galaxy Mall's 17.5, so it settles Rungkut, then Juanda, and stops. Four places settled instead of twenty-one.

For minutes, the estimate must not assume that the rest of the trip is slower than it could possibly be. The fastest any road allows is 70 km/h, so

$$h_{\text{min}}(v) = \frac{h_{\text{km}}(v)}{70} \times 60 \tag{8.6}$$

is never more than the true remaining time. This estimate is much weaker than the kilometer one, because most roads are far slower than 70 km/h, so A* will save less work on the fastest route; the lab in Section 8.6 measures how much.

8.3.5 Why the heuristic never overestimates, and why rounding matters

The heuristic of Equation (8.5) is admissible (never larger than the true cost), and even consistent in the sense of Chapter 3. For every road, Equation (8.2) makes $\ell(u, v) \geq 1.3\, d(u, v)$. The straight-line distance obeys the *triangle inequality*: going from u to the goal directly is never longer than going via v, $d(u,\text{goal}) \leq d(u, v) + d(v,\text{goal})$. Multiplying by 1.3 and using the first fact,

$$h_{\text{km}}(u) \leq 1.3\, d(u, v) + h_{\text{km}}(v) \leq \ell(u, v) + h_{\text{km}}(v) \tag{8.7}$$

which is exactly the consistency condition of Chapter 3; adding it up along any route shows that h_{km} never exceeds the true remaining distance.

The first version of this chapter's program rounded road lengths to the *nearest* tenth of a kilometer. Then a road of $1.3d = 6.84$ km became 6.8 km, *shorter* than the heuristic's 6.84, and the second inequality of Equation (8.7) failed. The test `test_heuristic_is_admissible` in Section 8.7, which compares the heuristic with the true cost for all 650 pairs of places, caught this at once. Rounding up restored the guarantee. The lesson reaches far beyond this program: a heuristic is admissible only with respect to the costs actually used, including their rounding.

8.3.6 How much work does it take?

Each place is settled once, and when it is settled each of its roads is relaxed once, so over the whole search there are at most $|E|$ relaxations for a graph with $|V|$ places and $|E|$ roads (each two-way road counted once per direction). Every successful relaxation pushes one entry onto the binary heap, and every entry is popped at most once; a push or a pop costs about $\log_2$ of the heap size. Altogether the running time is

$$T_{\text{Dijkstra}} = O((|V| + |E|)\log|V|) \tag{8.8}$$

For our map, $|V| = 26$ and there are 72 directed roads, so a whole search is a few hundred elementary steps, which is why the lab's 1,300 searches take a fraction of a second. For a city-sized road network with a million junctions, Equation (8.8) is around twenty million steps per search, still fast for one query but too slow for a service answering thousands of queries per second, which is where the heuristics of this chapter and the pre-processing mentioned in Section 8.8 come in. A* has the same worst case as Dijkstra's algorithm, because a useless heuristic ($h = 0$) turns it back into Dijkstra's algorithm; its advantage is in the typical case, and the lab in Section 8.6 measures it.

8.3.7 Relaxation by hand

Let us follow the first three settlements of Dijkstra's algorithm from ITS, using the road lengths the program computes. At the start, $g(\text{ITS}) = 0$ and every other place has $g = \infty$.

Settle ITS (0.0). Its roads lead to Keputih (1.9 km), Galaxy Mall (2.3 km) and Kenjeran (6.6 km). By Equation (8.3) each of the three costs drops from ∞: $g(\text{KPT}) = 1.9$, $g(\text{GXY}) = 2.3$, $g(\text{KNJ}) = 6.6$.

Settle Keputih (1.9), the smallest unsettled cost. Its road to Galaxy Mall is 3.9 km, which would give $1.9 + 3.9 = 5.8$; that is worse than the 2.3 already known, so nothing changes. Its road to Rungkut is 6.5 km, so $g(\text{RKT}) = \min(\infty, 1.9 + 6.5) = 8.4$.

Settle Galaxy Mall (2.3). Its road to Airlangga University, 3.4 km, gives $g(\text{UNA}) = 5.7$; its roads back to ITS and Keputih offer nothing cheaper.

The unsettled places are now Airlangga (5.7), Kenjeran (6.6) and Rungkut (8.4), and they will be settled in exactly that order, as rows 4, 5 and 8 of **Table 8.1** show; between them, Gubeng and the city hall are discovered and settled through Airlangga. Notice that the cost of Rungkut, 8.4, never changes again after it is first set: none of the places settled before it offers a cheaper road into Rungkut, and the proof of Equation (8.4) guarantees that, once Rungkut is itself settled, no route found later can be cheaper either.

8.4 The Algorithm as Pseudocode

Pseudocode 8.1 is A*; with $h = 0$ it is Dijkstra's algorithm, which is exactly how the program implements it.

Pseudocode 8.1 A* search on a weighted graph; Dijkstra's algorithm is the special case $h = 0$.

```
A-STAR(graph, start, goal, h)            // h = 0 gives DIJKSTRA
1  g[start] = 0; parent[start] = NIL
2  insert start into the priority queue with priority h(start)
3  while the queue is not empty
4      u = remove the entry with the smallest priority
5      if u is settled: continue            // an outdated entry
6      settle u
7      if u == goal: return the path via parent, and g[goal]
8      for each road (u, v) with weight w
9          if g[u] + w < g[v]               // relax the road
10             g[v] = g[u] + w; parent[v] = u
11             insert v with priority g[v] + h(v)
12 return FAIL
```

8.5 Building the Planner Step by Step

8.5.1 The map as data

The map is two CSV files. `data/places.csv` lists each place with a short identifier, its name and approximate, rounded coordinates:

```
id,name,lat,lon
PRK,Pelabuhan Tanjung Perak,-7.2000,112.7330
SMP,House of Sampoerna,-7.2310,112.7340
JMB,Jembatan Merah,-7.2370,112.7380
TUG,Tugu Pahlawan,-7.2458,112.7378
PTR,Stasiun Pasar Turi,-7.2470,112.7310
SRM,Jembatan Suramadu,-7.2150,112.7760
KNJ,Pantai Kenjeran,-7.2370,112.7960
BLK,Balai Kota,-7.2590,112.7470
TP,Tunjungan Plaza,-7.2626,112.7390
GUB,Stasiun Gubeng,-7.2653,112.7520
UNA,Universitas Airlangga,-7.2716,112.7580
GXY,Galaxy Mall,-7.2750,112.7810
ITS,Kampus ITS,-7.2820,112.7950
KPT,Profitina Laundry Keputih,-7.2940,112.8000
BKL,Taman Bungkul,-7.2910,112.7400
CPW,Ciputra World,-7.2920,112.7190
KBS,Kebun Binatang Surabaya,-7.2960,112.7370
PKW,Pakuwon Mall,-7.2890,112.6760
RYL,Royal Plaza,-7.3080,112.7350
WIY,Profitina Laundry Wiyung,-7.3110,112.6900
UNS,Kampus UNESA Ketintang,-7.3150,112.7280
RKT,Profitina Laundry Rungkut,-7.3250,112.7680
MAS,Masjid Al-Akbar,-7.3365,112.7150
WAR,Bundaran Waru,-7.3440,112.7310
PUR,Terminal Purabaya,-7.3510,112.7250
JUA,Bandara Juanda,-7.3798,112.7870
```

`data/roads.csv` lists the roads, each joining two places and classified as toll, arterial or local:

```
a,b,kind
PRK,SMP,local
SMP,JMB,local
JMB,TUG,local
TUG,PTR,local
TUG,BLK,arterial
JMB,SRM,arterial
SRM,KNJ,arterial
KNJ,ITS,arterial
ITS,KPT,local
ITS,GXY,arterial
GXY,KPT,local
GXY,UNA,arterial
UNA,GUB,local
GUB,BLK,local
BLK,TP,local
TP,TUG,arterial
TP,BKL,arterial
GUB,KBS,arterial
BKL,KBS,arterial
KBS,RYL,arterial
RYL,UNS,arterial
UNS,MAS,arterial
MAS,WAR,arterial
WAR,PUR,arterial
RYL,WAR,arterial
CPW,BKL,arterial
CPW,PKW,arterial
PKW,WIY,local
WIY,UNS,arterial
KPT,RKT,arterial
RKT,JUA,arterial
RKT,MAS,arterial
WAR,JUA,toll
PUR,JUA,arterial
PRK,PTR,toll
PTR,WAR,toll
```

Keeping the map in data files means that a larger map, even one exported from a real map database, needs no change to the program.

8.5.2 The graph

Listing 8.1 reads the files and builds the graph.

Listing 8.1 `citygraph.py`: the haversine distance, the rounding-up rule and the `CityGraph` class with its adjacency lists.

```
"""A small road graph of Surabaya: places, roads, distances and travel times.

Coordinates are approximate and rounded; a road's length is the straight-line
distance times a detour factor, and its speed depends on the kind of road."""
import csv
import math
from pathlib import Path

DATA = Path(__file__).parent / "data"
DETOUR = 1.3                                    # roads are longer than a crow flies
SPEED_KMH = {"toll": 70, "arterial": 30, "local": 20}

def haversine(p, q):
    """Great-circle distance in km between two (lat, lon) points in degrees."""
    r = 6371.0                                  # mean radius of the Earth, km
    la1, lo1, la2, lo2 = map(math.radians, (*p, *q))
    a = (math.sin((la2 - la1) / 2) ** 2 +
         math.cos(la1) * math.cos(la2) * math.sin((lo2 - lo1) / 2) ** 2)
    return 2 * r * math.asin(math.sqrt(a))

def up(x):
    """Round up to one decimal, so a road is never shorter than A* assumes."""
    return math.ceil(x * 10 - 1e-9) / 10

class CityGraph:
    def __init__(self, folder=DATA):
        self.name, self.pos = {}, {}
        with open(folder / "places.csv", encoding="utf8") as f:
            for row in csv.DictReader(f):
                self.name[row["id"]] = row["name"]
                self.pos[row["id"]] = (float(row["lat"]), float(row["lon"]))
        self.adj = {p: [] for p in self.pos}    # place -> [(next, km, minutes)]
        with open(folder / "roads.csv", encoding="utf8") as f:
            for row in csv.DictReader(f):
                a, b, kind = row["a"], row["b"], row["kind"]
                km = up(haversine(self.pos[a], self.pos[b]) * DETOUR)
                minutes = up(km / SPEED_KMH[kind] * 60)
                self.adj[a].append((b, km, minutes))
                self.adj[b].append((a, km, minutes))   # roads are two-way
```

Listing 8.1 (Continued) *citygraph.py: the haversine distance, the rounding-up rule and the CityGraph class with its adjacency lists.*

```
    def find(self, text):
        """Accept an id ('ITS') or part of a name ('juanda')."""
        if text.upper() in self.pos:
            return text.upper()
        hits = [p for p, n in self.name.items() if text.lower() in n.lower()]
        if len(hits) != 1:
            raise KeyError(f"'{text}' matches {len(hits)} places")
        return hits[0]
```

`haversine` is Equation (8.1). The line `map(math.radians, (*p, *q))` unpacks both coordinate pairs into one sequence of four numbers and converts each to radians; the four results are then assigned to four variables at once. `up` rounds up to one decimal; the tiny `1e-9` prevents a value such as 6.8, stored in binary as 6.800000000000001, from being rounded up to 6.9.

`CityGraph` stores the graph as an *adjacency list*: a dictionary that maps every place to a list of `(neighbor, km, minutes)` tuples, one per road leaving it. Each road is added in both directions, because Surabaya's roads in our model are two-way. An adjacency list uses memory in proportion to the number of roads, which suits road maps: a junction connects to a handful of roads, not to every other junction. `find` lets the user type either an identifier or part of a name, and refuses ambiguous input, so "laundry" (three matches) is rejected but "juanda" is accepted.

8.5.3 Dijkstra and A*

Listing 8.2 is **Pseudocode 8.1** in Python.

Listing 8.2 `routes.py`: A* on a weighted graph, returning the path, its cost and the places settled; Dijkstra's algorithm is A* with a zero heuristic.

```
"""Dijkstra's algorithm and A* on a weighted graph, with a work counter."""
import heapq

KM, MINUTES = 1, 2                              # which number of an edge to use

def dijkstra(graph, start, goal, weight=KM):
    return astar(graph, start, goal, weight, h=lambda place: 0.0)

def astar(graph, start, goal, weight=KM, h=None):
    """Cheapest path from start to goal; returns (path, cost, settled)."""
    h = h or (lambda place: 0.0)
    best = {start: 0.0}                         # cheapest known cost so far
    parent = {start: None}
    frontier = [(h(start), start)]
    settled, done = [], set()                   # places whose cost is final
    while frontier:
        f, place = heapq.heappop(frontier)
        if place in done:
            continue                            # an outdated heap entry
        done.add(place)
        settled.append(place)
        if place == goal:
            path = []
            while place is not None:
                path.append(place)
                place = parent[place]
            return path[::-1], best[goal], settled
        for edge in graph.adj[place]:
            nxt, cost = edge[0], best[place] + edge[weight]
            if cost < best.get(nxt, float("inf")):
                best[nxt] = cost                # a cheaper way to nxt: relax
                parent[nxt] = place
                heapq.heappush(frontier, (cost + h(nxt), nxt))
    return None, float("inf"), settled
```

The constants `KM` and `MINUTES` are the positions of the two weights inside an edge tuple, so `edge[weight]` picks the right one and the same function finds the shortest or the fastest route. `dijkstra` simply calls `astar` with a heuristic that always returns 0, which makes clear that the two algorithms differ in nothing else. The priority queue is `heapq` again; as in Chapters 3 and 4, a place may be pushed several times with decreasing priorities, and the set `done` skips the outdated entries. The list `settled` keeps the order in which places were settled, which the application reports and the figures draw.

8.5.4 The application

Listing 8.3 plans the shortest and the fastest route between two places and prints them road by road.

Listing 8.3 `route_app.py`: finds the shortest and the fastest route with both algorithms, checks that they agree, and prints the legs.

```
"""Plan a route across Surabaya: the shortest and the fastest.

usage: python route_app.py FROM TO      e.g.  python route_app.py ITS juanda
"""
import sys

from citygraph import DETOUR, SPEED_KMH, CityGraph, haversine
from routes import KM, MINUTES, astar, dijkstra

def show_route(g, path):
    for a, b in zip(path, path[1:]):
        km, minutes = next((e[1], e[2]) for e in g.adj[a] if e[0] == b)
        print(f"   {g.name[a]:<27} -> {g.name[b]:<27}{km:>5.1f} km"
              f"{minutes:>6.1f} min")

def main():
    g = CityGraph()
    start = g.find(sys.argv[1] if len(sys.argv) > 1 else "ITS")
    goal = g.find(sys.argv[2] if len(sys.argv) > 2 else "juanda")
    fastest = max(SPEED_KMH.values())

    def h_km(p):                                # never more than the true km
        return DETOUR * haversine(g.pos[p], g.pos[goal])

    def h_min(p):                               # the same, at the top speed
        return h_km(p) / fastest * 60

    print(f"{len(g.pos)} places, {sum(map(len, g.adj.values())) // 2} roads")
    print(f"From {g.name[start]} to {g.name[goal]}; "
          f"straight line {haversine(g.pos[start], g.pos[goal]):.1f} km")
    for label, weight, h, unit in (("Shortest", KM, h_km, "km"),
                                   ("Fastest", MINUTES, h_min, "min")):
        path, cost, settled_d = dijkstra(g, start, goal, weight)
        path_a, cost_a, settled_a = astar(g, start, goal, weight, h)
        assert abs(cost - cost_a) < 1e-9        # both must find the same cost
        print(f"\n{label} route: {cost:.1f} {unit}  (Dijkstra settled "
              f"{len(settled_d)} places, A* settled {len(settled_a)})")
        show_route(g, path)

if __name__ == "__main__":
    main()
```

The two heuristics are inner functions that remember `goal`, `g` and `fastest` from `main`. `assert` stops the program with an error if its condition is false; here it checks, on every run, that Dijkstra's algorithm and A* found routes of the same cost, as the theory says they must. `next(...)` with a generator expression finds the first edge from `a` that leads to `b`, to print that leg's length and time.

8.6 Running It

The delivery between two outlets, from Keputih in the east to Wiyung in the west:

```
(.venv) $ python route_app.py Keputih Wiyung
```

```
26 places, 36 roads
From Profitina Laundry Keputih to Profitina Laundry Wiyung; straight line 12.3 km

Shortest route: 22.4 km  (Dijkstra settled 25 places, A* settled 14)
   Profitina Laundry Keputih   -> Galaxy Mall                3.9 km  11.7 min
   Galaxy Mall                 -> Universitas Airlangga      3.4 km   6.8 min
   Universitas Airlangga       -> Stasiun Gubeng             1.3 km   3.9 min
   Stasiun Gubeng              -> Kebun Binatang Surabaya    5.0 km  10.0 min
   Kebun Binatang Surabaya     -> Royal Plaza                1.8 km   3.6 min
   Royal Plaza                 -> Kampus UNESA Ketintang     1.5 km   3.0 min
   Kampus UNESA Ketintang      -> Profitina Laundry Wiyung   5.5 km  11.0 min

Fastest route: 47.0 min  (Dijkstra settled 25 places, A* settled 23)
   Profitina Laundry Keputih   -> Profitina Laundry Rungkut  6.5 km  13.0 min
   Profitina Laundry Rungkut   -> Masjid Al-Akbar             7.8 km  15.6 min
   Masjid Al-Akbar             -> Kampus UNESA Ketintang     3.7 km   7.4 min
   Kampus UNESA Ketintang      -> Profitina Laundry Wiyung   5.5 km  11.0 min
```

The two routes are completely different, as **Figure 8.1** shows. The shortest, 22.4 km, goes straight through the city center past Galaxy Mall, Gubeng station and the zoo. The fastest, 47.0 minutes, swings south over arterial roads through Rungkut and past the Al-Akbar mosque: it is longer, but avoids the slow local streets. A* settled 14 places instead of 25 for the shortest route, but 23 instead of 25 for the fastest, because the minutes heuristic of Equation (8.6) is weak, exactly as predicted in Section 8.3.4. From ITS to the airport:

```
(.venv) $ python route_app.py ITS juanda
```

```
26 places, 36 roads
From Kampus ITS to Bandara Juanda; straight line 10.9 km

Shortest route: 16.8 km  (Dijkstra settled 21 places, A* settled 4)
   Kampus ITS                  -> Profitina Laundry Keputih  1.9 km   5.7 min
   Profitina Laundry Keputih   -> Profitina Laundry Rungkut  6.5 km  13.0 min
   Profitina Laundry Rungkut   -> Bandara Juanda             8.4 km  16.8 min

Fastest route: 35.5 min  (Dijkstra settled 22 places, A* settled 9)
   Kampus ITS                  -> Profitina Laundry Keputih  1.9 km   5.7 min
   Profitina Laundry Keputih   -> Profitina Laundry Rungkut  6.5 km  13.0 min
   Profitina Laundry Rungkut   -> Bandara Juanda             8.4 km  16.8 min
```

Here shortest and fastest coincide, through the two eastern outlets. For the shortest route A* settled 4 places where Dijkstra's algorithm settled 21; **Figure 8.2** shows which, and **Table 8.1** gave the reason.

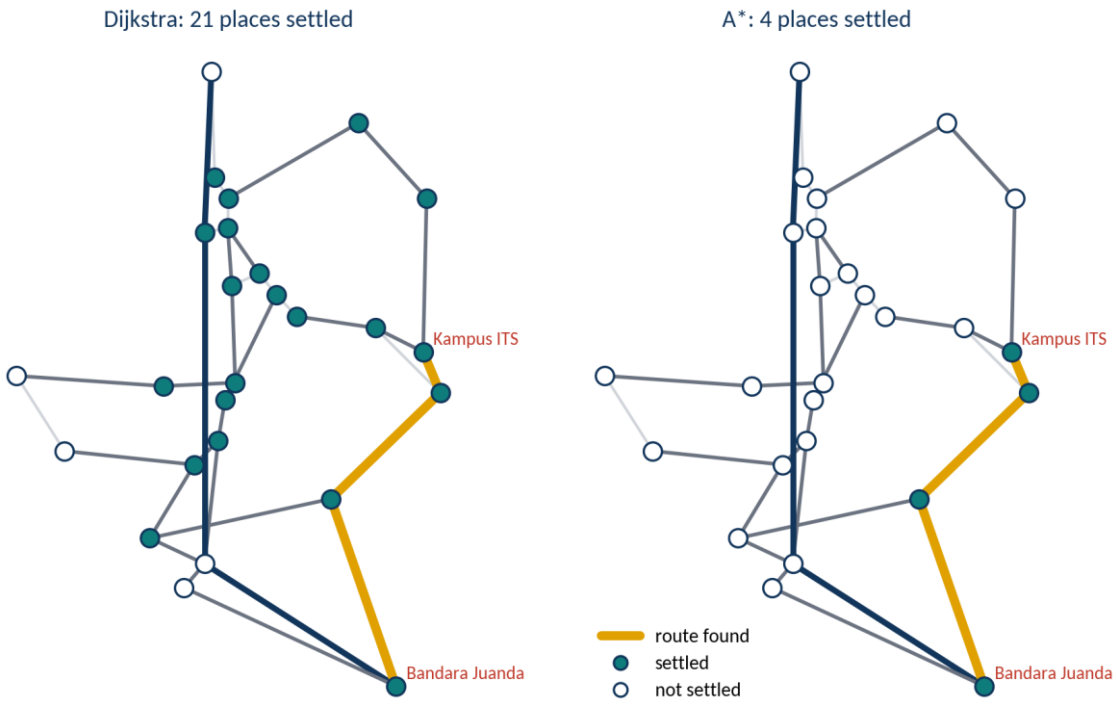

Figure 8.2 The places settled (teal) while searching for the shortest route from ITS to Juanda: Dijkstra's algorithm settles almost the whole map, A* only the four places on the route.

One route is an anecdote, so **Listing 8.4** runs both algorithms on all $26 \times 25 = 650$ ordered pairs of places, for both weights.

Listing 8.4 `route_lab.py`: compares the work of Dijkstra's algorithm and A* on all 650 ordered pairs of places.

```
"""Compare Dijkstra and A* on every ordered pair of places."""
from citygraph import DETOUR, SPEED_KMH, CityGraph, haversine
from routes import KM, MINUTES, astar, dijkstra

def main():
    g = CityGraph()
    places = sorted(g.pos)
    top = max(SPEED_KMH.values())
    print(f"{len(places) * (len(places) - 1)} ordered pairs of places")
    print(f"{'weight':<8}{'Dijkstra settles':>18}{'A* settles':>12}"
          f"{'saving':>9}{'same cost':>11}")
    for label, weight, scale in (("km", KM, 1.0), ("minutes", MINUTES, 60 / top)):
        d_total = a_total = same = pairs = 0
        for s in places:
            for t in places:
                if s == t:
                    continue
                h = lambda p: DETOUR * haversine(g.pos[p], g.pos[t]) * scale
                _, cost_d, set_d = dijkstra(g, s, t, weight)
                _, cost_a, set_a = astar(g, s, t, weight, h)
                d_total += len(set_d)
                a_total += len(set_a)
                same += abs(cost_d - cost_a) < 1e-9
                pairs += 1
        print(f"{label:<8}{d_total / pairs:>18.1f}{a_total / pairs:>12.1f}"
              f"{1 - a_total / d_total:>9.0%}{same:>7}/{pairs}")

if __name__ == "__main__":
    main()
```

The heuristic is created inside the loop as a `lambda` that uses the current goal `t`; `scale` converts kilometers into minutes at top speed for the time weight, which is Equation (8.6). The whole run takes a fraction of a second:

```
650 ordered pairs of places
weight    Dijkstra settles  A* settles   saving  same cost
km                    14.0         6.3      55%    650/650
minutes               14.0         9.9      30%    650/650
```

Over all pairs, Dijkstra's algorithm settled 14 places on average before reaching the goal. A* settled 6.3 for kilometers, a saving of 55 percent, and 9.9 for minutes, a saving of 30 percent. In all 1,300 searches both algorithms found routes of exactly the same cost, which is the practical proof that the heuristics are admissible. On a map with a million junctions instead of 26, the same percentages mean the difference between an answer in a fraction of a second and a noticeable wait.

8.7 Testing It

Listing 8.5 checks the distance formula against the known length of a degree of latitude, the symmetry of the roads, the admissibility of the heuristic on all 650 pairs, and two known routes.

Listing 8.5 `test_routes.py`: tests of the haversine formula, the graph, the admissibility of the heuristic and two known routes.

```
"""Tests for the Surabaya route planner. Run: python -m unittest -v"""
import itertools
import unittest

from citygraph import DETOUR, CityGraph, haversine
from routes import KM, MINUTES, astar, dijkstra

G = CityGraph()

class RouteTests(unittest.TestCase):
    def test_haversine(self):
        # one degree of latitude is about 111.2 km everywhere
        self.assertAlmostEqual(haversine((0, 0), (1, 0)), 111.19, places=2)

    def test_graph(self):
        self.assertEqual(len(G.pos), 26)
        self.assertEqual(G.find("juanda"), "JUA")
        for a, edges in G.adj.items():          # every road goes both ways
            for b, km, _ in edges:
                self.assertIn(a, [e[0] for e in G.adj[b]])

    def test_heuristic_is_admissible(self):
        for s, t in itertools.permutations(G.pos, 2):
            _, cost, _ = dijkstra(G, s, t, KM)
            self.assertLessEqual(DETOUR * haversine(G.pos[s], G.pos[t]),
                                 cost + 1e-9)

    def test_known_route(self):
        path, cost, _ = dijkstra(G, "ITS", "JUA", KM)
        self.assertEqual(path, ["ITS", "KPT", "RKT", "JUA"])
        self.assertAlmostEqual(cost, 16.8)

    def test_fastest_uses_toll(self):
        path, _, _ = astar(G, "PRK", "JUA", MINUTES)
        self.assertEqual(path, ["PRK", "PTR", "WAR", "JUA"])

if __name__ == "__main__":
    unittest.main()
```

`itertools.permutations(G.pos, 2)` produces every ordered pair of different places. The test of admissibility is the one that caught the rounding error described in Section 8.3.5; the small tolerance `1e-9` absorbs the last-digit errors of floating-point arithmetic.

```
test_fastest_uses_toll (test_routes.RouteTests.test_fastest_uses_toll) ... ok
test_graph (test_routes.RouteTests.test_graph) ... ok
test_haversine (test_routes.RouteTests.test_haversine) ... ok
test_heuristic_is_admissible (test_routes.RouteTests.test_heuristic_is_admissible) ... ok
test_known_route (test_routes.RouteTests.test_known_route) ... ok

----------------------------------------------------------------------
Ran 5 tests in 0.029s

OK
```

8.8 Improving It

Real map data. OpenStreetMap, the free, collaboratively made world map, contains Surabaya's streets with their geometry, one-way restrictions and road classes, under an open license [5]. Exporting the city's road network and loading it into `CityGraph` would turn this toy into a real planner, with tens of thousands of junctions; the algorithms would not change.

One-way streets and turn costs. Many central streets in Surabaya are one-way. Add a column to `roads.csv` and add only one direction for those roads. Left turns across traffic and U-turns can be given extra cost by modeling junction arms as separate nodes.

Time-dependent travel times. A road's speed at 7:00 differs from its speed at 13:00. Time-dependent Dijkstra lets the weight of a road depend on the time at which it is entered, which still works as long as leaving later never lets you arrive earlier.

Faster queries. Navigation services pre-process the map once so that each query touches only a few hundred nodes, with techniques such as *contraction hierarchies* and landmark-based heuristics (ALT), which replace the straight line by much tighter lower bounds.

Many stops. A van that visits ten customers must also choose the *order* of the visits. That is the travelling salesman problem, whose route lengths come from exactly this chapter's shortest paths; Chapter 77 builds a delivery-route agent for it.

8.9 Common Mistakes, and How to Avoid Them

Negative weights. Dijkstra's algorithm requires non-negative weights; the proof of Equation (8.4) fails without them. Discounts or rewards on a route must be modeled differently (for example with the Bellman-Ford algorithm).

Stopping when the goal is discovered instead of settled. The first time the goal is *reached* as a neighbor, its cost may not be final; a cheaper route may still come through a place not yet settled. Stop only when the goal is taken out of the priority queue, as line 7 of **Pseudocode 8.1** does.

Mixing units. A heuristic in kilometers combined with weights in minutes gives nonsense. Scale the heuristic to the unit of the weights, as Equation (8.6) does.

Using latitude and longitude as flat coordinates. One degree of longitude near Surabaya is about 110 km, one degree of latitude about 111 km, but near the poles a degree of longitude shrinks toward zero. Use the haversine formula, or at least scale longitude by $\cos\varphi$, rather than the plain Euclidean distance between degrees.

Rounding that breaks admissibility. As Section 8.3.5 showed, rounding weights to the nearest value can make them smaller than the heuristic. Round up, or compare the heuristic with the rounded weights in a test.

Forgetting that roads go both ways, or that some do not. A graph built with one direction per road can make half the city unreachable; one built with two directions for one-way streets sends cars the wrong way. Test that every road a user expects to use in both directions appears twice in the adjacency list.

8.10 Chapter Summary

- A road map is a weighted graph; our Surabaya map has 26 places and 36 roads, with lengths from the haversine formula (Equation (8.1)) and a detour factor, and times from typical speeds (Equation (8.2)).
- Dijkstra's algorithm settles places in order of their cost from the start and relaxes roads (Equation (8.3)); with non-negative weights a settled cost is final (Equation (8.4)).
- A* adds a straight-line estimate (Equation (8.5), Equation (8.6)); it is consistent by the triangle inequality (Equation (8.7)), but only if road lengths are never rounded below it.

- Between Keputih and Wiyung, the shortest route is 22.4 km through the center and the fastest 47.0 minutes around the south.
- A search costs $O((|V| + |E|)\log|V|)$ (Equation (8.8)); over 650 pairs, A* settled 55 percent fewer places than Dijkstra's algorithm for distance and 30 percent fewer for time, always with the same cost.

8.11 Exercises

1. Using Equation (8.1), compute by hand (with a calculator) the straight-line distance between Tugu Pahlawan and Tunjungan Plaza from the coordinates in `places.csv`.
2. By Equation (8.2), how long does the program say the toll road from Stasiun Pasar Turi to Bundaran Waru takes, if its length is 14.1 km?
3. In **Table 8.1**, why is Pantai Kenjeran settled by Dijkstra's algorithm but never by A*? Answer with the numbers in the table.
4. Mark the roads JMB–TUG and TUG–BLK as one-way (only in the direction written) and find how the routes from Balai Kota to Jembatan Merah change.
5. Replace the detour factor in the heuristic by 1.5 (keeping 1.3 for the roads). Run `route_lab.py`. What happens to the savings and to the "same cost" column, and why?
6. Add a road from Galaxy Mall to Taman Bungkul (arterial). Which routes change, and does A* still agree with Dijkstra's algorithm?
7. Write `nearest_outlet(place)`, which returns the Profitina Laundry outlet with the shortest route to a given place, and use it to assign every place on the map to an outlet.

8.12 Solutions to the Exercises

1. Tugu Pahlawan is at $(-7.2458, 112.7378)$ and Tunjungan Plaza at $(-7.2626, 112.7390)$. The differences are $\Delta\varphi = -0.0168°$ and $\Delta\lambda = 0.0012°$, that is -0.000293 and 0.0000209 radians. Then $\sin^2(\Delta\varphi/2) \approx 2.15 \times 10^{-8}$, and $\cos\varphi_1 \cos\varphi_2 \sin^2(\Delta\lambda/2) \approx 0.984 \times 1.09 \times 10^{-10} \approx 1.07 \times 10^{-10}$. The square root of their sum is about 1.470×10^{-4}, and $d \approx 2 \times 6371 \times 1.470 \times 10^{-4} \approx 1.87$ km.

2. $t = 14.1/70 \times 60 \approx 12.09$ minutes, which the program rounds up to 12.1; `python route_app.py PRK juanda`, whose fastest route uses this toll road, prints exactly 14.1 km and 12.1 minutes for that leg.

3. Kenjeran is 6.6 km from ITS, less than the 16.8 km to Juanda, so Dijkstra's algorithm, which only looks at g, settles it on the way. A* looks at f: Kenjeran's $f = 6.6 + 20.7 = 27.3$ is larger than Juanda's final $f = 16.8$, so A* finishes before Kenjeran reaches the front of the queue.

4. Add a column `oneway` to `roads.csv` and change the loop in `CityGraph.__init__` so that it always adds `(b, …)` to `adj[a]`, but adds `(a, …)` to `adj[b]` only when `oneway` is `no`. Before the change, the shortest route from Balai Kota to Jembatan Merah is BLK, TUG, JMB, 3.7 km. With both roads one-way in the written direction, Balai Kota can no longer reach Tugu Pahlawan directly and Tugu Pahlawan can no longer reach Jembatan Merah, so the shortest route becomes BLK, TP, TUG, PTR, PRK, SMP, JMB: 17.3 km around the harbor. One-way streets can change routes dramatically, which is why real planners must know them.

5. A factor of 1.5 makes the heuristic larger than the true remaining distance for some places (the roads use only 1.3), so it is no longer admissible. In our run the saving for kilometers rose from 55

to 58 percent, because A* is pushed harder toward the goal, but the "same cost" count fell from 650 to 637: for 13 pairs A* returned a longer route than Dijkstra's algorithm. This is the weighted A* trade-off of Chapter 3, obtained by accident.

6. Add the line `GXY,BKL,arterial` to `roads.csv`; the program computes its length as 6.4 km. In our run the shortest distance changed for 70 of the 650 ordered pairs, mostly between the east and north-east (Kenjeran, ITS, Galaxy Mall) and the south and west (Bungkul, the zoo, Royal Plaza, Wiyung); Kenjeran to Taman Bungkul, for example, fell from 18.7 to 15.3 km. A* still agreed with Dijkstra's algorithm on all 650 pairs, because the new road's length is rounded up like the others.

7. One possible solution:

```
def nearest_outlet(g, place):
    outlets = ["KPT", "RKT", "WIY"]
    return min(outlets, key=lambda o: dijkstra(g, place, o, KM)[1])
```

A single run of Dijkstra's algorithm from each outlet, without a goal, would be faster: it gives the distance from that outlet to every place at once, and each place is then assigned to the outlet with the smallest distance.

Chapter 9

A Genetic Algorithm Scheduler

Some problems have far too many possible answers to search systematically and no neat rule that always finds the best. Deciding the order in which a laundry processes the day's orders is one of them: twenty jobs can be put in more than two billion billion orders. In this chapter we let the answers *evolve*. A *genetic algorithm* keeps a population of candidate schedules, lets the better ones "reproduce" by combining their parts, adds small random changes, and repeats for a couple of hundred generations, imitating natural selection. By the end of the chapter you will be able to encode a schedule as a permutation, decode it into start and finish times on parallel work stations, measure its quality as weighted tardiness, implement tournament selection, order crossover, swap mutation and elitism, compare a genetic algorithm with a simple rule and with random search on real laundry orders, check it against the true optimum on a small instance, and judge when a genetic algorithm is the right tool.

9.1 A Busy Saturday at Rungkut

It is Saturday morning at the Rungkut outlet of Profitina Laundry. Twenty orders are waiting: bags of clothes to wash, dry and fold, express orders that customers want back before lunch, a suit and a kebaya for dry cleaning, bed covers, a pair of shoes. One of the three washing stations is out of service for maintenance, so two stations must do everything. Customers have been promised pick-up times, and every minute an order is late at the counter is a minute a customer waits, or leaves unhappy. Express orders count three times as much, because those customers paid extra.

Which order should the staff take next? Experienced staff use rules of thumb: "the most urgent first", "the quick ones first". Such rules are fast and often good, but they are not always best, because they look at one order at a time and ignore how the choices interact. A perfect answer would require trying every possible sequence, which for twenty orders is out of the question, as we will compute in a moment.

A genetic algorithm takes a middle road; it belongs to the family of local and evolutionary search methods surveyed by Russell and Norvig [1]. Invented by John Holland in the 1960s and 1970s [2] and popularized by David Goldberg's textbook [3], it borrows three ideas from biology: a *population* of different solutions, *selection* of the fitter ones as parents, and *variation* by recombination and mutation. Genetic algorithms, and evolutionary methods more generally, are used for timetables, vehicle routes, antenna shapes, factory schedules and machine-learning model designs, wherever the space of possibilities is huge and a good answer is worth more than a proof of the best one.

9.2 The Idea in Plain Words

A *schedule* here is simply an *order* of the jobs. Given an order, the stations work as a becak rank works at a busy market: whenever a station becomes free, it takes the next job in the list. So the order decides everything: which station does which job, when each job starts and when it finishes. We call the order the *chromosome*, and its entries the *genes*.

The *fitness* of an order is how late the jobs finish, in total, counting express minutes three times. Lower is better.

The algorithm keeps 60 orders, the *population*, starting with random ones. Each *generation* it builds a new population:

1. **Selection.** Pick three orders at random and let the best of them be a parent. This *tournament* is repeated for the second parent. Good orders win tournaments more often, but even mediocre ones sometimes get a chance, which keeps the population varied.
2. **Crossover.** Combine the two parents into a child: copy a stretch of the first parent unchanged, and fill the remaining positions with the missing jobs in the order in which they appear in the second parent. The child inherits a block of good decisions from one parent and the general order of the other.
3. **Mutation.** Occasionally swap two jobs in the child, so that the population keeps exploring new orders.
4. **Elitism.** Copy the two best orders of the old population into the new one unchanged, so that the best solution found so far is never lost.

Picture a group of becak drivers trying to find good routes around the city. Each evening they compare how long their routes took; the drivers with the quicker routes share them, a new driver combines the first half of one route with the second half of another, and now and then someone tries a small detour just to see. After a few weeks the group's routes are much better than any one driver's first guess, although nobody ever computed the best route.

9.3 The Math, Gently

9.3.1 From an order to a schedule

Let the jobs be numbered $1, \dots, n$; job j needs p_j minutes, is due d_j minutes after opening, and has weight w_j (3 for express, 1 otherwise). An order $\pi = (\pi_1, \dots, \pi_n)$ is a permutation of the jobs. With m stations, all free at time 0, the *list-scheduling* rule takes the jobs in order and starts each on the station that becomes free first. If that station is free at time S, the job's completion time is

$$C_{\pi_k} = S + p_{\pi_k}, \qquad S = \min_{\text{stations}} (\text{time the station is free}) \tag{9.1}$$

and that station is then busy until C_{π_k}.

9.3.2 Weighted tardiness

A job is late by $\max(0, C_j - d_j)$ minutes: zero if it finishes on time, otherwise the minutes by which it misses its due time. The cost of an order is the *total weighted tardiness*

$$T(\pi) = \sum_{j=1}^{n} w_j \max(0,\ C_j - d_j) \tag{9.2}$$

A small worked example shows how it is computed. Take three jobs on two stations: job a takes 30 minutes and is due at 30; job b takes 20 minutes, is due at 20 and has weight 2; job c takes 40 minutes and is due at 45. In the order (a, b, c), job a starts on station 1 at time 0 and ends at 30; job b starts on station 2 at 0 and ends at 20; station 2 is free first, at 20, so job c starts there and

ends at 60. Only c is late, by $60 - 45 = 15$ minutes, so $T = 1 \times 15 = 15$. The test in Section 9.7 checks exactly this example.

Minimizing Equation (9.2) on parallel machines is *NP-hard*: no algorithm is known that finds the optimum in time that grows only polynomially with the number of jobs, and most researchers believe none exists [4].

9.3.3 How many orders are there?

The first job can be any of the n, the second any of the remaining $n - 1$, and so on, so there are

$$n! = n \times (n - 1) \times \cdots \times 1 \tag{9.3}$$

orders. For our 20 jobs that is $20! \approx 2.4 \times 10^{18}$. Evaluating a billion orders per second, trying them all would take about 77 years. For 9 jobs, however, it is only $9! = 362{,}880$, which a laptop tries in a few seconds; we use such a small instance in Section 9.6 to check the genetic algorithm against the true optimum.

9.3.4 Selection pressure

In a tournament of size k drawn from a population of N, how often does the single best individual become a parent? It becomes a parent whenever it is among the k drawn, and the probability of that is

$$P(\text{best is chosen}) = 1 - \frac{\binom{N-1}{k}}{\binom{N}{k}} = \frac{k}{N} \tag{9.4}$$

where $\binom{N}{k}$, read "N choose k", is the number of ways to choose k individuals out of N. With $k = 3$ and $N = 60$ that is $3/60 = 5\%$ per tournament, or about three times the $1/60$ of a purely random choice. The *worst* individual can never win a tournament, and middling individuals win sometimes. The tournament size is the knob that sets this *selection pressure*: a larger k favors the best more strongly and converges faster, at the risk of the whole population becoming copies of one early leader.

9.3.5 The cost of the search

Each generation evaluates the whole population once, so a run with population N and G generations evaluates

$$E = N\,(G + 1) \tag{9.5}$$

orders, including the random first population. With $N = 60$ and $G = 200$ that is $60 \times 201 = 12{,}060$ evaluations, a vanishing fraction, about 5×10^{-15}, of the 20! orders. For a fair comparison, the random-search baseline in Section 9.6 gets exactly the same number of evaluations.

9.3.6 Why does crossover help?

Random search in Section 9.6 will try as many orders as the genetic algorithm and do far worse, so what does the genetic algorithm know that random search does not? The usual explanation is Holland's *building-block hypothesis* [2]. A good order of the jobs contains good *parts*: "the three express orders early, one on each station", "the long bed-cover jobs not back to back on the same station", "the big wash after the lunch rush". Tournament selection makes orders that contain

such parts more likely to become parents; order crossover copies a whole slice of one parent, and so a whole good part, into the child, while filling the rest in the relative order of the other parent, which keeps that parent's good parts roughly intact as well. A child can therefore combine a good beginning found by one lineage with a good ending found by another, something random search can never do, because it never remembers anything.

Mutation plays a complementary role. Without it, a population could only rearrange the parts its first random members happened to contain; with it, every job can eventually move to every position. Elitism, finally, makes the progress of the best solution a ratchet: it can go up, never down.

The hypothesis is an explanation, not a theorem, and there are problems on which crossover helps little. The honest test is empirical, which is why this chapter compares the genetic algorithm with random search under the same budget, with a simple rule, and, on a small instance, with the proven optimum.

9.4 The Algorithm as Pseudocode

Pseudocode 9.1 summarizes the genetic algorithm used in this chapter; **Table 9.1** lists its settings.

Pseudocode 9.1 The genetic algorithm: tournament selection, order crossover, swap mutation and elitism.

```
GENETIC-ALGORITHM(cost, n)
1  population = 60 random permutations of 1..n
2  repeat for 200 generations
3      new = copies of the 2 best members of population      // elitism
4      while new has fewer than 60 members
5          p1 = best of 3 random members; p2 = the same      // tournaments
6          child = ORDER-CROSSOVER(p1, p2) with probability 0.9, else a copy of p1
7          with probability 0.3: swap two random positions of child
8          add child to new
9      population = new
10 return the member of population with the smallest cost
```

Table 9.1 The settings of the genetic algorithm, as defaults of `genetic_algorithm`.

Setting	Value	Role
population size N	60	how many orders are kept at once
generations G	200	how long evolution runs
tournament size k	3	selection pressure, Equation (9.4)
crossover probability	0.9	how often a child combines two parents
mutation probability	0.3	how often a child gets a random swap
elite	2	best orders carried over unchanged

Order crossover (OX), in line 6, is designed for permutations. An ordinary crossover that copies the first half of one parent and the second half of the other would produce an invalid order in which some jobs appear twice and others not at all. **Figure 9.1** shows how OX avoids this: it copies a random slice of the first parent into the same positions of the child, and fills the other positions, from left to right, with the missing jobs in the order in which they appear in the second parent [5].

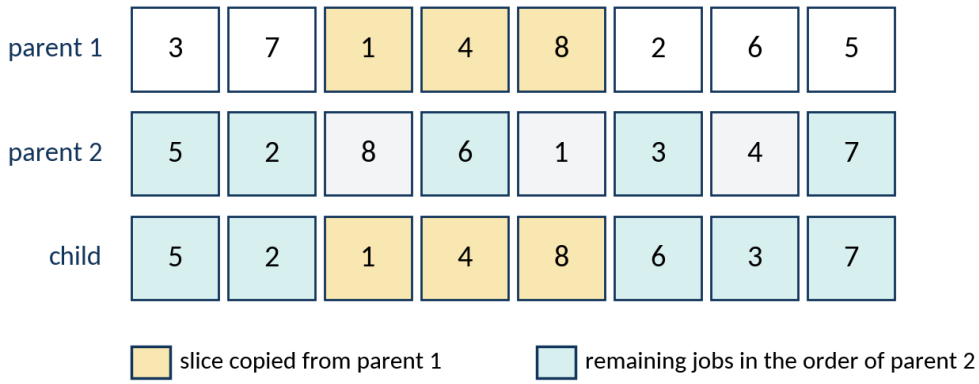

Figure 9.1 Order crossover on eight jobs: the slice 1, 4, 8 is copied from parent 1, and the remaining jobs 5, 2, 6, 3, 7 are filled in the order in which they appear in parent 2.

9.5 Building the Scheduler Step by Step

9.5.1 The jobs

The jobs are twenty real orders from the sample data of Profitina Laundry: the last twenty orders received at the Rungkut outlet between March 27 and 31, 2026, with their service and quantity. The processing time of each job follows from a simple model of the services, shown in **Table 9.2**; the pick-up times, in minutes after the 08:00 opening, were drawn at random with a fixed seed for this lesson, with express orders due before noon.

Table 9.2 The processing-time model used to turn orders into jobs.

Service	Minutes
S0001 wash, dry and fold; S0002 express	20 + 8 per kg
S0003 ironing	12 per kg
S0004 dry cleaning, shirt	25 per item
S0005 dry cleaning, suit	60 per item
S0006 dry cleaning, dress or kebaya	45 per item
S0007 dry cleaning, jacket	40 per item
S0008 bed cover	70 per item

```

B1469,S0004,2,50,420,1
```

The twenty jobs need 1,245 minutes of work, so two stations need at least $1245/2 = 622.5$ minutes, more than ten hours, to finish them; since the last pick-ups are at 17:00, nine hours after opening, some lateness is unavoidable, and the question is how little.

9.5.2 Decoding and cost

Listing 9.1 turns an order into a schedule and measures its cost.

Listing 9.1 `scheduler.py`: reading the jobs, list scheduling on parallel stations, weighted tardiness and the earliest-due-date rule.

```
"""Laundry jobs on parallel stations: decode an order into a schedule and
measure how late the jobs finish (total weighted tardiness)."""
import csv
import heapq
from collections import namedtuple
from pathlib import Path

Job = namedtuple("Job", "name service units minutes due weight")
DAY_START = 8 * 60                              # the shop opens at 08:00

def load_jobs(path=Path(__file__).parent / "data" / "jobs.csv"):
    with open(path, encoding="utf8") as f:
        return [Job(r["job"], r["service"], int(r["units"]), int(r["minutes"]),
                    int(r["due"]), int(r["weight"])) for r in csv.DictReader(f)]

def decode(order, jobs, stations=2):
    """Give each job, in the given order, to the station that is free first.

    Returns a list of (job index, station, start, end) in minutes after 08:00.
    """
    free = [(0, s) for s in range(stations)]  # (time the station is free, id)
    plan = []
    for j in order:
        start, s = heapq.heappop(free)
        end = start + jobs[j].minutes
        plan.append((j, s, start, end))
        heapq.heappush(free, (end, s))
    return plan

def tardiness(order, jobs, stations=2):
    """Total weighted minutes late: sum of weight * max(0, end - due)."""
    return sum(jobs[j].weight * max(0, end - jobs[j].due)
               for j, _, _, end in decode(order, jobs, stations))

def edd(jobs):
    """Earliest-due-date rule: the most urgent job first."""
    return sorted(range(len(jobs)), key=lambda j: (jobs[j].due, j))
```

Listing 9.1 (Continued) *scheduler.py: reading the jobs, list scheduling on parallel stations, weighted tardiness and the earliest-due-date rule.*

```
def clock(minutes):
    """Minutes after opening -> 'hh:mm'."""
    t = DAY_START + minutes
    return f"{t // 60:02d}:{t % 60:02d}"
```

`Job` is a *named tuple*: a tuple whose fields also have names, so that `job.minutes` reads better than `job[3]`. `decode` implements Equation (9.1) with a heap of `(free time, station)` pairs: `heappop` gives the station that is free first, and after the job is placed the station goes back into the heap with its new free time. Ties are broken by the station number, so station 1 is used first when several are free, which makes the schedule reproducible. `tardiness` is Equation (9.2) as a one-line sum.

`edd` is the classic *earliest due date* rule: sort the jobs by due time. It is the rule of thumb an experienced worker would use, and it is our first baseline. `clock` converts minutes after opening into a time of day for printing.

9.5.3 The genetic algorithm

Listing 9.2 is the genetic algorithm. It knows nothing about laundry: it minimizes any function `cost` of a permutation, which means it can be reused for any ordering problem.

Listing 9.2 `ga.py`: order crossover, swap mutation, the genetic algorithm of **Pseudocode 9.1**, and random search as a baseline.

```
"""A genetic algorithm for permutation problems: tournament selection,
order crossover, swap mutation and elitism."""
import random

def order_crossover(p1, p2, rng):
    """OX: copy a slice of p1, fill the rest in the order the jobs appear in p2."""
    n = len(p1)
    a, b = sorted(rng.sample(range(n), 2))
    child = [None] * n
    child[a:b + 1] = p1[a:b + 1]
    kept = set(p1[a:b + 1])
    rest = [g for g in p2 if g not in kept]
    for i in list(range(0, a)) + list(range(b + 1, n)):
        child[i] = rest.pop(0)
    return child

def swap_mutation(order, rng):
    i, j = rng.sample(range(len(order)), 2)
    order[i], order[j] = order[j], order[i]

def genetic_algorithm(cost, n, pop_size=60, generations=200, tournament=3,
                      p_cross=0.9, p_mut=0.3, elite=2, seed=1):
    """Minimize cost(permutation of range(n)). Returns (best, history, evals)."""
    rng = random.Random(seed)
    pop = [rng.sample(range(n), n) for _ in range(pop_size)]
    fit = [cost(p) for p in pop]
    evals = pop_size
    history = []                                # (best, average) per generation

    def pick():                                 # tournament: best of k random
        contenders = rng.sample(range(pop_size), tournament)
        return pop[min(contenders, key=lambda i: fit[i])]
```

Listing 9.2 (Continued) *ga.py: order crossover, swap mutation, the genetic algorithm of Pseudocode 9.1, and random search as a baseline.*

```
    for _ in range(generations):
        ranked = sorted(range(pop_size), key=lambda i: fit[i])
        new = [pop[i][:] for i in ranked[:elite]]   # elitism: keep the best
        while len(new) < pop_size:
            p1, p2 = pick(), pick()
            child = order_crossover(p1, p2, rng) if rng.random() < p_cross \
                else p1[:]
            if rng.random() < p_mut:
                swap_mutation(child, rng)
            new.append(child)
        pop = new
        fit = [cost(p) for p in pop]
        evals += pop_size
        history.append((min(fit), sum(fit) / pop_size))
    best = min(range(pop_size), key=lambda i: fit[i])
    return pop[best], history, evals

def random_search(cost, n, evals, seed=1):
    """The baseline: try `evals` random permutations and keep the best."""
    rng = random.Random(seed)
    best, best_cost = None, float("inf")
    for _ in range(evals):
        p = rng.sample(range(n), n)
        c = cost(p)
        if c < best_cost:
            best, best_cost = p, c
    return best, best_cost
```

`order_crossover` chooses the slice `a..b` with `rng.sample(range(n), 2)`, two different positions, sorted. It copies the slice, collects the other jobs in the order of the second parent with a list comprehension, and fills the free positions left to right. `swap_mutation` changes the list in place.

`genetic_algorithm` follows **Pseudocode 9.1**. The population is a list of lists and `fit` holds their costs, computed once per individual per generation. The inner function `pick` is the tournament: `rng.sample(range(pop_size), tournament)` draws three different indexes and `min(..., key=...)` returns the one with the lowest cost. The first `elite` members of the sorted ranking are copied with `[:]`, which makes a real copy of each list, so that later mutations of a child can never change an elite parent by accident. The line ending in a backslash continues on the next line, a way of keeping long expressions within the page width. `history` records the best and the average cost of each generation for the plot in Section 9.6, and the function returns the number of evaluations, which is Equation (9.5).

`random_search` is the simplest possible competitor: it tries the given number of random orders and keeps the best.

9.5.4 The application

Listing 9.3 runs the three methods on the day's jobs and prints the genetic algorithm's schedule station by station.

Listing 9.3 `schedule_app.py`: the EDD rule, random search and the genetic algorithm on the twenty jobs, and the resulting schedule.

```
"""Schedule one day of laundry jobs on 2 stations and compare three methods."""
import time

from ga import genetic_algorithm, random_search
from scheduler import clock, decode, edd, load_jobs, tardiness

def main():
    jobs = load_jobs()
    cost = lambda order: tardiness(order, jobs)
    print(f"{len(jobs)} jobs, {sum(j.minutes for j in jobs)} minutes of work, "
          "2 stations")
    t0 = time.perf_counter()
    best, history, evals = genetic_algorithm(cost, len(jobs), seed=1)
    secs = time.perf_counter() - t0
    _, rnd_cost = random_search(cost, len(jobs), evals, seed=1)
    print(f"{'method':<34}{'weighted minutes late':>22}")
    print(f"{'earliest due date (EDD) rule':<34}{cost(edd(jobs)):>22}")
    print(f"{'random search, ' + format(evals, ',') + ' tries':<34}{rnd_cost:>22}")
    print(f"{'genetic algorithm, 200 generations':<34}{cost(best):>22}")
    print(f"GA time: {secs:.1f} s; best after generations 1, 10, 50, 200: "
          + ", ".join(str(history[g - 1][0]) for g in (1, 10, 50, 200)))
    print("\nGA schedule (start-end, due, minutes late x weight):")
    plan = sorted(decode(best, jobs), key=lambda t: (t[1], t[2]))
    for j, s, start, end in plan:
        job = jobs[j]
        late = max(0, end - job.due) * job.weight
        note = f"  late {late}" if late else ""
        print(f"  station {s + 1}  {clock(start)}-{clock(end)}  {job.name} "
              f"{job.service} due {clock(job.due)}{note}")

if __name__ == "__main__":
    main()
```

9.6 Running It

```
(.venv) $ python schedule_app.py
```

```
20 jobs, 1245 minutes of work, 2 stations
method                            weighted minutes late
earliest due date (EDD) rule                        401
random search, 12,060 tries                         678
genetic algorithm, 200 generations                  303
GA time: 0.3 s; best after generations 1, 10, 50, 200: 641, 436, 307, 303

GA schedule (start-end, due, minutes late x weight):
  station 1  08:00-09:00  B1446 S0005 due 12:00
  station 1  09:00-09:44  B1460 S0002 due 10:30
  station 1  09:44-10:44  B1458 S0001 due 12:00

  station 2  13:58-14:58  B1455 S0001 due 15:00
  station 2  14:58-15:58  B1454 S0001 due 16:00
  station 2  15:58-16:50  B1461 S0001 due 17:00
  station 2  16:50-18:30  B1441 S0004 due 17:00  late 90
```

The earliest-due-date rule leaves 401 weighted minutes of lateness. Random search, with the same 12,060 evaluations as the genetic algorithm, does much worse, 678: blind luck rarely stumbles on a good order among 2.4×10^{18}. The genetic algorithm reaches 303, a quarter less than the rule of thumb, in about a third of a second. The best cost after generations 1, 10, 50 and 200 shows how it got there: 641 in the random first generation, 436 after ten generations, 307 after fifty, and then only small refinements.

Figure 9.2 draws the whole run. The best cost falls steeply in the first thirty generations and then levels off; the average cost of the population falls with it but stays higher, because mutation keeps adding worse variants, which is exactly what keeps the search exploring.

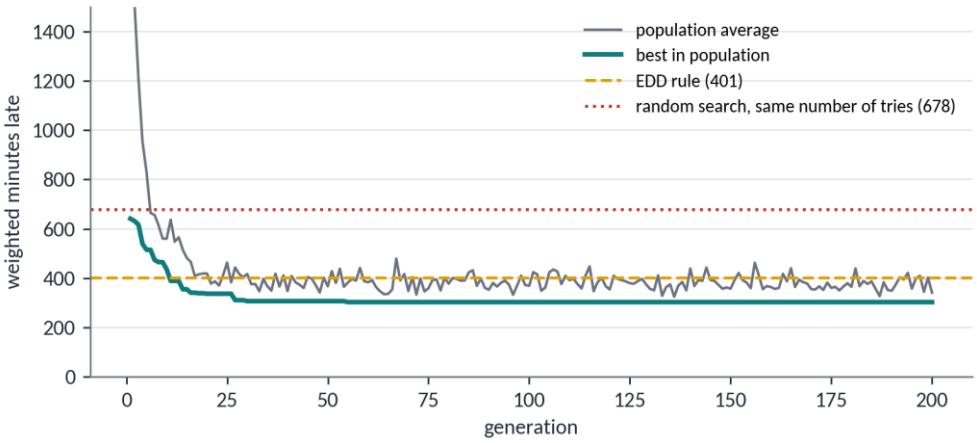

Figure 9.2 The best and average cost in each generation of the run above, compared with the EDD rule and with random search given the same number of evaluations.

Figure 9.3 draws the schedule as a *Gantt chart*, one row per station and one bar per job, with each job's due time marked above its bar. All express orders (B1460, B1465 and B1437) are finished by 10:00. Three jobs are late: the jacket B1432 by 18 minutes, the shirts B1441 by 90

minutes, and the large wash B1427 by 195 minutes. The algorithm has deliberately pushed a few long, low-weight jobs to the end of the day to keep everything else on time; a manager could see from the chart that one more station for the afternoon, or an earlier pick-up promise for B1427, would remove most of the lateness.

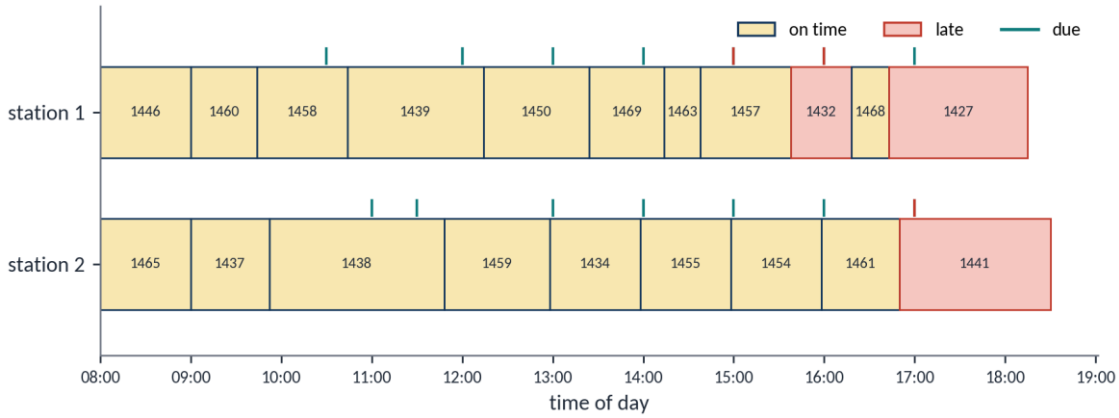

Figure 9.3 The genetic algorithm's schedule for the two stations (job numbers without the letter B); late jobs are red, and the ticks above the bars mark the due times.

Is 303 good? One run is not enough to tell, because a genetic algorithm is random. **Listing 9.4** repeats the comparison with ten different seeds and, to know the true optimum, solves a smaller instance, the first nine jobs on one station, by trying all 9! = 362,880 orders.

Listing 9.4 `ga_lab.py`: ten runs of the genetic algorithm and of random search, and a check against the exact optimum of a 9-job instance.

```
"""How reliable is the GA? Ten runs on the day's jobs, and a small instance
(9 jobs, 1 station) whose optimum is found by trying all 9! = 362,880 orders."""
import itertools
import statistics

from ga import genetic_algorithm, random_search
from scheduler import edd, load_jobs, tardiness

def main():
    jobs = load_jobs()
    cost = lambda order: tardiness(order, jobs)
    ga_costs, rnd_costs = [], []
    for seed in range(1, 11):
        best, _, evals = genetic_algorithm(cost, len(jobs), seed=seed)
        ga_costs.append(cost(best))
        rnd_costs.append(random_search(cost, len(jobs), evals, seed=seed)[1])
    print(f"20 jobs, 10 seeds: EDD {cost(edd(jobs))}")
    for name, c in (("GA", ga_costs), ("random search", rnd_costs)):
        print(f"  {name:<14} best {min(c)}, median {statistics.median(c)}, "
              f"worst {max(c)}")

    small = jobs[:9]                            # the first 9 jobs, one station
    small_cost = lambda order: tardiness(order, small, stations=1)
    optimum = min(small_cost(p) for p in itertools.permutations(range(9)))
    found = [small_cost(genetic_algorithm(small_cost, 9, generations=60,
                                          seed=seed)[0]) for seed in range(1, 11)]
    print(f"9 jobs, 1 station: optimum {optimum} (all 362,880 orders tried), "
          f"EDD {small_cost(edd(small))}")
    print(f"  GA runs: {found}; optimum found in "
          f"{sum(c == optimum for c in found)}/10")

if __name__ == "__main__":
    main()
```

The whole lab takes a few seconds, most of it for the exhaustive search:

```
20 jobs, 10 seeds: EDD 401
  GA             best 301, median 302.0, worst 405
  random search  best 592, median 665.0, worst 724
9 jobs, 1 station: optimum 408 (all 362,880 orders tried), EDD 484
  GA runs: [408, 408, 408, 408, 408, 408, 408, 408, 408, 432]; optimum found in 9/10
```

Over ten seeds the genetic algorithm's median is 302, and its best 301; random search's median is 665. One of the ten runs, however, ended at 405, slightly *worse* than the EDD rule: the population converged on a mediocre order early and never escaped. This is typical of genetic algorithms and has a typical remedy: run the algorithm several times with different seeds, or start the population with a few good orders such as the EDD order, and keep the best result. On the small instance the true optimum is 408, the EDD rule gives 484, and the genetic algorithm found the optimum in nine of ten runs, the tenth ending at 432. So on a problem where we can check, the genetic algorithm is usually optimal and always close, which gives some confidence that 301 is close to the best possible for the full day, although we cannot prove it.

9.7 Testing It

Listing 9.5 checks that crossover and mutation always produce valid permutations, the hand-worked example of Section 9.3.2, and that the genetic algorithm beats the EDD rule on the day's jobs without its best cost ever getting worse.

Listing 9.5 `test_ga.py`: tests for crossover, mutation, decoding and the behavior of the genetic algorithm.

```
"""Tests for the GA scheduler. Run: python -m unittest -v"""
import random
import unittest

from ga import genetic_algorithm, order_crossover, swap_mutation
from scheduler import Job, decode, edd, load_jobs, tardiness

class GATests(unittest.TestCase):
    def test_crossover_gives_a_permutation(self):
        rng = random.Random(0)
        for _ in range(100):
            p1, p2 = rng.sample(range(10), 10), rng.sample(range(10), 10)
            self.assertEqual(sorted(order_crossover(p1, p2, rng)), list(range(10)))

    def test_mutation_keeps_the_jobs(self):
        order = list(range(6))
        swap_mutation(order, random.Random(1))
        self.assertEqual(sorted(order), list(range(6)))
        self.assertNotEqual(order, list(range(6)))

    def test_decode_by_hand(self):
        jobs = [Job("a", "S", 1, 30, 30, 1), Job("b", "S", 1, 20, 20, 2),
                Job("c", "S", 1, 40, 45, 1)]
        plan = decode([0, 1, 2], jobs, stations=2)
        self.assertEqual(plan, [(0, 0, 0, 30), (1, 1, 0, 20), (2, 1, 20, 60)])
        self.assertEqual(tardiness([0, 1, 2], jobs, stations=2), 15)

    def test_ga_beats_edd_on_the_day(self):
        jobs = load_jobs()
        cost = lambda order: tardiness(order, jobs)
        best, history, _ = genetic_algorithm(cost, len(jobs), seed=1)
        self.assertLess(cost(best), cost(edd(jobs)))
        bests = [b for b, _ in history]
        self.assertEqual(bests, sorted(bests, reverse=True))  # never worse

if __name__ == "__main__":
    unittest.main()
```

The last test checks a consequence of elitism: because the two best orders survive every generation unchanged, the best cost in `history` can never increase. Sorting the list in descending order and comparing it with itself is a compact way to check that it never goes up.

9.8 Improving It

Seed the population. Put the EDD order, and a few small variations of it, into the first population. The algorithm then starts from a good solution rather than from random ones, and the bad run of Section 9.6 becomes much less likely.

Better mutation. Besides swapping two jobs, move one job to another position, or reverse a stretch of the order (*inversion*). Different mutations let the search take different kinds of small steps.

Local search inside the GA. After creating a child, try all swaps of neighboring jobs and keep any that lower the cost. Such *memetic algorithms* combine the broad exploration of the GA with the precision of hill climbing.

Adaptive settings. Start with a high mutation probability to explore, and lower it as the generations pass. Or run several populations, *islands*, that occasionally exchange their best members.

Richer schedules. Real laundries have stations of different kinds (washers, dryers, ironing tables), jobs that need several of them in sequence, and staff breaks. The chromosome can stay a permutation; only `decode` has to learn the new rules. That separation of the search from the problem is the genetic algorithm's greatest practical strength.

Know the alternatives. For small instances an exact method (such as the constraint solvers of Chapter 5 or integer programming) proves the optimum; for this particular problem well-designed dispatching rules come close to the GA at a fraction of the effort. A genetic algorithm is a good choice when the problem is too irregular for exact methods and there is no strong rule.

9.9 Common Mistakes, and How to Avoid Them

Invalid children. One-point crossover of the kind used for bit strings produces permutations with repeated and missing jobs. Use a crossover designed for permutations, such as OX, and test that every child is a permutation, as `test_crossover_gives_a_permutation` does.

Aliasing elite members. If an elite member is put into the new population without copying (`new.append(pop[i])` instead of `pop[i][:]`), a later in-place mutation of a child that happens to be the same list object changes the elite too, and the best solution is silently lost.

Comparing with an unfair baseline. A genetic algorithm that is compared with a single random order looks brilliant. Give baselines the same number of evaluations, as this chapter does with random search, and always compare with the simple rule that an expert would use.

Trusting one run. The GA is random; report several seeds, as `ga_lab.py` does, or at least try a few before trusting a result.

Premature convergence. Too large a tournament, too low a mutation rate, or too small a population lets one early good order take over the population, after which crossover only recombines copies of itself. Watch the average cost in **Figure 9.2**: if it collapses onto the best cost, diversity is gone.

Optimizing the wrong objective. The GA optimizes exactly Equation (9.2), including its weights. If express orders matter even more, or if a job must never be more than an hour late, the objective has to say so; the algorithm will happily exploit any loophole in it, as the very late job B1427 shows.

9.10 Chapter Summary

- A schedule is an order of the jobs; list scheduling turns it into start and completion times on parallel stations (Equation (9.1)), and its cost is the total weighted tardiness (Equation (9.2)).

- Twenty jobs have $20! \approx 2.4 \times 10^{18}$ orders (Equation (9.3)); the problem is NP-hard, so exhaustive search is impossible.
- The genetic algorithm (**Pseudocode 9.1**) evolves a population by tournament selection (Equation (9.4)), order crossover (**Figure 9.1**), swap mutation and elitism, using $N(G+1)$ evaluations (Equation (9.5)).
- On a real day of Rungkut orders with two stations it reached 303 weighted minutes of lateness against 401 for the earliest-due-date rule and 678 for random search with the same budget.
- Over ten seeds the median was 302, but one run ended at 405; on a 9-job instance with a known optimum of 408, the GA found the optimum in nine of ten runs.

9.11 Exercises

1. For the three jobs of Section 9.3.2, compute the weighted tardiness of the orders (b, a, c) and (c, b, a).
2. Using Equation (9.4), what is the probability that the best of 60 individuals is chosen in a tournament of size 5? Of size 60?
3. Apply order crossover by hand to the parents (1, 2, 3, 4, 5, 6) and (6, 5, 4, 3, 2, 1) with the slice at positions 1 to 3 (counting from 0).
4. Seed the first population of `genetic_algorithm` with the EDD order and rerun `ga_lab.py`. What happens to the worst of the ten runs?
5. Run the scheduler with three stations (`stations=3` in `tardiness`). What are the costs of the EDD rule and the genetic algorithm, and what does that tell you about the value of the third station?
6. Add an *inversion* mutation that reverses a random slice of the order, use it instead of the swap, and compare the median of ten runs.
7. Change the objective so that no job may be more than 60 minutes late (add a large penalty for each such job) and look at how the schedule changes.

9.12 Solutions to the Exercises

1. Order (b, a, c): b starts on station 1 at 0 and ends at 20; a starts on station 2 at 0 and ends at 30; station 1 is free first, at 20, so c runs from 20 to 60 and is 15 minutes late: $T = 15$. Order (c, b, a): c runs on station 1 from 0 to 40, b on station 2 from 0 to 20, and a on station 2 from 20 to 50, 20 minutes late: $T = 20$. Job c finishes at 40, 5 minutes early. So (a, b, c) and (b, a, c) are the better orders here.

2. $k/N = 5/60 \approx 8.3\%$ for $k = 5$. For $k = 60$ the tournament contains the whole population and the best always wins, $60/60 = 100\%$: selection becomes deterministic and diversity disappears quickly.

3. The slice of the first parent at positions 1 to 3 is (2, 3, 4), copied to the same positions: (_, 2, 3, 4, _, _). The remaining jobs in the order of the second parent are 6, 5, 1, and they fill positions 0, 4 and 5: the child is (6, 2, 3, 4, 5, 1).

4. Replace the first individual of the initial population by the EDD order (passed in as an extra argument). The worst run can then never end above the EDD cost of 401, because elitism keeps the EDD order, or something better, in every generation. In our run with this change, all ten seeds ended at 301 or 303: the bad run disappeared.

5. With `stations=3` the day becomes easy: both the EDD rule and the genetic algorithm find schedules in which no job is late. The third station is worth all 300 or so weighted minutes of lateness on this day, which is the kind of number a manager can weigh against the cost of repairing the machine quickly.

6. An inversion mutation: choose `i < j` and set `order[i:j + 1] = order[i:j + 1][::-1]`. It keeps most neighbor relations of the order intact, which often suits scheduling problems. Whether it improves the median on this instance is an experiment; report the ten costs for both mutations side by side.

7. In a copy of `tardiness`, add `1000` for every job with `end - job.due > 60`. In our run the genetic algorithm still left one job, B1427, more than an hour late, and a moment's thought shows why this cannot be avoided: two stations need at least 622.5 minutes for the day's work, so the last job finishes at 18:22 or later, while the latest due time is 17:00; whichever job is last is at least 83 minutes late. The penalty did change the rest of the schedule (the shirts B1441 are now exactly 60 minutes late, just inside the limit), and the total weighted tardiness rose from 303 to 318. An objective can only ask for what is possible; checking a requirement against a simple bound like this one is often quicker than running the algorithm.

Chapter 10
A Fuzzy-Logic Controller for a Fan

"If it is hot and humid, turn the fan up high." Everybody understands this rule, and nobody needs to be told exactly where "hot" begins. A computer does: classic logic knows only true and false, so a program must decide that 30.0 °C is hot and 29.9 °C is not, and its fan then jumps from one speed to another as the thermometer crosses the line. *Fuzzy logic* lets a statement be partly true, so that 29.9 °C and 30.0 °C are both "somewhat hot", to almost the same degree. In this chapter, the last of Part 1, we build a small fuzzy-inference engine and use it to control a fan from the temperature and humidity of a room, the kind of controller that has been built into fans, air conditioners, washing machines and rice cookers since the 1990s. By the end of the chapter you will be able to describe vague words with membership functions, combine them with fuzzy AND and OR, write a rule base in plain words, compute the output of a Mamdani controller step by step by hand, implement the whole engine in about sixty lines of Python, reuse it for the classic tipping problem, and compare the smooth behavior of a fuzzy controller with the jumps of a crisp one.

10.1 Hot, Humid and a Little Bit Vague

Anyone who lives in Surabaya knows the question well: is it hot enough to switch the fan to its highest setting? The answer depends on more than the temperature. At 30 °C in dry air, a light breeze is pleasant; at 30 °C with the air heavy with moisture after an afternoon rain, the same temperature feels oppressive, because sweat no longer evaporates. A good fan setting depends on both quantities, and on both only gradually.

Engineers used to control such devices with *thresholds*: below 26 °C off, up to 31 °C medium, above that full speed. The thresholds are easy to program and terrible to live with. On a day hovering around 31 °C the fan roars, stops, and roars again, and the rules cannot express "humid makes it feel hotter" without adding a thicket of extra thresholds.

In 1965, Lotfi Zadeh, an electrical engineer at the University of California, Berkeley, who was born in Baku and grew up in Tehran, proposed *fuzzy sets*: sets to which an element can belong to a degree between 0 and 1 [1]. Ten years later Ebrahim Mamdani and Sedrak Assilian in London used fuzzy rules to control a laboratory steam engine, the first fuzzy controller [2]. Japanese companies then put the idea into everyday products: the Sendai subway, opened in 1987, used fuzzy control for smooth starting and braking, and fuzzy washing machines, cameras and air conditioners followed. Today fuzzy control is an ordinary engineering tool with its own textbooks [3] and open-source libraries, such as scikit-fuzzy, whose latest release, 0.5.0, dates from August 2024 [4].

Fuzzy logic belongs in a part of the book about classic AI because it is, in the end, a rule-based system like the expert system of Chapter 7: a human writes rules in words, and a program applies them. What is new is how it handles vagueness: not with the certainty factors of Chapter 7, which describe how sure we are that a statement is true, but with degrees of truth, which describe how *much* a statement is true.

10.2 The Idea in Plain Words

Ask ten becak drivers when a day becomes “hot” and you will get ten answers between 29 and 33 °C. Nobody will say that 31 °C is simply “not hot”. Fuzzy logic takes this seriously: instead of a line that divides “hot” from “not hot”, each vague word gets a *membership function*, a curve that says for every temperature how hot, from 0 to 1, that temperature is. At 30 °C, “hot” might be 0; at 32 °C, 0.25; at 35 °C and above, 1. A temperature can belong to two words at once: 32 °C is “warm” to degree 0.5 and “hot” to degree 0.25.

A fuzzy controller then works in four steps.

1. **Fuzzify.** Turn each measured number into degrees of membership in each word: 32 °C becomes warm 0.5, hot 0.25; 75 % humidity becomes normal 0.19, humid 0.67.
2. **Apply the rules.** Each rule, such as “IF temperature is warm AND humidity is humid THEN speed is high”, fires to the degree that its conditions are true. For AND we take the smaller of the two degrees: a chain is as strong as its weakest link, as in Chapter 7.
3. **Combine the conclusions.** Each fired rule proposes its output word, cut off at the rule’s strength. The proposals of all rules are laid on top of each other into one combined shape.
4. **Defuzzify.** Turn the combined shape back into one number, the fan speed, by taking its balance point, the *centroid*: the point where the shape, cut out of cardboard, would balance on a finger.

The result changes smoothly with the inputs, because every step is smooth: a slightly warmer room makes some rules a little stronger and others a little weaker, and the balance point moves a little.

10.3 The Math, Gently

10.3.1 From crisp sets to fuzzy sets

An ordinary, *crisp* set A of temperatures, such as “hot means 31 °C or more”, can be described by its *characteristic function*

$$\chi_A(x) = \begin{cases} 1 & \text{if } x \in A \\ 0 & \text{if } x \notin A \end{cases} \tag{10.1}$$

which jumps from 0 to 1 at the boundary. A *fuzzy set* $\tilde{A}$ replaces the jump by a *membership function* $\mu_{\tilde{A}}(x)$ that may take any value from 0 to 1 [1]. The most common shapes are made of straight lines. A *triangle* with feet at a and c and its peak at b is

$$\mu(x) = \begin{cases} 0 & x \le a \text{ or } x \ge c \\ \frac{x-a}{b-a} & a < x \le b \\ \frac{c-x}{c-b} & b < x < c \end{cases} \tag{10.2}$$

and a *trapezoid* with corners $a \le b \le c \le d$ rises from a to b, stays at 1 from b to c, and falls from c to d:

$$\mu(x) = \max\left(0,\ \min\left(\frac{x-a}{b-a},\ 1,\ \frac{d-x}{d-c}\right)\right) \tag{10.3}$$

where a vertical side ($a = b$ or $c = d$) simply means the function starts or ends at 1. **Figure 10.1** shows the membership functions of our fan: four words for the temperature, three for the humidity and five for the fan speed. Neighboring words overlap, so that as the temperature rises one word fades out while the next fades in.

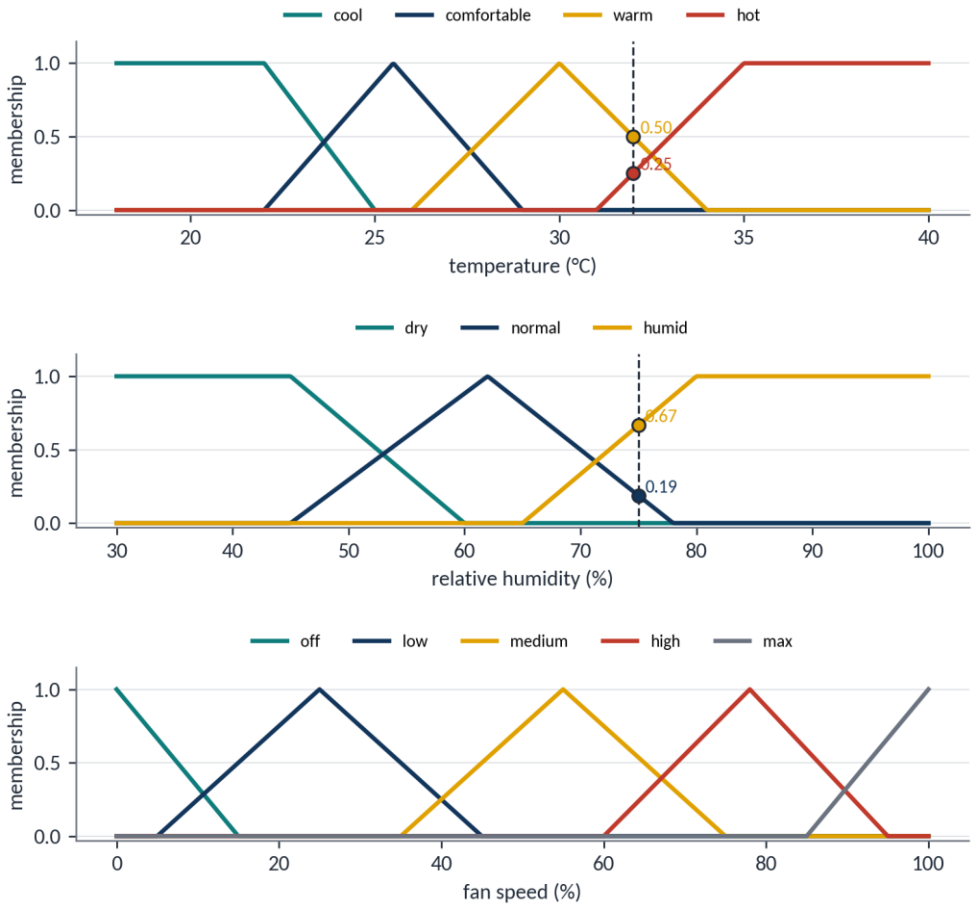

Figure 10.1 The membership functions of the fan controller; the dashed lines mark the worked example of Section 10.3.4, 32 °C and 75 % humidity, with the degrees read off each curve.

Let us check two of the values in the figure with Equation (10.2) and Equation (10.3). "Warm" is the triangle (26,30,34); at 32 °C we are on the falling side, so $\mu = (34 - 32)/(34 - 30) = 2/4 = 0.5$. "Hot" is the trapezoid (31,35,40,40); at 32 °C we are on the rising side, so $\mu = (32 - 31)/(35 - 31) = 1/4 = 0.25$.

10.3.2 Fuzzy AND, OR and NOT

With degrees of truth, the logical connectives become arithmetic. The standard choice, Zadeh's, is

$$\mu_{A \wedge B} = \min(\mu_A, \mu_B), \qquad \mu_{A \vee B} = \max(\mu_A, \mu_B), \qquad \mu_{\neg A} = 1 - \mu_A \tag{10.4}$$

When the degrees are only 0 and 1, these reduce exactly to the truth tables of ordinary logic: $\min(1,0) = 0$ is "true AND false is false", $\max(1,0) = 1$ is "true OR false is true". Fuzzy logic is therefore an *extension* of classical logic, not a replacement for it.

10.3.3 Rules, clipping, aggregation and the centroid

A rule "IF A AND B THEN C" fires with strength $\alpha = \min(\mu_A(x), \mu_B(y))$. In a *Mamdani* controller its conclusion is the output word C *clipped* at that strength:

$$\mu'_C(z) = \min(\alpha,\ \mu_C(z)) \tag{10.5}$$

The clipped conclusions of all rules $r = 1, \ldots, R$ are combined by taking, at each output value z, the highest of them:

$$\mu_{\text{out}}(z) = \max_r \mu'_{C_r}(z) \tag{10.6}$$

and the crisp output is the centroid of that combined shape, the z at which it balances:

$$z^* = \frac{\int z\,\mu_{\text{out}}(z)\,dz}{\int \mu_{\text{out}}(z)\,dz} \approx \frac{\sum_i z_i\ \mu_{\text{out}}(z_i)}{\sum_i \mu_{\text{out}}(z_i)} \tag{10.7}$$

The integrals are areas; the program approximates them by sums over output values z_i spaced 0.1 apart, the same way a physics student finds the center of mass of an irregular plate by cutting it into thin strips.

10.3.4 A worked example: 32 °C and 75 % humidity

Fuzzify. From **Figure 10.1**: warm 0.5 and hot 0.25, as computed above; the other temperature words are 0. For the humidity, "normal" is the triangle (45,62,78) and 75 lies on its falling side, $\mu = (78-75)/(78-62) = 3/16 \approx 0.19$; "humid" is the trapezoid (65,80,100,100), $\mu = (75-65)/(80-65) = 10/15 \approx 0.67$.

Apply the rules. The rule base, which Section 10.5 lists in full, has one rule for each combination of a temperature word and a humidity word, except that "cool" needs only one rule. Four rules have both conditions above zero:

- warm AND normal ⇒ medium, with $\min(0.5,0.19) = 0.19$;
- warm AND humid ⇒ high, with $\min(0.5,0.67) = 0.5$;
- hot AND normal ⇒ high, with $\min(0.25,0.19) = 0.19$;
- hot AND humid ⇒ max, with $\min(0.25,0.67) = 0.25$.

Combine. By Equation (10.5) and Equation (10.6): "medium" is clipped at 0.19, "high" at $\max(0.5,0.19) = 0.5$, and "max" at 0.25. **Figure 10.2** shows the three clipped shapes and their upper outline.

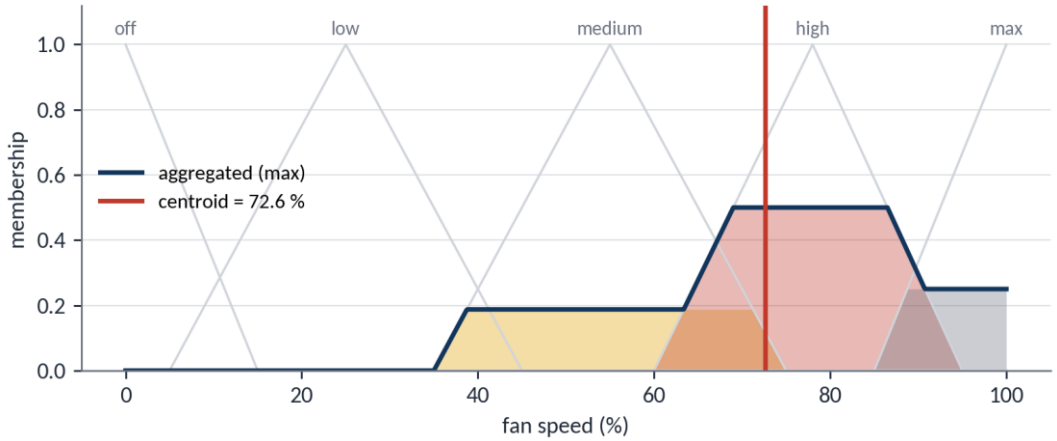

Figure 10.2 Mamdani inference for 32 °C and 75 % humidity: the output words medium, high and max clipped at their rule strengths (shaded), their maximum (dark outline), and its centroid, 72.6 %.

Defuzzify. The combined shape has most of its area around "high" (between 60 and 95), some to the left in "medium" and a little to the right in "max". Its balance point, computed by Equation (10.7), is $z^* \approx 72.6$ %. Notice that no single rule said 72.6: the number is a compromise between the three conclusions, weighted by how strongly each was supported.

10.3.5 Why the crisp controller jumps, in numbers

The crisp controller of Section 10.7 switches from 50 % to 100 % when the temperature crosses 31 °C (at humidity below 70 %). At 30.9 °C and 60 % humidity it runs at 50 %; at 31.0 °C, a change no person could feel, it runs at 100 %, twice as fast and noticeably louder. On a day when the temperature drifts between 30.8 and 31.2 °C, the fan switches back and forth every few minutes. Engineers fight this with *hysteresis*, a second threshold for switching back down, but every added threshold is one more number that has to be tuned by hand.

The fuzzy controller at the same two temperatures fuzzifies 30.9 °C as warm 0.775 and hot 0, and 31.0 °C as warm 0.75 and hot 0: the degrees of "warm" differ by only 0.025, the rule strengths therefore differ by at most 0.025, and the clipped shapes and their centroid move only slightly. In general, if every membership function changes by at most δ when an input changes a little, every rule strength also changes by at most δ, because min and max never change by more than their arguments do. The output of a fuzzy controller is thus continuous whenever its membership functions are, which is the mathematical reason for the smooth surface in Section 10.7; the exception we will meet there comes from the centroid, not from the rules.

10.4 The Algorithm as Pseudocode

Pseudocode 10.1 summarizes the whole inference.

Pseudocode 10.1 Mamdani fuzzy inference with min for AND, clipping, max aggregation and a sampled centroid.

```
MAMDANI(inputs, rules, output variable)
1  for each input variable v: degree[v][w] = μ_w(value of v) for every word w
2  for each rule r with conditions c1..ck and output word C
3      α[r] = MIN over the conditions (or MAX for an OR rule)
4  num = den = 0
5  for z = low, low + step, ..., high                  // sample the output
6      μ = MAX over rules r of MIN(α[r], μ_C(z))        // clip, then aggregate
7      num = num + z · μ;  den = den + μ
8  return num / den                                    // the centroid
```

10.5 Building the Controller Step by Step

10.5.1 The engine

Listing 10.1 is the general engine. Like the expert-system shell of Chapter 7, it knows nothing about fans: the variables, words and rules are given to it.

Listing 10.1 `fuzzy.py`: triangular and trapezoidal membership functions, fuzzy variables, and a Mamdani controller with centroid defuzzification.

```
"""A small Mamdani fuzzy-inference engine: membership functions, rules with
AND (min) and OR (max), clipping, max-aggregation and centroid defuzzification."""

def triangle(a, b, c):
    """Membership rising from a to a peak at b, falling to zero at c."""
    def mu(x):
        if x <= a or x >= c:
            return 1.0 if x == b else 0.0      # a == b or b == c: a vertical side
        return (x - a) / (b - a) if x <= b else (c - x) / (c - b)
    return mu

def trapezoid(a, b, c, d):
    """Rising from a to b, flat (1) from b to c, falling from c to d."""
    def mu(x):
        if x < a or x > d:
            return 0.0
        if b <= x <= c:
            return 1.0
        return (x - a) / (b - a) if x < b else (d - x) / (d - c)
    return mu

class Variable:
    def __init__(self, name, low, high, terms):
        self.name, self.low, self.high = name, low, high
        self.terms = terms                     # term name -> membership function

    def fuzzify(self, x):
        """Degree of membership of x in every term."""
        return {t: round(mu(x), 4) for t, mu in self.terms.items()}

class Controller:
    def __init__(self, inputs, output, rules, step=0.1):
        self.inputs = {v.name: v for v in inputs}
        self.output = output
        self.rules = rules          # (op, [(variable, term), ...], output term)
        self.step = step            # resolution of the output universe
```

Listing 10.1 (Continued) *fuzzy.py: triangular and trapezoidal membership functions, fuzzy variables, and a Mamdani controller with centroid defuzzification.*

```
    def infer(self, **values):
        """Return (crisp output, rule strengths, memberships of the inputs)."""
        degrees = {n: v.fuzzify(values[n]) for n, v in self.inputs.items()}
        strengths = []
        for op, conditions, term in self.rules:
            ds = [degrees[var][t] for var, t in conditions]
            strengths.append((term, min(ds) if op == "and" else max(ds)))
        # aggregate: at each point take the highest clipped output membership
        num = den = 0.0
        n = round((self.output.high - self.output.low) / self.step)
        for i in range(n + 1):
            y = self.output.low + i * self.step
            mu = max((min(s, self.output.terms[t](y)) for t, s in strengths),
                     default=0.0)
            num += y * mu
            den += mu
        crisp = num / den if den else (self.output.low + self.output.high) / 2
        return crisp, strengths, degrees
```

Membership functions as closures. `triangle(a, b, c)` does not compute a membership; it *returns a function* `mu` that remembers `a`, `b` and `c` and computes Equation (10.2) for any `x`. This is

the closure idiom of Chapter 7 again, and it lets each word of each variable carry its own shape. The first line of `mu` handles vertical sides: if `a == b`, the triangle starts at 1, which we use for the "off" and "max" speeds at the ends of the range. `trapezoid` is Equation (10.3) written out by cases.

Variables. A `Variable` has a name, a range and a dictionary of words (the *terms*) with their membership functions; `fuzzify` evaluates them all for one value, which is step 1 of the idea.

The controller. A rule is a tuple `(op, conditions, output term)`, with `op` either `"and"` or `"or"`. `infer` takes the input values as *keyword arguments* (`**values` collects them into a dictionary), fuzzifies them, and computes each rule's strength with `min` or `max`, which is Equation (10.4). The loop over `i` samples the output range in steps of `self.step`; for each sample `y` the generator expression inside `max(...)` clips every rule's output term at the rule's strength, Equation (10.5), and takes the largest, Equation (10.6); `num` and `den` accumulate the sums of Equation (10.7). `default=0.0` covers the case of an empty rule list. If no rule fires at all, `den` is zero and the controller returns the middle of the range rather than dividing by zero; a well-designed rule base, whose words cover the whole input range, never reaches that line. The method returns the crisp value together with the rule strengths and the degrees, so that the caller can explain the result.

10.5.2 The fan

Listing 10.2 defines the fan's variables and rules and prints a full explanation for one reading.

Listing 10.2 `fan.py`: the membership functions and rule base of the fan controller, and an explanation of one inference.

```
"""A fuzzy fan controller for a hot, humid room.

usage: python fan.py TEMPERATURE HUMIDITY      e.g.  python fan.py 32 75
"""
import sys

from fuzzy import Controller, Variable, trapezoid, triangle

temperature = Variable("temperature", 18, 40, {    # degrees Celsius
    "cool": trapezoid(18, 18, 22, 25),
    "comfortable": triangle(22, 25.5, 29),
    "warm": triangle(26, 30, 34),
    "hot": trapezoid(31, 35, 40, 40)})
humidity = Variable("humidity", 30, 100, {          # relative humidity, percent
    "dry": trapezoid(30, 30, 45, 60),
    "normal": triangle(45, 62, 78),

FAN = Controller([temperature, humidity], speed, RULES)
```

Listing 10.2 (Continued) *fan.py: the membership functions and rule base of the fan controller, and an explanation of one inference.*

```
def describe(t, h):
    crisp, strengths, degrees = FAN.infer(temperature=t, humidity=h)
    print(f"Temperature {t:g} C, humidity {h:g} %")
    for name, d in degrees.items():
        active = ", ".join(f"{term} {mu:.2f}" for term, mu in d.items() if mu)
        print(f"  {name:<12} {active}")
    print("  rules that fire:")
    for (op, conds, term), (_, s) in zip(RULES, strengths):
        if s > 0:
            text = f" {op.upper()} ".join(f"{v} is {x}" for v, x in conds)
            print(f"    IF {text} THEN speed is {term}   ({s:.2f})")
    print(f"  fan speed: {crisp:.1f} %")

if __name__ == "__main__":
    t = float(sys.argv[1]) if len(sys.argv) > 1 else 32
    h = float(sys.argv[2]) if len(sys.argv) > 2 else 75
    describe(t, h)
```

The membership functions are exactly those of **Figure 10.1**. The ten rules are easiest to read as a table, **Table 10.1**: the row is the temperature, the column the humidity, and the cell the fan speed.

"Cool" switches the fan off whatever the humidity, and the other rows raise the speed with both temperature and humidity. Designing such a table is the real work of fuzzy control, and it is done with the knowledge of the people who will use the device, as for the expert system of Chapter 7.

Table 10.1 The fan's rule base; each cell is one rule "IF temperature is (row) AND humidity is (column) THEN speed is (cell)", and the row "cool" is a single rule with no humidity condition.

Temperature \ humidity	Dry	Normal	Humid
cool	off	off	off
comfortable	off	low	medium
warm	low	medium	high
hot	high	high	max

`describe` calls `FAN.infer` and prints the non-zero degrees, the rules that fired with their strengths, and the speed. Because a rule's conditions are a list of pairs, the text of the rule is rebuilt with `join`, using the rule's own operator, so the printout always matches the rule base.

10.6 Running It

The worked example of Section 10.3.4:

```
(.venv) $ python fan.py 32 75
```

```
Temperature 32 C, humidity 75 %
  temperature  warm 0.50, hot 0.25
  humidity     normal 0.19, humid 0.67
  rules that fire:
    IF temperature is warm AND humidity is normal THEN speed is medium   (0.19)
    IF temperature is warm AND humidity is humid THEN speed is high   (0.50)
    IF temperature is hot AND humidity is normal THEN speed is high   (0.19)
    IF temperature is hot AND humidity is humid THEN speed is max   (0.25)
  fan speed: 72.6 %
```

Every number agrees with the hand calculation: the four degrees, the four rules with strengths 0.19, 0.50, 0.19 and 0.25, and the fan speed of 72.6 %. A pleasant evening, 24 °C and 50 % humidity:

```
(.venv) $ python fan.py 24 50
```

```
Temperature 24 C, humidity 50 %
  temperature  cool 0.33, comfortable 0.57
  humidity     dry 0.67, normal 0.29
  rules that fire:
    IF temperature is cool THEN speed is off   (0.33)
    IF temperature is comfortable AND humidity is dry THEN speed is off   (0.57)
    IF temperature is comfortable AND humidity is normal THEN speed is low   (0.29)
  fan speed: 18.3 %
```

Here 24 °C is partly "cool" and partly "comfortable", and 50 % partly "dry" and partly "normal". Two rules propose "off" and one proposes "low" with a smaller strength, so the fan turns slowly, at 18.3 %.

A sweltering afternoon after rain, 36 °C and 90 % humidity:

```
(.venv) $ python fan.py 36 90
```

```
Temperature 36 C, humidity 90 %
  temperature  hot 1.00
  humidity     humid 1.00
  rules that fire:
    IF temperature is hot AND humidity is humid THEN speed is max   (1.00)
  fan speed: 95.0 %
```

Only one rule fires, fully, and yet the fan runs at 95.0 %, not 100 %. The reason is the centroid of Equation (10.7): the output word "max" is the triangle (85,100,100), and the balance point of that right-angled triangle lies one third of the way from its vertical side, at $100 - 15/3 = 95$. A Mamdani controller with centroid defuzzification can never reach the very ends of its output range, because every output word has some width. If full speed must be reachable, the output range can be extended beyond 100 and the result clipped, or the "max" word replaced by a narrower one.

Each of these printouts also shows a quiet strength of fuzzy control: its answers explain themselves. A user who asks "why is the fan so loud?" can be shown the rules that fired and how strongly, in the same words in which the rules were written, exactly as the expert system of Chapter 7 answered "how?".

The same engine solves the *tipping problem*, the classic textbook example of fuzzy control, in which the size of a restaurant tip depends on the quality of the service and of the food, both rated from 0 to 10. **Listing 10.3** defines it; note the two OR rules.

Listing 10.3 `tip.py`: the classic fuzzy tipping problem with three rules, two of them using OR.

```
"""The classic fuzzy tipping problem, solved with the same engine.

usage: python tip.py SERVICE FOOD      (both from 0 to 10)
"""
import sys

from fuzzy import Controller, Variable, trapezoid, triangle

service = Variable("service", 0, 10, {"poor": trapezoid(0, 0, 2, 5),
                                      "good": triangle(2, 5, 8),
                                      "excellent": trapezoid(5, 8, 10, 10)})
food = Variable("food", 0, 10, {"rancid": trapezoid(0, 0, 1, 4),
                                "delicious": trapezoid(6, 9, 10, 10)})
tip = Variable("tip", 0, 30, {"cheap": triangle(0, 5, 10),
                              "average": triangle(10, 15, 20),
                              "generous": triangle(20, 25, 30)})

RULES = [
    ("or", [("service", "poor"), ("food", "rancid")], "cheap"),
    ("and", [("service", "good")], "average"),
    ("or", [("service", "excellent"), ("food", "delicious")], "generous"),
]

TIP = Controller([service, food], tip, RULES)

if __name__ == "__main__":
    s = float(sys.argv[1]) if len(sys.argv) > 1 else 6.5
    f = float(sys.argv[2]) if len(sys.argv) > 2 else 9.8
    value, strengths, _ = TIP.infer(service=s, food=f)
    for (op, conds, term), (_, st) in zip(RULES, strengths):
        text = f" {op.upper()} ".join(f"{v} is {x}" for v, x in conds)
        print(f"IF {text} THEN tip is {term:<9} strength {st:.2f}")
    print(f"service {s:g}, food {f:g}  ->  tip {value:.1f} %")
```

```
IF service is poor OR food is rancid THEN tip is cheap     strength 0.00
IF service is good THEN tip is average   strength 0.50
IF service is excellent OR food is delicious THEN tip is generous  strength 1.00
service 6.5, food 9.8  ->  tip 20.7 %
```

Good but not excellent service (6.5) and nearly perfect food (9.8) give a tip of 20.7 %: the OR rule for a generous tip fires fully because of the food, and the rule for an average tip fires at half strength because of the service, so the result lies between “average” (15 %) and “generous” (25 %). Tipping is not a strong custom in Indonesia, but the example shows how little code a new fuzzy system needs once the engine exists: three variables and three rules.

10.7 Fuzzy Versus Crisp

What do we gain over thresholds? **Listing 10.4** prints the fan’s *control surface*, its speed over a grid of temperatures and humidities, and compares its smoothness with a crisp controller that uses hard thresholds.

Listing 10.4 `fuzzy_lab.py`: the control surface of the fuzzy fan, and the largest change in speed caused by a 0.1 °C step, for the fuzzy and the crisp controller.

```
"""The fan's control surface, compared with a crisp three-step controller."""
from fan import FAN

def crisp(t, h):
    """A thermostat-style rule: fixed speeds with hard thresholds."""
    if t < 26:
        return 0.0
    return 50.0 if t < 31 and h < 70 else 100.0

def main():
    temps = list(range(22, 39, 2))
    hums = (40, 55, 70, 85)
    print("fuzzy fan speed (%)        temperature (C)")
    print("humidity " + "".join(f"{t:>6}" for t in temps))
    for h in hums:
        row = [FAN.infer(temperature=t, humidity=h)[0] for t in temps]
        print(f"{h:>6} % " + "".join(f"{v:>6.0f}" for v in row))
    # the largest change caused by a 0.1-degree step, at 70 % humidity
    steps = [round(20 + 0.1 * i, 1) for i in range(201)]
    for name, f in (("fuzzy", lambda t: FAN.infer(temperature=t, humidity=70)[0]),
                    ("crisp", lambda t: crisp(t, 70))):
        values = [f(t) for t in steps]
        jump = max(abs(b - a) for a, b in zip(values, values[1:]))
        print(f"{name}: largest change for a 0.1 C step at 70 % humidity: "
              f"{jump:.1f} points")

if __name__ == "__main__":
    main()
```

```
fuzzy fan speed (%)        temperature (C)
humidity     22    24    26    28    30    32    34    36    38
    40 %      5     6     5    22    25    43    78    78    78
    55 %      5    22    22    39    43    49    78    78    78
    70 %      5    34    38    52    63    66    81    81    81
    85 %      5    45    55    68    78    80    95    95    95
fuzzy: largest change for a 0.1 C step at 70 % humidity: 7.4 points
crisp: largest change for a 0.1 C step at 70 % humidity: 100.0 points
```

The table shows the speed rising gradually with both temperature and humidity: at 30 °C the fan runs at 25 % in dry air, 43 % at 55 % humidity, 63 % at 70 % and 78 % at 85 %, exactly the "humidity makes it feel hotter" behavior that is hard to express with thresholds. **Figure 10.3** draws the full surface next to the crisp controller's three flat plateaus. The last two lines quantify the difference: sweeping the temperature from 20 to 40 °C in steps of 0.1 °C at 70 % humidity, the crisp controller jumps from 0 to 100 % in a single step, while the largest change of the fuzzy controller is 7.4 points.

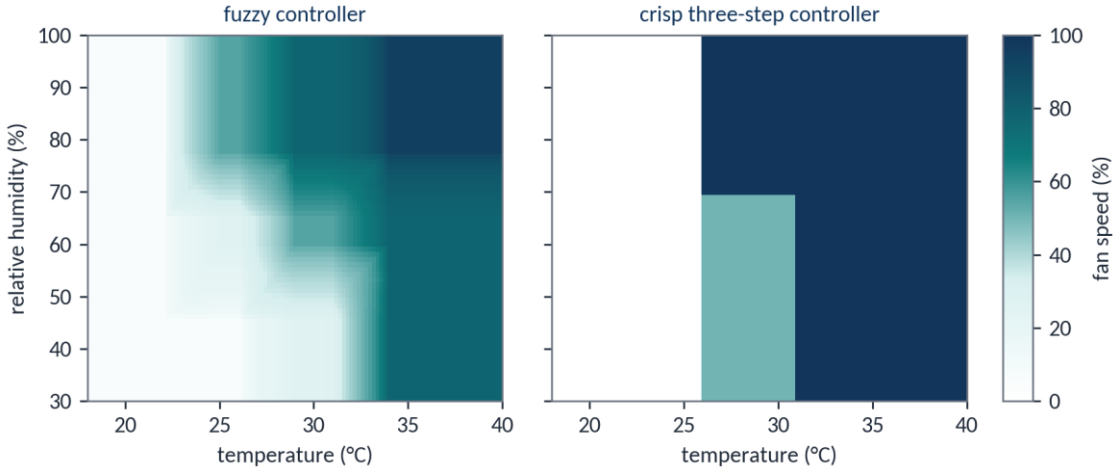

Figure 10.3 Fan speed over temperature and humidity: the fuzzy controller changes gradually, the crisp controller in three abrupt steps.

That 7.4-point step deserves an honest look, because it shows a real property of Mamdani controllers. It happens between 22.0 and 22.1 °C, exactly where "comfortable" begins. Below 22 °C only the "off" rule fires; just above it, the "low" rule starts to fire with a tiny strength. Although the rule is weak, its clipped triangle is 40 points wide, and even a thin slice of it pulls the centroid of Equation (10.7) noticeably to the right. The output is still continuous, but it is steep where a rule begins to fire. Overlapping the membership functions more generously, or using a different defuzzification method, softens such spots; Section 10.9 names some options.

10.8 Testing It

Listing 10.5 checks the membership functions against hand-computed values, the worked example's degrees, the centroid of a single symmetric triangle (which must be its peak), that the fan never slows down noticeably as a humid room heats up, and the tipping result.

Listing 10.5 `test_fuzzy.py`: tests for membership functions, fuzzification, the centroid, the fan's behavior and the tipping example.

```
"""Tests for the fuzzy engine and the fan. Run: python -m unittest -v"""
import unittest

from fan import FAN, temperature
from fuzzy import Controller, Variable, trapezoid, triangle
from tip import TIP

class FuzzyTests(unittest.TestCase):
    def test_membership_functions(self):
        mu = triangle(26, 30, 34)
        self.assertEqual([mu(x) for x in (26, 28, 30, 32, 34)],
                         [0.0, 0.5, 1.0, 0.5, 0.0])
        tr = trapezoid(31, 35, 40, 40)
        self.assertEqual([tr(30), tr(33), tr(37), tr(40)], [0.0, 0.5, 1.0, 1.0])

    def test_fuzzify_worked_example(self):
        self.assertEqual(temperature.fuzzify(32),
                         {"cool": 0.0, "comfortable": 0.0, "warm": 0.5,
                          "hot": 0.25})

    def test_centroid_of_symmetric_term(self):
        out = Variable("y", 0, 10, {"mid": triangle(2, 5, 8)})
        x = Variable("x", 0, 1, {"any": trapezoid(0, 0, 1, 1)})
        c = Controller([x], out, [("and", [("x", "any")], "mid")])
        self.assertAlmostEqual(c.infer(x=0.5)[0], 5.0, places=6)

    def test_fan_increases_with_heat_when_humid(self):
        speeds = [FAN.infer(temperature=t, humidity=85)[0] for t in range(24, 39)]
        for a, b in zip(speeds, speeds[1:]):   # allow tiny sampling wobbles
            self.assertGreaterEqual(b, a - 0.1)

    def test_tip(self):
        self.assertAlmostEqual(TIP.infer(service=6.5, food=9.8)[0], 20.7, places=1)

if __name__ == "__main__":
    unittest.main()
```

The monotonicity test allows a wobble of 0.1 points. Without it, the test fails: between 30 and 31 °C at 85 % humidity the computed speed drops from 77.67 to 77.65 %, a dip caused by sampling the output at steps of 0.1 in Equation (10.7), not by the rules. A test that demands exact monotonicity from a numerical approximation tests the approximation, not the design; the tolerance says what we really care about.

10.9 Improving It

Other shapes and operators. Gaussian or bell-shaped membership functions give smoother surfaces than triangles. The product $\mu_A \mu_B$ instead of min for AND, and the probabilistic sum $\mu_A +$

$\mu_B - \mu_A\mu_B$ instead of max for OR, make every input influence the output at every point, which removes the flat patches of **Figure 10.3**.

Sugeno controllers. A Takagi-Sugeno controller replaces the output words by numbers or linear formulas ("THEN speed $= 20 + 2 \times$ temperature") and the centroid by a weighted average of the rule outputs. It is faster, smoother and easier to tune automatically, and it is the usual choice in embedded controllers [5].

Learning the rules. Instead of writing the membership functions by hand, they can be fitted to recorded data: an *adaptive neuro-fuzzy inference system* (ANFIS) tunes them like the weights of a neural network, a bridge to Part 4 of this book.

A library. For larger systems, scikit-fuzzy [4] provides the same building blocks with more shapes, operators and defuzzification methods, and plotting helpers. Having written the engine yourself, you will know exactly what the library does.

A laundry dryer. The same engine could set the drying time of a Profitina Laundry dryer from the load's weight and its moisture after spinning, two vague quantities for which a human operator also thinks in words like "heavy" and "still quite wet".

10.10 Common Mistakes, and How to Avoid Them

Gaps in the input coverage. If some input value belongs to no word at all, no rule fires and the centroid is undefined. Check that neighboring membership functions overlap across the whole range; the engine's fallback to the middle of the range is a safety net, not a design.

Confusing degrees of truth with probabilities. "The room is hot to degree 0.25" does not mean "there is a 25 % chance that the room is hot". The temperature is known exactly; what is vague is the word. Probability, from Part 2 on, models uncertainty about facts; fuzziness models vagueness of words.

Too few samples in the centroid. A coarse step in Equation (10.7) makes the output jagged. The step of 0.1 on a range of 100 uses 1,001 samples, enough to make the error invisible in the printed decimals, apart from the tiny dip found by the test.

Contradictory rules. Two rules with the same conditions and very different conclusions ("hot → max" and "hot → off") produce a centroid in the middle, a speed that neither rule wanted. Write the rule base as a table, like **Table 10.1**, so that every combination has exactly one conclusion.

Tuning by trial and error only. Changing a membership function to fix one reading often breaks another. Look at the whole control surface, as the lab does, after every change.

10.11 Chapter Summary

- A fuzzy set gives each value a degree of membership between 0 and 1 instead of the 0 or 1 of a crisp set (Equation (10.1)); triangles (Equation (10.2)) and trapezoids (Equation (10.3)) are the usual shapes.
- Fuzzy AND, OR and NOT are min, max and $1 - \mu$ (Equation (10.4)), and reduce to classical logic when degrees are 0 or 1.
- A Mamdani controller fuzzifies the inputs, fires rules, clips their output words (Equation (10.5)), aggregates them with max (Equation (10.6)) and defuzzifies by the centroid (Equation (10.7)).

- For 32 °C and 75 % humidity four rules fired and the fan runs at 72.6 %, exactly as computed by hand; the same engine gave a 20.7 % tip for service 6.5 and food 9.8.
- The fuzzy fan changes speed gradually with both inputs, with a largest jump of 7.4 points per 0.1 °C, against a jump of 100 points for a crisp threshold controller.

10.12 Exercises

1. Using Equation (10.2), compute the membership of 27 °C in "comfortable" (triangle 22, 25.5, 29) and in "warm" (triangle 26, 30, 34).
2. Show that Equation (10.4) gives the ordinary truth table of AND and OR when $\mu_A, \mu_B \in \{0,1\}$, and compute $\mu_{A \wedge \neg A}$ for $\mu_A = 0.4$. What does the result say about the law "A and not A is always false"?
3. For 28 °C and 70 % humidity, list the rules that fire and their strengths by hand; then run `python fan.py 28 70` and compare.
4. Replace `min` by the product for AND in `Controller.infer` and rerun `fuzzy_lab.py`. What happens to the largest 0.1 °C step?
5. Add a third input, "occupied" (0 or 1, whether anyone is in the room), with a rule that turns the fan off when the room is empty.
6. Build a Sugeno version of the fan: give each output word a single number (off 0, low 25, medium 55, high 78, max 100) and compute the output as the weighted average of these numbers with the rule strengths as weights. Compare with the Mamdani output at 32 °C and 75 %.
7. Design the membership functions and at least six rules for a fuzzy laundry dryer whose inputs are the load (kg, 0 to 12) and the moisture after spinning (%, 20 to 80) and whose output is the drying time (minutes, 20 to 90).

10.13 Solutions to the Exercises

1. "Comfortable" at 27: $27 > 25.5$, so we are on the falling side, $\mu = (29 - 27)/(29 - 25.5) = 2/3.5 \approx 0.57$. "Warm" at 27: rising side, $\mu = (27 - 26)/(30 - 26) = 0.25$.

2. With 0 and 1: $\min(1,1) = 1$ and $\min(1,0) = \min(0,1) = \min(0,0) = 0$, the AND table; $\max(0,0) = 0$ and all other combinations give 1, the OR table. For $\mu_A = 0.4$, $\mu_{\neg A} = 0.6$ and $\mu_{A \wedge \neg A} = \min(0.4,0.6) = 0.4$, not 0. In fuzzy logic the law of contradiction holds only for crisp statements: a room that is "somewhat hot" is also "somewhat not hot".

3. At 28 °C: comfortable $= (29 - 28)/3.5 \approx 0.29$, warm $= (28 - 26)/4 = 0.5$. At 70 %: normal $= (78 - 70)/16 = 0.5$, humid $= (70 - 65)/15 \approx 0.33$. The four rules comfortable-normal (low, 0.29), comfortable-humid (medium, 0.29), warm-normal (medium, 0.5) and warm-humid (high, 0.33) fire; "medium" is clipped at $\max(0.29,0.5) = 0.5$. The program prints the same four rules and a speed of about 52 %, which is the value in the lab's table at 28 °C and 70 %.

4. Change `min(ds) if op == "and"` to `math.prod(ds) if op == "and"` (and import `math`). Products are smaller than minimums when both degrees are below 1, so weak combinations become weaker still. In our run the largest change for a 0.1 °C step fell from 7.4 to 3.2 points, still at 22 °C, because the "low" rule now starts to fire with the product of two small degrees instead of the smaller of them; the output for 32 °C and 75 % became 74.0 %.

5. Add `Variable("occupied", 0, 1, {"no": trapezoid(0, 0, 0, 0.5), "yes": trapezoid(0.5, 1, 1, 1)})` and the rule `("and", [("occupied", "no")], "off")`, and add the condition `("occupied", "yes")` to every other rule. With `occupied=0` every other rule has

strength 0, only "off" fires, and the centroid is 5 %, the balance point of the "off" triangle. A truly silent fan needs one more step: a crisp rule outside the fuzzy system that switches the power off when nobody is present.

6. With the exact strengths of Section 10.3.4, medium 0.1875, high 0.5 and 0.1875, and max 0.25, the Sugeno output is $(0.1875 \times 55 + 0.5 \times 78 + 0.1875 \times 78 + 0.25 \times 100)/(0.1875 + 0.5 + 0.1875 + 0.25) = 88.94/1.125 \approx 79.1$ %. It is a little higher than the Mamdani value of 72.6 %, because a Sugeno average ignores the widths of the output words (the wide "medium" and "high" triangles pull the Mamdani centroid down), and it needs a single division instead of 1,001 samples.

7. A reasonable design: load light (trapezoid 0, 0, 3, 6), medium (triangle 3, 6, 9), heavy (trapezoid 6, 9, 12, 12); moisture damp (trapezoid 20, 20, 35, 50), wet (triangle 35, 50, 65), soaked (trapezoid 50, 65, 80, 80); time short (triangle 20, 20, 45), normal (triangle 35, 55, 75), long (triangle 65, 90, 90). Rules: light and damp give short; light and wet give short; light and soaked give normal; medium and damp give short; medium and wet give normal; medium and soaked give long; heavy and damp give normal; heavy and wet give long; heavy and soaked give long. Written as a table like **Table 10.1**, the design is easy to check with the laundry's operators before any code is run.

Chapter 11

House-Price Predictor: Linear Regression from Scratch and with scikit-learn

This chapter opens Part 2, *Learning from Data*. In Part 1 every clever thing our programs did was written down by us as a rule: a search strategy, a heuristic, an expert's advice, a fuzzy membership function. From now on the rules come out of examples. We start with the oldest and most useful learning method there is, *linear regression*, and use it to build an app that estimates the price of a house in Surabaya from its land area, its floor area, its number of bedrooms and its distance to the city center. By the end of the chapter you will be able to say in plain words what "the model learned" means; fit a straight line through data by hand, with a pencil; derive the formulas that make the fit exact; train the same model a second way, by *gradient descent*, and see why the size of each step matters; measure how good a prediction is with MAE, RMSE and R^2; read residuals to find what a model has missed; and wrap all of it in a small command-line app that answers with a price and an honest range around it.

11.1 Why a House-Price Predictor?

Pak Hendra wants to sell his house in Rungkut and buy a smaller one closer to his daughter's school. The first question every buyer and every seller asks is the same: *what is it worth?* An estate agent answers by remembering houses she has seen sold: "a house like yours, on about this much land, this far from the center, went for about two and a half billion last year." She does not have a formula. She has examples, and she has a feeling for how price moves when land grows or when the house sits farther out.

A regression model does the same thing, only explicitly and with numbers. We give it a table of houses whose prices we know. It finds how much each extra square meter of land tends to add, how much each extra kilometer from the center tends to take away, and a base amount on top of which everything sits. Then, for a house it has never seen, it adds up those contributions. The result is not magic and not a valuation certificate; it is a careful average of experience, written as a formula you can read.

That readability is why linear regression is still the first tool a data scientist reaches for, more than two centuries after Legendre published the method of least squares in 1805 [1]. It is fast, it needs very little data, every number in it means something, and when it fails it usually fails in a way you can see and fix. Even the large neural networks of Part 4 end in a layer that is exactly the linear model of this chapter. Learning it well here pays off in every later part of the book.

The app we build is small and useful:

```
python house_app.py --land 120 --building 100 --bedrooms 3 --dist 8
```

answers with an estimated price in billions of rupiah and a range that says how far off that estimate typically is. Along the way we write the whole method ourselves in NumPy, then repeat it in three lines of scikit-learn, the library that the rest of Part 2 relies on [2].

11.2 The Idea in Plain Words

Imagine that you have written the building area and the selling price of 300 houses on 300 cards, and you pin the cards onto a wall: the farther to the right, the bigger the building; the higher up, the more expensive the house. The cards do not form a perfect line, because price depends on more than building area, but they clearly drift upward as you move right. **Figure 11.1** shows exactly this wall, drawn from the data of this chapter.

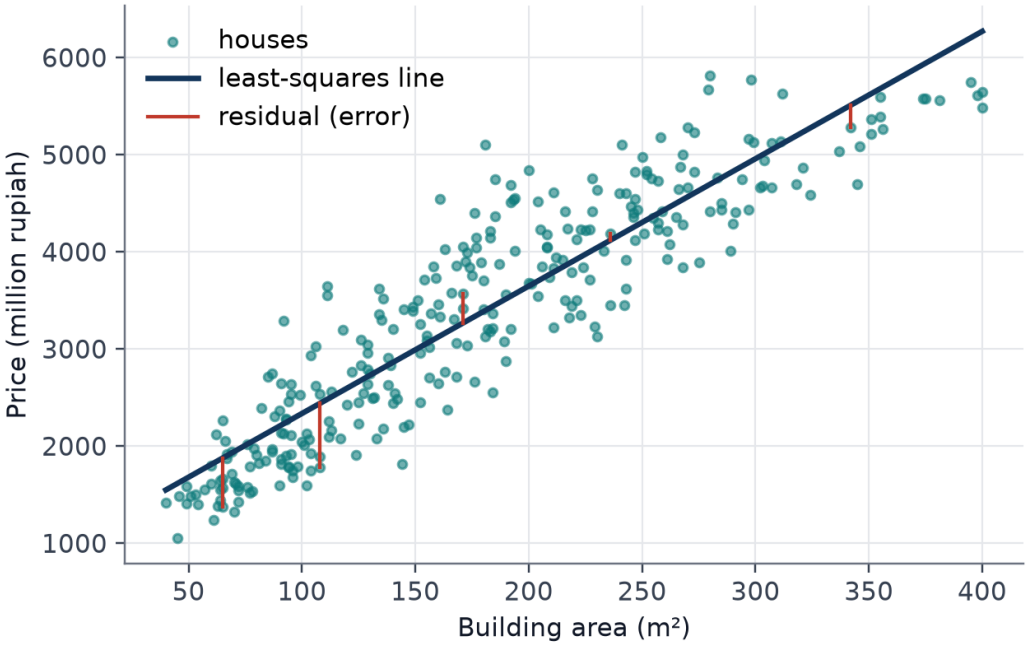

Figure 11.1 The 300 houses of `data/houses.csv`: building area against price, the least-squares line through them, and five residuals (the vertical gaps between a house and the line).

Now take a long, straight stick and hold it against the wall so that it passes as close as possible to all the cards at once. Where the stick crosses a given building area, you read off a "typical" price for that area. That stick is a *linear model*. Its slope says how many rupiah one extra square meter tends to add; its height says where the whole thing starts.

How do we decide which position of the stick is "as close as possible"? For every card, measure the vertical gap between the card and the stick. Some cards are above the stick, some below. A gap is called a *residual*, a word that simply means "what is left over" after the model has had its say. We want the gaps small overall. The classic choice, which we will justify in a moment, is to square every gap and add the squares up. The best stick is the one with the smallest sum of squared gaps. That is the entire idea of *least squares*.

There are two ways to find that best stick. The first is to work out, with a little algebra, a formula that lands on it directly. The second is to put the stick anywhere, see which way the total gap would shrink, nudge it a little that way, and repeat until it stops improving. The first way is exact and instant for problems of our size; the second way is how almost every modern learning method, including deep learning, is trained. We will do both, because both matter.

With four features instead of one (land, building, bedrooms, distance) the stick becomes a flat sheet in a five-dimensional space. We can no longer pin that onto a wall, but nothing else changes: each feature gets its own slope, called a *weight*, and there is still one starting height, called the *intercept* or *bias*. The price estimate is the intercept plus each feature times its weight.

> **KEY INSIGHT:** "The model learned" means only this: the program chose the numbers in a formula (the weights and the intercept) so that the formula agrees as well as possible with examples whose answers we already knew. Everything in this part of the book is a variation on that sentence.

11.3 The Mathematics, Gently

We introduce every symbol before using it. Nothing here needs more than school algebra and the idea of a slope.

11.3.1 A line through the points

Call the building area of a house x (in square meters) and its price y (in millions of rupiah). A straight line is described by two numbers: its slope w and its intercept b. The line's prediction for a house of area x is written $\hat{y}$ ("y-hat"; the hat means "estimated"):

$$\hat{y} = wx + b \tag{11.1}$$

In words: start at b and add w for every square meter. Equation (11.1) is the whole model for one feature.

We number our houses $i = 1, 2, \ldots, n$, where n is the number of houses ($n = 300$ in our file). House i has area x_i and price y_i, and the line predicts $\hat{y}_i = wx_i + b$ for it. Its residual is $y_i - \hat{y}_i$: positive if the house sold for more than the line says, negative if it sold for less.

11.3.2 Measuring how wrong a line is

We want one number that summarizes how wrong a line is on all the houses together. The *mean squared error* (MSE) squares every residual and takes the average:

$$J(w, b) = \frac{1}{n}\sum_{i=1}^{n}(y_i - (wx_i + b))^2 \tag{11.2}$$

The capital sigma Σ, with $i = 1$ written below it and n above, means "add up the following for i from 1 to n". We call the result J, the usual letter for a *cost* or *loss* function; it depends on the two numbers w and b we are free to choose.

Why square instead of just adding the gaps? Three reasons. Adding raw gaps lets a gap of $+500$ cancel a gap of -500, so a terrible line could score zero. Squaring makes every gap count as a positive amount. Squaring also punishes big mistakes much more than small ones: one gap of 400 costs as much as sixteen gaps of 100, which is usually what we want from a price estimate. And squaring gives a smooth bowl-shaped cost, so calculus can find its lowest point exactly. **Figure 11.2** draws that bowl for our 300 houses: every point of the picture is a choice of (w, b), and the rings are levels of equal cost.

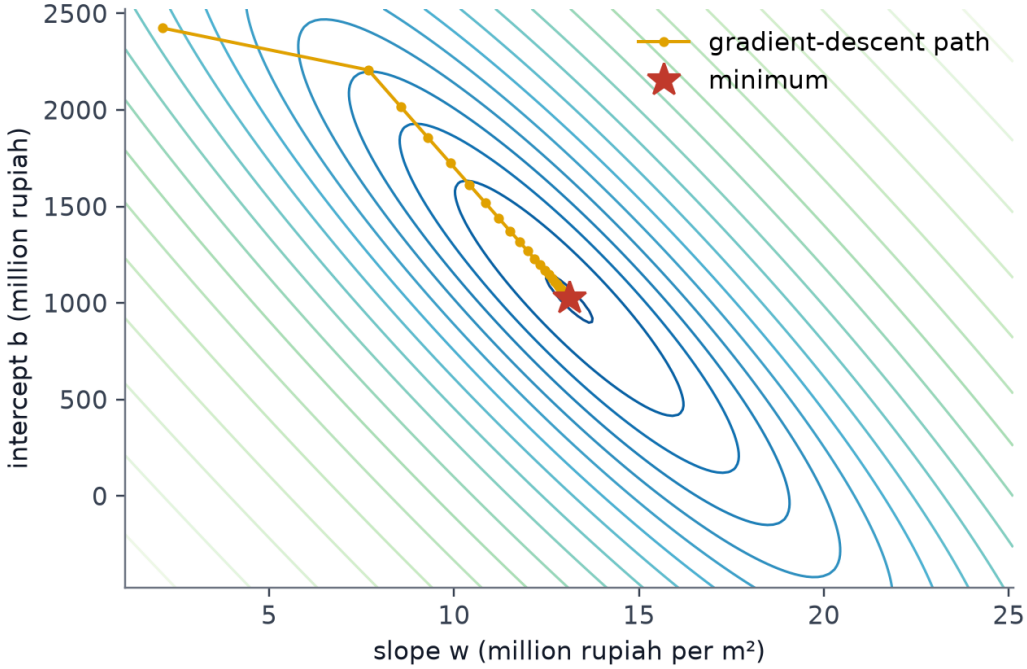

Figure 11.2 The cost $J(w, b)$ of Equation (11.2) over all lines, as contour rings (darker is lower), with a gradient-descent path (one dot every 60 steps) sliding down to the minimum marked by the star.

11.3.3 The best line, exactly

At the bottom of a smooth bowl the ground is flat in every direction: the slope of J with respect to w is zero, and so is its slope with respect to b. Setting those two derivatives to zero and solving (the algebra is short and is Exercise 11.2) gives two famous formulas. Write $\bar{x}$ for the average area and $\bar{y}$ for the average price. Then

$$w = \frac{\sum_{i=1}^{n}(x_i - \bar{x})\,(y_i - \bar{y})}{\sum_{i=1}^{n}(x_i - \bar{x})^2} \tag{11.3}$$

$$b = \bar{y} - w\bar{x} \tag{11.4}$$

Read Equation (11.3) slowly. The bottom adds up how far each area is from the average area, squared: that is how spread out the areas are. The top adds up, for every house, "how far its area is from average" times "how far its price is from average". If big houses tend to be expensive, both factors are positive together or negative together, so the top is large and positive and the slope comes out positive. Equation (11.4) then says that the best line always passes through the point of averages $(\bar{x}, \bar{y})$.

EXAMPLE. Four houses, with a pencil. Areas $x = 50,100,150,200$; prices $y = 1500,2100,2800,3200$.

Averages: $\bar{x} = 500/4 = 125$ and $\bar{y} = 9600/4 = 2400$.

Deviations of x: $-75, -25, 25, 75$. Deviations of y: $-900, -300, 400, 800$.

Products: $67500 + 7500 + 10000 + 60000 = 145000$. Squares of x deviations: $5625 + 625 + 625 + 5625 = 12500$.

Slope: $w = 145000/12500 = 11.6$ million rupiah per square meter. Intercept: $b = 2400 - 11.6 \times 125 = 950$.

> Predictions: 1530,2110,2690,3270. Residuals: $-30, -10, 110, -70$; they add up to zero, as they always do for a least-squares line with an intercept. MSE: $(900 + 100 + 12100 + 4900)/4 = 4500$, so the typical miss is $\sqrt{4500} \approx 67$ million rupiah.

11.3.4 Many features at once

A house has more than an area. Let a house be described by d numbers $x_1, x_2, \ldots, x_d$, its *features* (for us $d = 4$: land, building, bedrooms, distance). The model gives each feature its own weight w_j:

$$\hat{y} = b + w_1 x_1 + w_2 x_2 + \cdots + w_d x_d = b + \sum_{j=1}^{d} w_j \, x_j \tag{11.5}$$

To keep the formulas short we collect everything into arrays. Put the intercept and the weights into one column $\boldsymbol{\theta} = (b, w_1, \ldots, w_d)$ (theta, the usual name for "all the parameters"). Put the houses into a table A with one row per house, where each row starts with a 1 and then lists that house's features; the leading 1 is what multiplies b. Then all n predictions at once are the matrix product $A\boldsymbol{\theta}$, and the cost of Equation (11.2) becomes

$$J(\boldsymbol{\theta}) = \frac{1}{n} \, \| \, A\boldsymbol{\theta} - \mathbf{y} \, \|^2 \tag{11.6}$$

where $\mathbf{y}$ is the column of true prices and $\| \, \mathbf{v} \, \|^2$ means "the sum of the squares of the entries of $\mathbf{v}$". It is the same average of squared residuals, only written for every house and every feature in one line. In NumPy, $A\boldsymbol{\theta}$ is `A @ theta`.

11.3.5 Walking downhill: gradient descent

The *gradient* of J is the list of its slopes, one per parameter: how fast the cost rises if you nudge b, if you nudge w_1, and so on. For the cost of Equation (11.6) it has a compact form:

$$\nabla J(\boldsymbol{\theta}) = \frac{2}{n} A^{\top} (A\boldsymbol{\theta} - \mathbf{y}) \tag{11.7}$$

Here $A^{\top}$ ("A transpose") is A with rows and columns swapped, and $A\boldsymbol{\theta} - \mathbf{y}$ is the column of errors. So each entry of the gradient is "the errors, weighted by that feature, averaged, times two". If the errors are mostly positive on big houses, the gradient for the building weight is positive, meaning "the cost goes up if you raise this weight", so we should lower it.

The gradient points uphill. *Gradient descent* takes a small step the other way, over and over:

$$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \eta \, \nabla J(\boldsymbol{\theta}) \tag{11.8}$$

The arrow means "replace by". The Greek letter η (eta) is the *learning rate*: the size of each step. One pass of Equation (11.8) over the whole training set is called an *epoch*. The amber path in **Figure 11.2** is exactly this rule at work [3].

Choosing η is the art. Too small and the walk takes forever. Too large and every step overshoots the bottom of the bowl and lands higher up on the other side, then overshoots again, farther, until the numbers explode. **Figure 11.3** shows all three behaviors on our data.

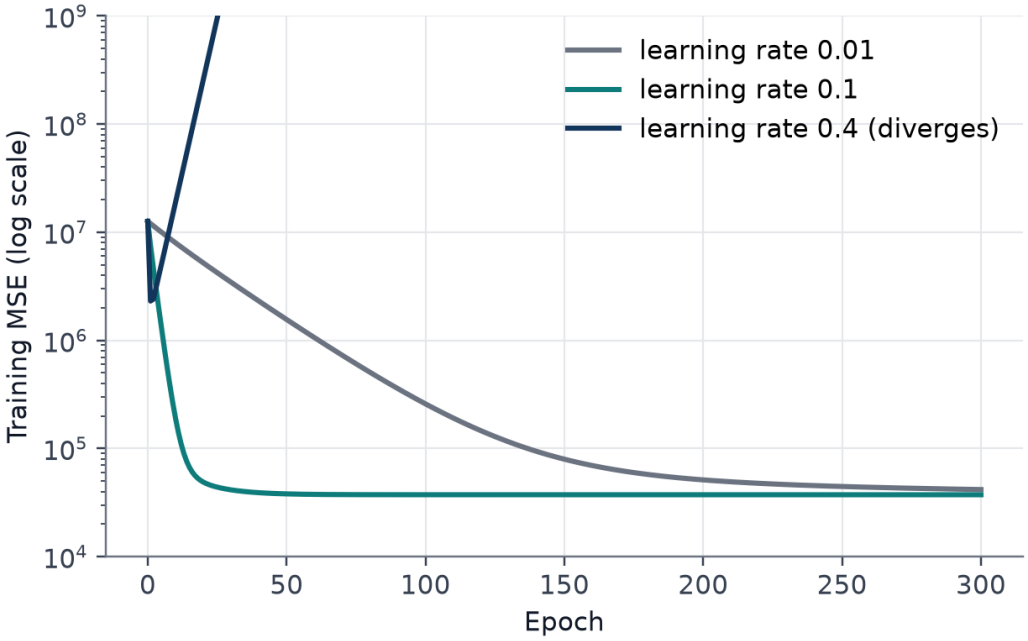

Figure 11.3 Training MSE per epoch of gradient descent on the four scaled features, for three learning rates: 0.01 creeps, 0.1 converges in about 30 epochs, 0.4 diverges.

Gradient descent works much better when every feature lives on a similar scale. Land area runs from 60 to 300 while bedrooms run from 1 to 6; the bowl is then a long, thin valley and the walk zigzags. The cure is *standardization*: replace every feature by its *z-score*

$$z = \frac{x - \mu}{\sigma} \tag{11.9}$$

where μ (mu) is the feature's mean over the training houses and σ (sigma) is its standard deviation, the typical distance from that mean. After Equation (11.9) every feature has mean 0 and spread 1. The weights we learn on the z-scores are "million rupiah per standard deviation"; to turn them back into "million rupiah per square meter" we undo the scaling:

$$w_j = \frac{\theta_j}{\sigma_j}, \qquad b = \theta_0 - \sum_{j=1}^{d} w_j \, \mu_j \tag{11.10}$$

where θ_0 is the intercept learned on the scaled data and θ_j the weight of feature j. Equation (11.10) follows by substituting Equation (11.9) into Equation (11.5) and collecting terms.

11.3.6 The normal equation

The bottom of the bowl can also be found in one jump. At the minimum the gradient of Equation (11.7) is zero, so $A^{\top}(A\boldsymbol{\theta} - \mathbf{y}) = \mathbf{0}$, which rearranges to

$$A^{\top} A \, \boldsymbol{\theta} = A^{\top} \mathbf{y} \tag{11.11}$$

These are the *normal equations*: $d + 1$ ordinary linear equations in $d + 1$ unknowns. For one feature they reduce exactly to Equation (11.3) and Equation (11.4). In code we never invert $A^{\top}A$ by hand; `numpy.linalg.lstsq` solves the least-squares problem in a numerically careful way [4]. For a few thousand rows and a few dozen features this is instant; Hastie, Tibshirani and Friedman

give the geometry behind it, the prediction as a projection of **y** onto the columns of A [5]. Gradient descent earns its place when the data or the model become too big for one jump, which is the everyday situation from Part 4 onward.

11.3.7 How good is good?

A model is judged on houses it did not see during training, the *test set*. Three numbers tell most of the story. The *mean absolute error* is the average size of a miss:

$$\mathrm{MAE} = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \tag{11.12}$$

The *root mean squared error* is the square root of the MSE, which brings the unit back to rupiah and, like the MSE, weighs big misses heavily:

$$\mathrm{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \tag{11.13}$$

And the *coefficient of determination* compares the model with the laziest possible predictor, "always guess the average price":

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \tag{11.14}$$

If the model is perfect the top of the fraction is zero and $R^2 = 1$. If it is no better than guessing the average, the fraction is 1 and $R^2 = 0$. On a test set R^2 can even be negative, which means "worse than the average"; Exercise 11.5 asks you to explain how. MAE and RMSE are in millions of rupiah and are what you would tell Pak Hendra; R^2 has no unit and is what you would use to compare models on the same data [6].

11.4 Building It Step by Step

11.4.1 The project folder

Open Visual Studio Code, create a folder `Chapter011`, and set up a virtual environment in it with Python 3.14 [7] exactly as in Chapter 1 (the commands are repeated in the folder's `README.md`). The libraries, pinned to the versions this chapter was run with, go into `requirements.txt`:

```
numpy==2.4.6
pandas==3.0.6
scikit-learn==1.9.1
pytest==9.1.1
```

At the time of writing, scikit-learn 1.9.1 (released September 10, 2026) is the current release [8], [9], and NumPy 2.4 and pandas 3.0 are the current major lines. Install them with `pip install -r requirements.txt`. **Table 11.1** lists the files we are about to write.

Table 11.1 The files of the house-price project.

File	Role
`make_houses.py`	generates the data set `data/houses.csv`
`simple_fit.py`	one feature, the exact line of Equation (11.3) and Equation (11.4)
`linreg.py`	the from-scratch library: split, scaling, gradient descent, normal equation, metrics
`sklearn_fit.py`	the same model with scikit-learn
`improve.py`	reading residuals and adding a better feature
`house_app.py`	the command-line app
`test_linreg.py`	automatic tests

11.4.2 The data

Real listings would be ideal, but they come with owners' names and phone numbers and change every week. For learning we want something better: data where we *know the true rule*, so that we can check whether the method finds it. `make_houses.py` in **Listing 11.1** invents 300 houses with a fixed random seed, so your file is identical to ours. The price follows a hidden rule, 11 million per square meter of land, 4.5 million per square meter of building, 35 million per bedroom, a premium for being close to the center that fades with distance, and random noise with a standard deviation of 140 million on top. The noise stands for everything a table cannot capture: the view, the paint, the seller's hurry.

Listing 11.1 `make_houses.py`: generating 300 houses with a hidden price rule and fixed seed.

```
# make_houses.py - generate the Surabaya house-price data set (data/houses.csv)
from pathlib import Path
import numpy as np
import pandas as pd

rng = np.random.default_rng(11)          # fixed seed: same houses every run
n = 300
land = rng.integers(60, 301, n)                              # m^2
building = np.clip(land * rng.uniform(0.6, 1.4, n), 36, 400).round()
bedrooms = np.clip((building / 45).round() + rng.integers(-1, 2, n), 1, 6)
dist = rng.uniform(1, 20, n).round(1)                        # km to city center
noise = rng.normal(0, 140, n)
# the "true" rule we pretend nobody knows (price in million rupiah)
premium = 1200 * np.exp(-dist / 4)           # near the center costs more
price = 250 + 11 * land + 4.5 * building + 35 * bedrooms + premium + noise
df = pd.DataFrame({"land_m2": land, "building_m2": building.astype(int),
                   "bedrooms": bedrooms.astype(int), "dist_km": dist,
                   "price_mrp": price.round().astype(int)})
out = Path(__file__).parent / "data" / "houses.csv"
df.to_csv(out, index=False)
print(df.head().to_string())
print(len(df), "houses written to", out.name)
```

```
   land_m2  building_m2  bedrooms  dist_km  price_mrp
0       92           65         1     19.0       1661
1       90           82         3      3.2       2392
2      252          252         6      2.5       4799
3      180          149         3      4.6       3389
4      202          219         5      5.2       3789
300 houses written to houses.csv
```

Notice one deliberate twist on the line that computes `premium`: the distance effect is curved, not straight. A linear model cannot represent a curve with one weight, and Section 11.6 shows how the residuals give that away.

11.4.3 One feature, by hand

Before any library, **Listing 11.2** turns Equation (11.3) and Equation (11.4) into five lines of NumPy, using only building area.

Listing 11.2 `simple_fit.py`: the exact least-squares line for one feature.

```
# simple_fit.py - one feature, exact least-squares line, no libraries but numpy
from pathlib import Path
import numpy as np
import pandas as pd

df = pd.read_csv(Path(__file__).parent / "data" / "houses.csv")
x = df["building_m2"].to_numpy(dtype=float)
y = df["price_mrp"].to_numpy(dtype=float)

x_bar, y_bar = x.mean(), y.mean()
w = np.sum((x - x_bar) * (y - y_bar)) / np.sum((x - x_bar) ** 2)
b = y_bar - w * x_bar
pred = w * x + b
mse = np.mean((y - pred) ** 2)

print(f"mean building area = {x_bar:.1f} m2, mean price = {y_bar:.1f} million")
print(f"slope w     = {w:.3f} million rupiah per m2")
print(f"intercept b = {b:.1f} million rupiah")
print(f"MSE = {mse:.0f}, RMSE = {np.sqrt(mse):.1f} million rupiah")
print(f"a 100 m2 house: {w * 100 + b:.0f} million rupiah")
```

```
mean building area = 178.2 m2, mean price = 3361.5 million
slope w     = 13.115 million rupiah per m2
intercept b = 1024.3 million rupiah
MSE = 248107, RMSE = 498.1 million rupiah
a 100 m2 house: 2336 million rupiah
```

Each extra square meter of building adds about 13.1 million rupiah. That is more than the 4.5 million in the hidden rule, and it is not a mistake: bigger buildings sit on bigger plots, so with building area alone the slope has to carry the effect of land as well. A one-feature model is really responding to the question "how does price change with building area, *if everything else changes along with it the way it usually does*?". The typical miss, an RMSE near 500 million, is large, because the other three features are missing.

11.4.4 The from-scratch library

Listing 11.3 is the heart of the chapter. Read it top to bottom; every function is a numbered equation from Section 11.3.

Listing 11.3 `linreg.py`: linear regression from scratch, trained by gradient descent and by the normal equation.

```python
# linreg.py - linear regression from scratch: gradient descent and normal equation
from pathlib import Path
import numpy as np
import pandas as pd

FEATURES = ["land_m2", "building_m2", "bedrooms", "dist_km"]
TARGET = "price_mrp"

def load(path=None):
    path = path or Path(__file__).parent / "data" / "houses.csv"
    df = pd.read_csv(path)
    return df[FEATURES].to_numpy(float), df[TARGET].to_numpy(float)

def split(X, y, test_frac=0.2, seed=42):
    idx = np.random.default_rng(seed).permutation(len(y))
    n_test = int(round(len(y) * test_frac))
    te, tr = idx[:n_test], idx[n_test:]
    return X[tr], X[te], y[tr], y[te]

class Scaler:
    # remembers the training mean and spread of every column
    def fit(self, X):
        self.mu, self.sigma = X.mean(axis=0), X.std(axis=0)
        return self

    def transform(self, X):
        return (X - self.mu) / self.sigma

def add_ones(X):
    return np.column_stack([np.ones(len(X)), X])
```

Listing 11.3 (Continued) *linreg.py: linear regression from scratch, trained by gradient descent and by the normal equation.*

```
def fit_gd(X, y, lr=0.1, epochs=500, report=100):
    A = add_ones(X)
    theta = np.zeros(A.shape[1])
    history = []
    for epoch in range(epochs + 1):
        err = A @ theta - y
        history.append(np.mean(err ** 2))
        if report and epoch % report == 0:
            print(f"epoch {epoch:4d}  MSE {history[-1]:12.1f}")
        grad = 2 / len(y) * A.T @ err
        theta -= lr * grad
    return theta, history

def fit_normal(X, y):
    A = add_ones(X)
    theta, *_ = np.linalg.lstsq(A, y, rcond=None)
    return theta

def predict(theta, X):
    return add_ones(X) @ theta

def mae(y, p):
    return np.mean(np.abs(y - p))

def rmse(y, p):
    return np.sqrt(np.mean((y - p) ** 2))

def r2(y, p):
    return 1 - np.sum((y - p) ** 2) / np.sum((y - y.mean()) ** 2)
```

Listing 11.3 (Continued) *linreg.py: linear regression from scratch, trained by gradient descent and by the normal equation.*

```
if __name__ == "__main__":
    X, y = load()
    X_tr, X_te, y_tr, y_te = split(X, y)
    sc = Scaler().fit(X_tr)
    theta, _ = fit_gd(sc.transform(X_tr), y_tr)
    theta_ne = fit_normal(sc.transform(X_tr), y_tr)
    print("gradient descent :", np.round(theta, 1))
    print("normal equation  :", np.round(theta_ne, 1))
    # undo the scaling so each weight is "million rupiah per unit"
    w = theta[1:] / sc.sigma
    b = theta[0] - np.sum(w * sc.mu)
    for name, wi in zip(FEATURES, w):
        print(f"  {name:12s} {wi:8.2f}")
    print(f"  {'intercept':12s} {b:8.1f}")
    p = predict(theta, sc.transform(X_te))
    print(f"test MAE {mae(y_te, p):.1f}  RMSE {rmse(y_te, p):.1f}  "
          f"R2 {r2(y_te, p):.3f}")
```

Walking through it:

- `load` reads the CSV with pandas and returns a NumPy table `X` of features (300 rows, 4 columns) and the column `y` of prices.

- `split` shuffles the row numbers with a fixed seed and keeps 20 percent (60 houses) aside as the test set. The model never sees them during training.
- `Scaler` implements Equation (11.9). It learns μ and σ from the *training* rows only and then applies the same numbers to any rows; Section 11.7 explains why that matters.
- `add_ones` builds the table A of Section 11.3.4 by putting a column of ones in front.
- `fit_gd` is gradient descent: `err` is $A\boldsymbol{\theta} - \mathbf{y}$, `grad` is Equation (11.7), and `theta -= lr * grad` is Equation (11.8). It records the MSE of every epoch so we can draw **Figure 11.3**.
- `fit_normal` solves Equation (11.11) with `lstsq`.
- `mae`, `rmse` and `r2` are Equation (11.12), Equation (11.13) and Equation (11.14), one line each.
- The block under `if __name__ == "__main__":` runs only when the file is executed directly, not when another file imports it. It trains both ways, converts the weights back with Equation (11.10), and evaluates on the test set.

Run it with `python linreg.py`:

```
epoch    0  MSE   12592778.8
epoch  100  MSE      37344.8
epoch  200  MSE      37334.3
epoch  300  MSE      37334.3
epoch  400  MSE      37334.3
epoch  500  MSE      37334.3
gradient descent : [3328.4  785.6  410.8   47.4 -214.5]
normal equation  : [3328.4  785.6  410.8   47.4 -214.5]
  land_m2         10.62
  building_m2      4.88
  bedrooms        27.60
  dist_km        -40.33
  intercept       886.5
test MAE 121.5  RMSE 153.2  R2 0.982
```

Four things are worth seeing. The cost falls from 12.6 million to about 37,000 in the first hundred epochs and then does not move: gradient descent has reached the bottom of the bowl. The two methods agree to every printed digit, as they must, since they solve the same problem. The weights, turned back into everyday units, are close to the hidden rule: 10.62 against 11 for land, 4.88 against 4.5 for building. They are not exact, because 240 noisy houses cannot pin a weight down perfectly, and bedrooms, strongly tied to building area, get the least precise estimate (27.60 against 35). And the distance weight, -40.33, is a straight-line compromise for a curved effect. On the 60 test houses the typical miss is 153 million rupiah and $R^2 = 0.982$: the model explains 98 percent of the variation in price.

11.4.5 The same model in scikit-learn

Everything above exists ready-made in scikit-learn, and from the next chapter on we use the library directly [10]. **Listing 11.4** chains a `StandardScaler` (our `Scaler`) and a `LinearRegression` (our `fit_normal`) into a *pipeline*, a single object that scales and then fits, and later scales and then predicts, always with the training statistics.

Listing 11.4 `sklearn_fit.py`: the same model as a scikit-learn pipeline, on the same split.

```python
# sklearn_fit.py - the same model in three lines of scikit-learn
from sklearn.linear_model import LinearRegression
from sklearn.metrics import mean_absolute_error, r2_score, root_mean_squared_error
from sklearn.pipeline import make_pipeline
from sklearn.preprocessing import StandardScaler
from linreg import FEATURES, load, split

X, y = load()
X_tr, X_te, y_tr, y_te = split(X, y)          # the same split as linreg.py

model = make_pipeline(StandardScaler(), LinearRegression())
model.fit(X_tr, y_tr)
p = model.predict(X_te)

lr = model[-1]
print("scaled weights:", lr.coef_.round(1), "intercept:", round(lr.intercept_, 1))
print(f"test MAE {mean_absolute_error(y_te, p):.1f}  "
      f"RMSE {root_mean_squared_error(y_te, p):.1f}  R2 {r2_score(y_te, p):.3f}")
house = [[120, 100, 3, 8.0]]
print(f"120 m2 land, 100 m2 building, 3 bedrooms, 8 km: "
      f"{model.predict(house)[0]:.0f} million rupiah")
```

```
scaled weights: [ 785.6  410.8   47.4 -214.5] intercept: 3328.4
test MAE 121.5  RMSE 153.2  R2 0.982
120 m2 land, 100 m2 building, 3 bedrooms, 8 km: 2409 million rupiah
```

The scaled weights and the metrics match ours digit for digit. That agreement is the best test there is: two independent routes to the same answer. The function `root_mean_squared_error` is the modern name for RMSE in scikit-learn [11]; old tutorials call `mean_squared_error(..., squared=False)`, an option that no longer exists in current releases.

11.4.6 The app

The app in **Listing 11.5** reads the four features from the command line with `argparse`, trains the model (it takes a fraction of a second, so we simply train at start-up), and prints the estimate together with a range of two test RMSEs either side. It also warns when a house lies outside the range of the training data, because a formula fitted on houses 1 to 20 km from the center has no experience of a house 25 km out.

Listing 11.5 `house_app.py`: the command-line house-price predictor.

```python
# house_app.py - ask for a house, answer with a price and an honest range
import argparse
import numpy as np
from sklearn.linear_model import LinearRegression
from sklearn.metrics import root_mean_squared_error
from sklearn.pipeline import make_pipeline
from sklearn.preprocessing import StandardScaler
from linreg import load, split

def with_dist2(X):
    return np.column_stack([X, X[:, 3] ** 2])

def train():
    X, y = load()
    X_tr, X_te, y_tr, y_te = split(X, y)
    model = make_pipeline(StandardScaler(), LinearRegression())
    model.fit(with_dist2(X_tr), y_tr)
    err = root_mean_squared_error(y_te, model.predict(with_dist2(X_te)))
    return model, err

def main():
    ap = argparse.ArgumentParser(description="Surabaya house-price predictor")
    ap.add_argument("--land", type=float, required=True, help="land area, m2")
    ap.add_argument("--building", type=float, required=True, help="floor area, m2")
    ap.add_argument("--bedrooms", type=int, required=True)
    ap.add_argument("--dist", type=float, required=True, help="km to center")
    a = ap.parse_args()
    if not (60 <= a.land <= 300 and 1 <= a.dist <= 20):
        print("warning: outside the range of the training data; "
              "treat the answer with extra care")
    model, err = train()
    x = np.array([[a.land, a.building, a.bedrooms, a.dist]])
    price = model.predict(with_dist2(x))[0]
    lo, hi = price - 2 * err, price + 2 * err
    print(f"estimated price: Rp {price / 1000:.2f} billion")
    print(f"likely range   : Rp {lo / 1000:.2f} - {hi / 1000:.2f} billion "
          f"(+/- 2 x test RMSE of {err:.0f} million)")

if __name__ == "__main__":
    main()
```

The app already uses the improved model of Section 11.6, with one extra column `dist_km` squared; the function `with_dist2` adds it. We come back to why in a moment.

11.5 Running It

In the terminal of VS Code, with the virtual environment active:

```
python house_app.py --land 120 --building 100 --bedrooms 3 --dist 8
```

```
estimated price: Rp 2.30 billion
likely range   : Rp 2.00 - 2.59 billion (+/- 2 x test RMSE of 147 million)
```

The whole run, including training, takes about 1.5 seconds on the laptop-class CPU of the build machine, most of it spent importing scikit-learn. The range is not decoration. With a test RMSE of 147 million, roughly 95 percent of honest estimates should land within two RMSEs of the truth when errors are roughly bell-shaped, which is what our generator makes them. An app that says “Rp 2.30 billion” without a range invites people to believe a precision the data do not support.

Now ask about a house the model has never seen anything like:

```
python house_app.py --land 90 --building 70 --bedrooms 2 --dist 25
```

```
warning: outside the range of the training data; treat the answer with extra care
estimated price: Rp 2.13 billion
likely range   : Rp 1.84 - 2.42 billion (+/- 2 x test RMSE of 147 million)
```

The warning fires. The price still comes out, because the formula will happily produce a number for any input, but the curved distance term was fitted between 1 and 20 km, and beyond 20 km the fitted curve turns back up and starts rewarding distance, which is nonsense. This is called *extrapolation*, and it is where regression models are least trustworthy.

Figure 11.4 plots the model's prediction against the true price for the 60 test houses. Points on the dashed diagonal are perfect predictions; the vertical distance to it is each house's error.

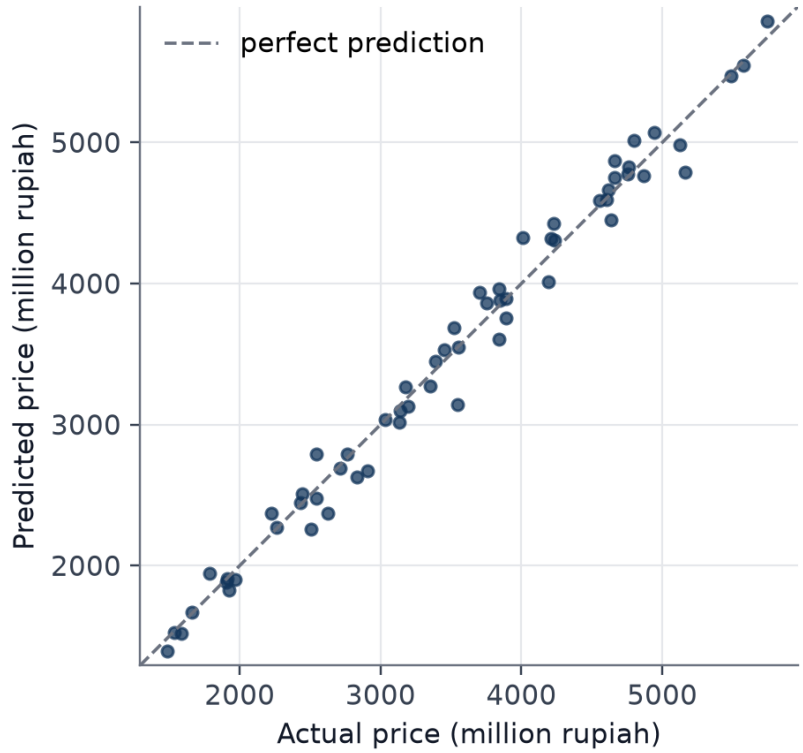

Figure 11.4 Predicted against actual price for the 60 test houses, using the improved model with `dist_km` squared.

11.6 Improving It

A model that scores $R^2 = 0.982$ looks finished. It is not, and the way to find out is to look at what it gets wrong. **Listing 11.6** computes the residuals of the four-feature model on the training houses and averages them per distance band. If a straight line in distance were right, every band would average close to zero.

Listing 11.6 `improve.py`: residuals per distance band, then the extra feature `dist_km` squared.

```
# improve.py - read the residuals, then add a curved distance feature
import numpy as np
from linreg import (Scaler, fit_normal, load, mae, predict, r2, rmse,
                    split)

def with_dist2(X):
    return np.column_stack([X, X[:, 3] ** 2])     # column 3 is dist_km

def evaluate(X_tr, X_te, y_tr, y_te, label):
    sc = Scaler().fit(X_tr)
    theta = fit_normal(sc.transform(X_tr), y_tr)
    p = predict(theta, sc.transform(X_te))
    print(f"{label:22s} MAE {mae(y_te, p):6.1f}  RMSE {rmse(y_te, p):6.1f}"
          f"  R2 {r2(y_te, p):.4f}")
    return theta, sc

X, y = load()
X_tr, X_te, y_tr, y_te = split(X, y)
theta, sc = evaluate(X_tr, X_te, y_tr, y_te, "four features")

# average residual per distance band: a straight line should leave ~0 everywhere
res = y_tr - predict(theta, sc.transform(X_tr))
bands = [(0, 3), (3, 6), (6, 10), (10, 15), (15, 21)]
for lo, hi in bands:
    m = (X_tr[:, 3] >= lo) & (X_tr[:, 3] < hi)
    print(f"  dist {lo:2d}-{hi:2d} km: mean residual {res[m].mean():7.1f}"
          f"  ({m.sum()} houses)")

evaluate(with_dist2(X_tr), with_dist2(X_te), y_tr, y_te, "plus dist_km squared")
```

```
four features          MAE  121.5  RMSE  153.2  R2 0.9818
  dist  0- 3 km: mean residual   210.3  (28 houses)
  dist  3- 6 km: mean residual    23.5  (37 houses)
  dist  6-10 km: mean residual  -147.9  (53 houses)
  dist 10-15 km: mean residual   -63.4  (71 houses)
  dist 15-21 km: mean residual   109.4  (51 houses)
plus dist_km squared   MAE  111.6  RMSE  146.7  R2 0.9834
```

The pattern is unmistakable, and **Figure 11.5** makes it visible: houses very close to the center are underpriced by about 210 million, houses 6 to 10 km out are overpriced by about 150 million, and far-out houses are underpriced again. Residuals that form a smile are the signature of a curved effect squeezed into a straight line.

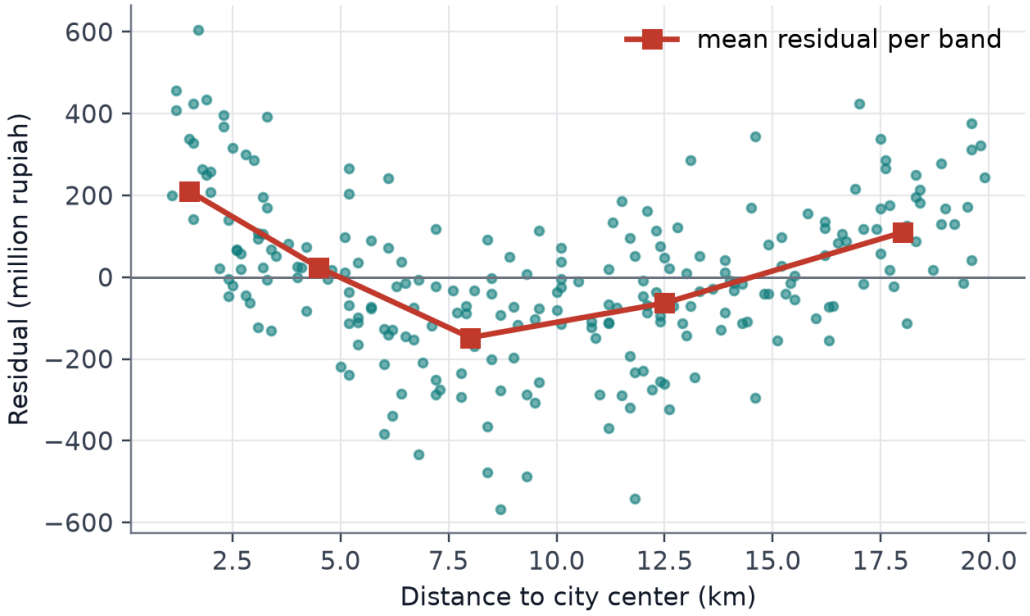

Figure 11.5 Residuals of the four-feature model against distance to the center. The band means (squares) form a smile: the true distance effect is curved.

The fix keeps the model linear in its weights and makes the features richer: we add a fifth column, the square of the distance. The model is still "intercept plus weights times features", so every formula of Section 11.3 applies unchanged, but now the fitted price can bend with distance. Test MAE drops from 121.5 to 111.6 and RMSE from 153.2 to 146.7.

Why not more? Because the noise in our generator has a standard deviation of 140 million. No model, however clever, can predict a random coin toss, and an RMSE of 146.7 is already within a few percent of that floor, which is called the *irreducible error*. When your test error approaches the noise level, stop polishing the model and go and collect better features (the condition of the roof, the width of the road), because that is where the remaining error lives.

Finally, a program that learns should be tested like any other program. **Listing 11.7** holds three small tests: the normal equation must recover a line we made ourselves, gradient descent must agree with the normal equation, and a perfect prediction must score $R^2 = 1$.

Listing 11.7 `test_linreg.py`: three tests for the from-scratch library.

```python
# test_linreg.py - run with:  python -m pytest -q
import numpy as np
from linreg import Scaler, fit_gd, fit_normal, predict, r2

def test_recovers_a_known_line():
    X = np.arange(10, dtype=float).reshape(-1, 1)
    y = 3 * X[:, 0] + 7
    theta = fit_normal(X, y)
    assert np.allclose(theta, [7, 3])

def test_gradient_descent_agrees_with_normal_equation():
    rng = np.random.default_rng(0)
    X = rng.normal(size=(50, 3))
    y = X @ np.array([1.0, -2.0, 0.5]) + 4 + rng.normal(0, 0.1, 50)
    sc = Scaler().fit(X)
    theta_gd, _ = fit_gd(sc.transform(X), y, epochs=300, report=0)
    theta_ne = fit_normal(sc.transform(X), y)
    assert np.allclose(theta_gd, theta_ne, atol=1e-6)

def test_perfect_prediction_has_r2_one():
    y = np.array([1.0, 2.0, 3.0])
    assert r2(y, y) == 1.0
    assert np.allclose(predict(np.array([0.0, 1.0]), y.reshape(-1, 1)), y)
```

```
python -m pytest -q
```

```
...                                                                  [100%]
3 passed in 0.61s
```

Chapter 96 is devoted to testing machine-learning code; for now, notice that tests on tiny data with a known answer are the fastest way to catch a sign error in a gradient.

11.7 Common Mistakes, and How to Avoid Them

Scaling with statistics from the whole data set. If `Scaler` learns μ and σ from all 300 houses, information about the test houses leaks into training, and the test score becomes slightly too optimistic. Always fit the scaler on the training rows and only *apply* it to the test rows. A scikit-learn pipeline does this for you, which is one reason to use one.

Forgetting to scale before gradient descent. On raw features the learning rate that suits bedrooms (values up to 6) is far too large for land (values up to 300), and the run diverges or crawls. Standardize first, as in Equation (11.9).

A learning rate that is too large. A cost that grows from one epoch to the next, or turns into `inf` or `nan`, means the steps overshoot. Divide the learning rate by 3 and try again. Exercise 11.3 computes the exact limit for our data.

Reading weights as causes. The one-feature slope of 13.1 million per square meter of building is not what adding a room would earn: it also carries the effect of the land that bigger buildings sit on. A weight tells you how the prediction moves when one feature changes *and the others stay fixed*, and only within the kind of data the model has seen.

Judging the model on its training data. A model always looks better on houses it has memorized. Report MAE, RMSE and R^2 on a test set that was put aside before any fitting. Chapter 20 replaces the single split with cross-validation.

Trusting predictions outside the data. A formula has no idea that it is extrapolating. Check inputs against the training ranges, as the app does, and say so.

Confusing MSE with RMSE. MSE is in "million rupiah squared", a unit nobody can picture. Report RMSE or MAE to people; use MSE inside the optimizer.

11.8 Chapter Summary

- A linear model predicts with an intercept plus a weight times each feature (Equation (11.1), Equation (11.5)). Learning means choosing those numbers to fit known examples.
- Least squares picks the numbers that minimize the mean squared error (Equation (11.2), Equation (11.6)). For one feature the answer is Equation (11.3) and Equation (11.4); in general it is the normal equation Equation (11.11).
- Gradient descent reaches the same answer by repeated small steps against the gradient (Equation (11.7), Equation (11.8)). It needs standardized features (Equation (11.9)) and a learning rate small enough not to diverge.
- MAE, RMSE and R^2 (Equation (11.12), Equation (11.13), Equation (11.14)) measured on a held-out test set tell you how good a model is, in rupiah and relative to guessing the average.
- Residual plots show what a model misses; a curved pattern calls for a richer feature, such as distance squared, while keeping the model linear in its weights.
- No model beats the noise in the data. When the test RMSE approaches the irreducible error, better features beat better algorithms.
- scikit-learn's `StandardScaler` + `LinearRegression` pipeline reproduces our from-scratch results exactly and is what we will use from now on.

11.9 Exercises

1. By hand, fit the least-squares line through the three points (1,2), (2,4), (3,5). Give w, b, the three residuals and the MSE.
2. Starting from Equation (11.2), set the derivative with respect to b to zero and show that it gives Equation (11.4). Then explain why the residuals of a least-squares line with an intercept always add up to zero.
3. **Figure 11.3** shows gradient descent diverging with learning rate 0.4 and converging with 0.1. Gradient descent on a quadratic cost converges exactly when $\eta < 2/\lambda_{\max}$, where $\lambda_{\max}$ is the largest eigenvalue of the curvature matrix $\frac{2}{n}A^{\top}A$. Write a program that computes this bound for our scaled training data.
4. Use the app for a house on 200 m² of land with a 180 m² building, 4 bedrooms, 3 km from the center. Compare the answer with the hidden rule of `make_houses.py` (without noise) and explain the difference.
5. Explain how R^2 can be negative on a test set, and give a tiny numerical example.
6. *Ridge regression* adds a penalty $\lambda \sum_j w_j^2$ to the cost, which changes the normal equation to $(A^{\top}A + \lambda P)\boldsymbol{\theta} = A^{\top}\mathbf{y}$, where P is the identity matrix with a 0 in the corner that belongs to the intercept [12]. Implement it and report the weights and test RMSE for $\lambda = 0,10,100,1000$.

11.10 Solutions to the Exercises

Exercise 11.1. $\bar{x} = 2$, $\bar{y} = 11/3 \approx 3.667$. Deviations of x: $-1,0,1$; of y: $-1.667,0.333,1.333$. Sum of products: $1.667 + 0 + 1.333 = 3$. Sum of squares of x deviations: 2. So $w = 3/2 = 1.5$ and $b = 3.667 - 1.5 \times 2 = 0.667$. Predictions: 2.167,3.667,5.167. Residuals: $-0.167,0.333,-0.167$ (sum zero). MSE: $(0.0278 + 0.1111 + 0.0278)/3 \approx 0.0556$.

Exercise 11.2. The derivative of J with respect to b is $\frac{\partial J}{\partial b} = -\frac{2}{n}\sum_{i=1}^{n}(y_i - wx_i - b)$. Setting it to zero gives $\sum y_i - w\sum x_i - nb = 0$; dividing by n gives $\bar{y} - w\bar{x} - b = 0$, which is Equation (11.4). The same equation, before dividing, says $\sum_i (y_i - \hat{y}_i) = 0$: the residuals add up to zero. This holds for any least-squares model that includes an intercept, because the intercept's own equation in Equation (11.11) is exactly that sum.

Exercise 11.3. Listing 11.8 builds $\frac{2}{n}A^{\top}A$ from the scaled training data and asks NumPy for its eigenvalues (`eigvalsh` is the routine for symmetric matrices).

Listing 11.8 `solutions/ex_stable_lr.py`: the largest stable learning rate for gradient descent on our data.

```
# ex_stable_lr.py - Exercise 11.3: the largest learning rate that still converges
import sys
from pathlib import Path
import numpy as np
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from linreg import Scaler, add_ones, load, split

X, y = load()
X_tr, _, y_tr, _ = split(X, y)
A = add_ones(Scaler().fit(X_tr).transform(X_tr))
H = 2 / len(y_tr) * A.T @ A              # the curvature of the MSE bowl
eig = np.linalg.eigvalsh(H)
print("eigenvalues:", np.round(eig, 3))
print(f"gradient descent converges for learning rates below {2 / eig.max():.3f}")
```

```
eigenvalues: [0.204 0.446 2.    2.001 5.349]
gradient descent converges for learning rates below 0.374
```

The bound 0.374 sits between 0.1 (converges) and 0.4 (diverges), exactly as **Figure 11.3** shows. The largest eigenvalue, 5.35, comes from land and building area moving together: the bowl is steepest in the direction where both change at once.

Exercise 11.4. The run:

```
python house_app.py --land 200 --building 180 --bedrooms 4 --dist 3
```

```
estimated price: Rp 4.00 billion
likely range   : Rp 3.71 - 4.29 billion (+/- 2 x test RMSE of 147 million)
```

Without noise, the hidden rule gives $250 + 11 \times 200 + 4.5 \times 180 + 35 \times 4 + 1200e^{-3/4} \approx 250 + 2200 + 810 + 140 + 567 = 3967$ million, that is Rp 3.97 billion. The app's 4.00 billion is off by about 30 million, well inside its stated range; the remaining gap comes from the weights being estimated from noisy data and from d^2 being only an approximation of the true exponential curve.

Exercise 11.5. R^2 compares the model's squared errors with those of "always predict the mean". On a test set the mean $\bar{y}$ in Equation (11.14) is the test mean, which the model never saw. A model that is badly wrong on the test set, for example because of extrapolation, can have larger squared errors than that constant guess, which makes the fraction exceed 1 and R^2 negative. Tiny

example: test prices 1,2,3 (mean 2, total squared deviation 2); predictions 3,2,1 give squared errors $4 + 0 + 4 = 8$, so $R^2 = 1 - 8/2 = -3$.

Exercise 11.6. Listing 11.9 adds λP to $A^\top A$ and solves.

Listing 11.9 `solutions/ex_ridge.py`: ridge regression by a modified normal equation.

```
# ex_ridge.py - Exercise 11.6: ridge regression by a modified normal equation
import sys
from pathlib import Path
import numpy as np
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from linreg import Scaler, add_ones, load, predict, rmse, split

def fit_ridge(X, y, lam):
    A = add_ones(X)
    P = np.eye(A.shape[1])
    P[0, 0] = 0                          # never shrink the intercept
    return np.linalg.solve(A.T @ A + lam * P, A.T @ y)

X, y = load()
X_tr, X_te, y_tr, y_te = split(X, y)
sc = Scaler().fit(X_tr)
for lam in [0, 10, 100, 1000]:
    th = fit_ridge(sc.transform(X_tr), y_tr, lam)
    err = rmse(y_te, predict(th, sc.transform(X_te)))
    print(f"lambda {lam:5d}: weights {np.round(th[1:], 1)}  test RMSE {err:.1f}")
```

```
lambda     0: weights [ 785.6  410.8   47.4 -214.5]  test RMSE 153.2
lambda    10: weights [ 721.6  400.9  101.9 -204.9]  test RMSE 153.8
lambda   100: weights [ 485.7  355.2  233.5 -148.9]  test RMSE 245.3
lambda  1000: weights [178.5 163.5 143.3 -41. ]  test RMSE 722.0
```

With $\lambda = 0$ we recover ordinary least squares. As λ grows the weights shrink toward zero and share the credit more evenly: at $\lambda = 10$ the bedroom weight doubles while land shrinks, because ridge prefers to spread weight across correlated features. Here more shrinkage only hurts the test RMSE, because we have 240 clean rows for 4 features and nothing to overfit. Ridge pays off when there are many features and few rows, a situation we will meet in Chapter 12 with thousands of words and a few hundred messages.

Chapter 12

Spam Filter: Logistic Regression

Chapter 11 predicted a number, a price. Many useful questions have a yes-or-no answer instead: is this message spam, will this customer come back, is this transaction a fraud? This chapter builds a filter for short text messages, in Indonesian and English, that answers "spam or not" together with a probability, and explains which words pushed it toward its verdict. By the end of the chapter you will be able to turn a message into a row of numbers with a *bag of words*; squeeze a linear score into a probability with the *sigmoid* function; say why *log-loss*, not squared error, is the right way to punish a wrong probability; derive the gradient of logistic regression and train it from scratch; stop the model from memorizing with an L2 penalty; read a confusion matrix and compute precision and recall; move the decision threshold on purpose to trade missed spam against lost messages; and build the same filter in scikit-learn with tf-idf and character n-grams.

12.1 Why a Spam Filter?

Bu Dewi runs the front desk of a laundry in Rungkut. Customers message her all day: "Is my bed cover ready?", "Can you pick up at 5?", "I've transferred 45 thousand by QRIS". Between those messages come others: "CONGRATULATIONS! Your number has won Rp 100 million, click this link", "Mama needs a 100k top-up, don't call, I'm in a meeting", "Your m-banking account is blocked, verify within 24 hours". Some are merely annoying. Some are traps. In January 2026 the Financial Services Authority (OJK) reported that its Indonesia Anti-Scam Centre had received 432,637 fraud reports in its first fourteen months, with losses of Rp 9.1 trillion; impersonation calls, fake shopping deals, investment offers and job offers were among the most common schemes [1]. By July 2026 the count had passed 608 thousand reports [2].

A person can spot most of these at a glance. The words give them away: *selamat*, *hadiah*, *klik*, *link*, the formal *Anda* from a stranger, the urgent "today only". Our filter learns to do the same from examples. It never receives a list of "bad words" from us. It receives 181 messages, each marked spam or not spam, and works out for itself how much each word should count.

The method is *logistic regression*, first described by Cox in 1958 for yes-or-no outcomes in statistics [3]. It is still the workhorse of text classification: fast to train, hard to break, and so transparent that the app can print, for every verdict, the words that pushed it and by how much [4]. Early machine-learning spam filters of the 2000s were built on exactly this kind of linear model [5]. And, as with linear regression, a neural-network text classifier from Part 4 ends in precisely the layer we build here.

12.2 The Idea in Plain Words

Think of a jury of words. Every word the filter knows has a fixed voting weight: *klik* has a strong positive weight (a vote for spam), *aku* a strong negative weight (a vote for "a real person writing"), *yang* almost zero (it tells us nothing). When a message arrives, every word in it casts its vote, the votes are added up, and a constant is added for the general mood of the court. The total is a *score*: large and positive means "clearly spam", large and negative means "clearly not", near zero means "hard to say".

A score from minus infinity to plus infinity is not what Bu Dewi wants to see. She wants a probability, a number between 0 and 1. So the filter passes the score through a soft S-shaped curve, the *sigmoid*, which squashes any score into that range: very negative scores become almost 0, very positive ones almost 1, and a score of exactly 0 becomes 0.5. Then a simple rule decides: if the probability is at least one half, call it spam.

Learning means finding the voting weights. We start with every weight at zero, so every message scores 0.5, "no idea". Then we show the filter the training messages. For each one it compares its probability with the truth. If a spam message got only 0.3, every word in that message had its weight nudged up a little; if a genuine message got 0.8, every word in it had its weight nudged down. After a few hundred passes the weights settle. Words that appear mostly in spam end up positive, words that appear mostly in normal messages end up negative, and words that appear everywhere end up near zero. **Figure 12.1** summarizes the whole path from a message to a verdict.

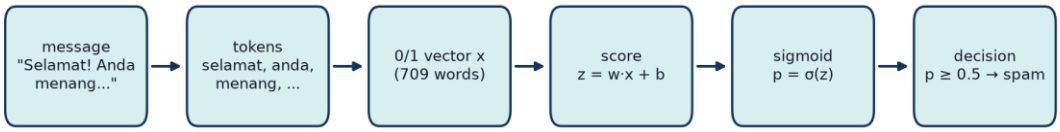

Figure 12.1 The spam filter from message to verdict: tokens, a 0/1 vector over the vocabulary, a linear score, the sigmoid, and a threshold.

> **KEY INSIGHT:** Logistic regression is linear regression's score with a sigmoid on top. The score is still "a bias plus weights times features"; only the way we read it (as a probability) and the way we judge it (by log-loss) change.

12.3 The Mathematics, Gently

12.3.1 From a message to a vector

A computer cannot weigh a sentence; it can weigh numbers. The simplest bridge is the *bag of words*. First we list every distinct word that appears in the training messages: this list is the *vocabulary*, and in our data it has $d = 709$ words. Then a message becomes a row of d numbers $\mathbf{x} = (x_1, x_2, \ldots, x_d)$, where $x_j = 1$ if word number j occurs in the message and $x_j = 0$ if it does not. The order of the words is thrown away; hence "bag". A message of ten words has ten 1s and 699 0s.

12.3.2 A score and a probability

Each word j has a weight w_j, and there is one bias b. The *score* of a message is

$$z = b + \sum_{j=1}^{d} w_j x_j = \mathbf{w} \cdot \mathbf{x} + b \tag{12.1}$$

where $\mathbf{w} \cdot \mathbf{x}$ (the *dot product*) is shorthand for the sum. Because x_j is 0 for absent words, the sum simply adds the weights of the words that are present. Equation (12.1) is exactly the linear model of Chapter 11.

The *sigmoid* (or *logistic*) function turns a score into a number between 0 and 1:

$$\sigma(z) = \frac{1}{1 + e^{-z}} \tag{12.2}$$

Here $e \approx 2.718$ is the base of natural logarithms. When z is large, e^{-z} is tiny and $\sigma(z)$ is close to 1; when z is very negative, e^{-z} is huge and $\sigma(z)$ is close to 0; at $z = 0$ we get $1/(1 + 1) = 0.5$. **Figure 12.2** draws it. Logistic regression declares

$$p = P(\text{spam} \mid \mathbf{x}) = \sigma(\mathbf{w} \cdot \mathbf{x} + b) \tag{12.3}$$

read "the probability of spam given the message $\mathbf{x}$".

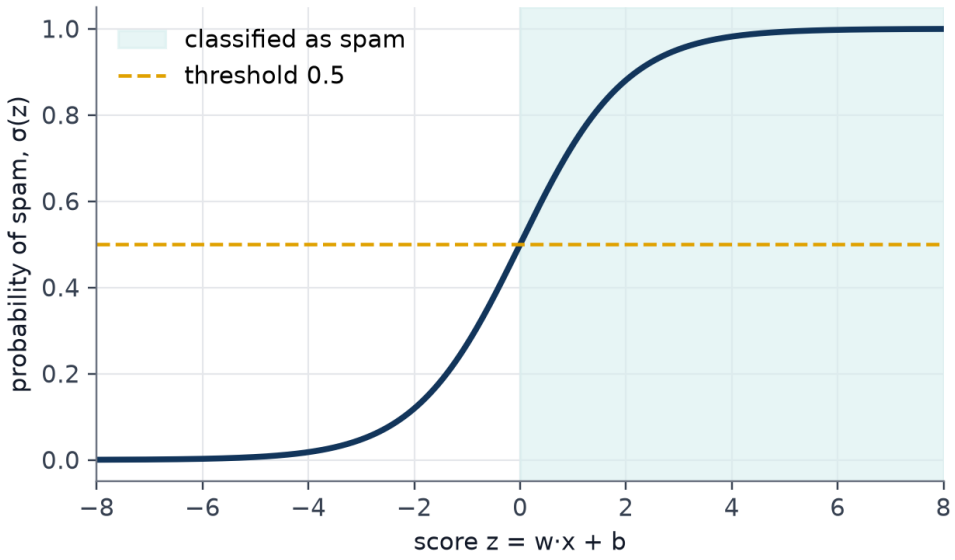

Figure 12.2 The sigmoid of Equation (12.2). Scores above zero give probabilities above one half; with the usual threshold of 0.5, the shaded half of the axis is classified as spam.

Why this particular curve? Solve Equation (12.3) for z and you get

$$\ln \frac{p}{1 - p} = \mathbf{w} \cdot \mathbf{x} + b \tag{12.4}$$

The fraction $p/(1 - p)$ is the *odds* ("four to one" means $p = 0.8$), and ln is the natural logarithm. So Equation (12.4) says that each word adds a fixed amount w_j to the *log-odds* of spam. A word with $w_j = 0.69$ doubles the odds, because $e^{0.69} \approx 2$. That is a clean, readable meaning for every weight, and it is why the model is called *logistic*.

EXAMPLE. A toy filter knows three words: $w_{\text{klik}} = 1.2$, $w_{\text{hadiah}} = 0.9$, $w_{\text{aku}} = -1.5$, and $b = -0.8$.

"klik untuk hadiah": $z = -0.8 + 1.2 + 0.9 = 1.3$, so $p = 1/(1 + e^{-1.3}) = 1/(1 + 0.2725) = 0.786$. Spam.

"aku klik": $z = -0.8 + 1.2 - 1.5 = -1.1$, so $p = 1/(1 + e^{1.1}) = 1/(1 + 3.004) = 0.250$. Not spam.

The word *untuk* is not in the toy vocabulary, so it contributes nothing.

12.3.3 Punishing a wrong probability: log-loss

Every training message i has a true label y_i, with $y_i = 1$ for spam and $y_i = 0$ otherwise, and the model gives it a probability p_i. How bad is a given p_i? Squared error, $(y_i - p_i)^2$, is at most 1 even

for a confident, completely wrong answer, and with a sigmoid it produces a bumpy cost with flat regions where learning stalls. The right measure asks: *how much probability did the model give to what actually happened?* If the message was spam, that is p_i; if not, it is $1 - p_i$. We take the negative logarithm of that probability:

$$\ell_i = -[y_i \ln p_i + (1 - y_i)\ln(1 - p_i)] \tag{12.5}$$

Only one of the two terms is alive for any message, because y_i is 0 or 1. **Figure 12.3** shows the penalty: giving the truth probability 0.9 costs 0.11, giving it 0.5 costs 0.69, and giving it 0.1 costs 2.30. A model that says "certainly not spam" ($p \to 0$) about a spam message pays a penalty that grows without bound. This measure is called *log-loss* or *cross-entropy*.

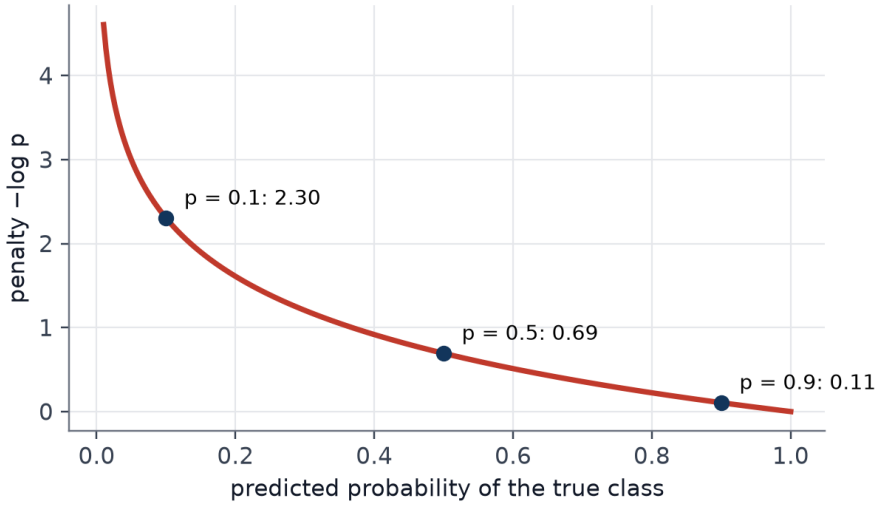

Figure 12.3 The log-loss penalty $-\ln p$ for the probability p that the model gave to the true class: small for confident right answers, unbounded for confident wrong ones.

In the toy example, if "klik untuk hadiah" is spam the loss is $-\ln 0.786 = 0.241$, and if "aku klik" is a genuine message the loss is $-\ln(1 - 0.250) = 0.288$.

The training cost is the average log-loss over the n training messages plus a penalty on large weights:

$$J(\mathbf{w}, b) = \frac{1}{n}\sum_{i=1}^{n} \ell_i + \frac{\lambda}{2}\sum_{j=1}^{d} w_j^2 \tag{12.6}$$

The second term is the *L2 penalty*, or *regularization*, with strength λ (lambda). Why do we need it? We have 709 words and only 127 training messages. Many words occur in a single message. Without a penalty, the model could push the weight of such a word toward infinity and "explain" that one message perfectly, which is memorizing, not learning. The penalty makes every unit of weight cost something, so only words that help on many messages earn large weights. It is the same idea as ridge regression in Exercise 11.6.

12.3.4 The gradient, and why it is so simple

To train by gradient descent we need the slope of J with respect to every weight. Two facts make this short. First, the sigmoid has a famous derivative: $\sigma'(z) = \sigma(z)(1 - \sigma(z))$ (differentiate Equation (12.2); Exercise 12.2 walks through it). Second, when we differentiate ℓ_i with respect to

the score z_i, the factors $p_i(1-p_i)$ from the sigmoid cancel against the $1/p_i$ and $1/(1-p_i)$ from the logarithms, leaving only

$$\frac{\partial \ell_i}{\partial z_i} = p_i - y_i \tag{12.7}$$

"prediction minus truth", the same error signal as in linear regression. Since $z_i = \mathbf{w} \cdot \mathbf{x}_i + b$, the chain rule multiplies by x_{ij} for weight j and by 1 for the bias. Averaging over messages and adding the derivative of the penalty:

$$\nabla_{\mathbf{w}} J = \frac{1}{n} X^{\top}(\mathbf{p} - \mathbf{y}) + \lambda \mathbf{w}, \qquad \frac{\partial J}{\partial b} = \frac{1}{n}\sum_{i=1}^{n}(p_i - y_i) \tag{12.8}$$

Here X is the table of training vectors (one message per row), $\mathbf{p}$ the column of predicted probabilities and $\mathbf{y}$ the column of labels. Gradient descent then repeats the update of Chapter 11:

$$\mathbf{w} \leftarrow \mathbf{w} - \eta \nabla_{\mathbf{w}} J, \qquad b \leftarrow b - \eta \frac{\partial J}{\partial b} \tag{12.9}$$

Read Equation (12.8) in words: for every message, the error $p_i - y_i$ is spread over the words the message contains. A spam message given too low a probability has a negative error, so the gradient for its words is negative and the update *raises* their weights. That is the jury nudging described in Section 12.2, now as a formula. Unlike linear regression, there is no formula that jumps straight to the minimum, so iterative training is not optional here; fortunately the log-loss cost is convex (a single bowl with no false bottoms), so gradient descent always finds the best weights [6].

12.3.5 Judging a classifier

On test messages we compare verdicts with truth and count four kinds of outcome. A *true positive* (TP) is spam flagged as spam; a *false positive* (FP) is a genuine message wrongly flagged; a *false negative* (FN) is spam that slipped through; a *true negative* (TN) is a genuine message let through. The four counts form the *confusion matrix*. Accuracy, $(TP + TN)/n$, hides which mistakes were made, so we use two more questions. Of the messages we flagged, how many were really spam?

$$\text{precision} = \frac{TP}{TP + FP} \tag{12.10}$$

And of the spam that arrived, how much did we catch?

$$\text{recall} = \frac{TP}{TP + FN} \tag{12.11}$$

The two pull against each other. Flag everything and recall is perfect but precision is poor; flag only the most blatant messages and precision is perfect but recall is poor. For Bu Dewi a false positive (a customer's "sudah transfer" buried in the spam folder) costs more than a false negative (one more "you won a car" to delete), so she wants high precision first. Chapter 20 adds the F1 score, ROC curves and cross-validation to this toolkit.

12.4 Building It Step by Step

12.4.1 The data

The folder `Chapter012` has the same `requirements.txt` as Chapter 11 and a data file, `data/sms.csv`, with 181 short messages written for this book: 70 spam and 111 genuine, most in Indonesian and some in English, in the styles you meet on an Indonesian phone. Public collections such as the SMS Spam Collection exist [7], but they are English-only and must be downloaded; ours ships with the code and runs offline. The first lines:

```
label,text
ham,Cucian atas nama Dewi sudah selesai dan bisa diambil mulai jam 4 sore
ham,"Promo akhir bulan di laundry kita: cuci 5 kilo gratis setrika, berlaku untuk semua
pelanggan"
ham,Mau titip beli pulsa? Aku sedang di minimarket
spam,Your bank card is blocked. Send your PIN and card number to unlock it immediately
ham,"Terima kasih sudah datang ke acara kemarin, fotonya sudah aku kirim ke grup"
```

The genuine messages deliberately contain “spam words” now and then (*promo*, *gratis*, *hadiah*, *transfer*), and some spam avoids them, so the task is not trivial.

12.4.2 From text to numbers

Listing 12.1 holds everything that touches raw text: a tokenizer, the loader, a *stratified* split (the test set gets the same share of spam as the whole set, 30 percent of each class), and a bag-of-words vectorizer.

Listing 12.1 `textprep.py`: tokens, a stratified split and a 0/1 bag-of-words vectorizer.

```
# textprep.py - turn messages into numbers: tokens, a vocabulary, a count table
import csv
import re
from pathlib import Path
import numpy as np

TOKEN = re.compile(r"[a-z0-9]+")

def tokens(text):
    return TOKEN.findall(text.lower())

def load(path=None):
    path = path or Path(__file__).parent / "data" / "sms.csv"
    with open(path, encoding="utf8") as f:
        rows = list(csv.DictReader(f))
    texts = [r["text"] for r in rows]
    y = np.array([1 if r["label"] == "spam" else 0 for r in rows])
    return texts, y

def stratified_split(y, test_frac=0.3, seed=7):
    rng = np.random.default_rng(seed)
    test = []
    for cls in (0, 1):
        idx = rng.permutation(np.flatnonzero(y == cls))
        test.extend(idx[: int(round(len(idx) * test_frac))])
    test = np.array(sorted(test))
    train = np.setdiff1d(np.arange(len(y)), test)
    return train, test

class BagOfWords:
    def fit(self, texts, min_count=1):
        counts = {}
        for t in texts:
            for w in set(tokens(t)):
                counts[w] = counts.get(w, 0) + 1
        words = sorted(w for w, c in counts.items() if c >= min_count)
        self.vocab = {w: j for j, w in enumerate(words)}
        return self
```

Listing 12.1 (Continued) *textprep.py: tokens, a stratified split and a 0/1 bag-of-words vectorizer.*

```
    def transform(self, texts):
        X = np.zeros((len(texts), len(self.vocab)))
        for i, t in enumerate(texts):
            for w in tokens(t):
                j = self.vocab.get(w)
                if j is not None:  # words never seen in training are skipped
                    X[i, j] = 1.0
        return X
```

The tokenizer keeps runs of letters and digits after lower-casing, so “KLIK bit.ly/Hadiah-2026!” becomes `klik`, `bit`, `ly`, `hadiah`, `2026`. `BagOfWords.fit` builds the vocabulary from the training messages only, and `transform` ignores words it has never seen, exactly as a deployed filter must do when a new message contains a new word.

12.4.3 Logistic regression from scratch

Listing 12.2 implements Sections 12.3.2 to 12.3.5.

Listing 12.2 `logreg.py`: logistic regression trained by gradient descent with an L2 penalty.

```python
# logreg.py - logistic regression from scratch for the spam filter
import numpy as np
from textprep import BagOfWords, load, stratified_split

def sigmoid(z):
    return 1.0 / (1.0 + np.exp(-z))

def log_loss(y, p, eps=1e-12):
    p = np.clip(p, eps, 1 - eps)
    return -np.mean(y * np.log(p) + (1 - y) * np.log(1 - p))

class LogisticRegressionGD:
    def __init__(self, lr=0.5, epochs=400, lam=0.01):
        self.lr, self.epochs, self.lam = lr, epochs, lam

    def fit(self, X, y, report=100):
        n, d = X.shape
        self.w, self.b = np.zeros(d), 0.0
        for epoch in range(self.epochs + 1):
            p = sigmoid(X @ self.w + self.b)
            if report and epoch % report == 0:
                print(f"epoch {epoch:3d}  log-loss {log_loss(y, p):.4f}")
            err = p - y                              # the gradient's key quantity
            self.w -= self.lr * (X.T @ err / n + self.lam * self.w)
            self.b -= self.lr * err.mean()
        return self

    def predict_proba(self, X):
        return sigmoid(X @ self.w + self.b)

    def predict(self, X, threshold=0.5):
        return (self.predict_proba(X) >= threshold).astype(int)

def confusion(y, yhat):
    tp = int(np.sum((y == 1) & (yhat == 1)))
    fp = int(np.sum((y == 0) & (yhat == 1)))
    fn = int(np.sum((y == 1) & (yhat == 0)))
    tn = int(np.sum((y == 0) & (yhat == 0)))
    return tp, fp, fn, tn
```

Listing 12.2 (Continued) *logreg.py: logistic regression trained by gradient descent with an L2 penalty.*

```
def report(y, yhat):
    tp, fp, fn, tn = confusion(y, yhat)
    acc = (tp + tn) / len(y)
    prec = tp / (tp + fp) if tp + fp else 0.0
    rec = tp / (tp + fn) if tp + fn else 0.0
    print(f"TP {tp}  FP {fp}  FN {fn}  TN {tn}")
    print(f"accuracy {acc:.3f}  precision {prec:.3f}  recall {rec:.3f}")

if __name__ == "__main__":
    texts, y = load()
    tr, te = stratified_split(y)
    bow = BagOfWords().fit([texts[i] for i in tr])
    X_tr = bow.transform([texts[i] for i in tr])
    X_te = bow.transform([texts[i] for i in te])
    print(f"{len(tr)} training and {len(te)} test messages, "
          f"{len(bow.vocab)} words in the vocabulary")
    model = LogisticRegressionGD().fit(X_tr, y[tr])
    report(y[te], model.predict(X_te))
    words = np.array(sorted(bow.vocab, key=bow.vocab.get))
    order = np.argsort(model.w)
    print("most spammy :", " ".join(words[order[::-1][:10]]))
    print("most hammy  :", " ".join(words[order[:10]]))
```

The class `LogisticRegressionGD` is the whole model. In `fit`, the line `p = sigmoid(X @ self.w + self.b)` is Equation (12.3) for all messages at once; `err = p - y` is Equation (12.7); the two update lines are Equation (12.8) and Equation (12.9) with $\lambda = 0.01$ and $\eta = 0.5$. The function `log_loss` clips probabilities away from exactly 0 and 1 before taking logarithms, because ln0 is minus infinity. `confusion` and `report` count the four outcomes and compute accuracy, Equation (12.10) and Equation (12.11). At the end the script sorts the vocabulary by weight and prints the ten most "spammy" and ten most "hammy" words (*ham* is the traditional name for genuine mail).

```
127 training and 54 test messages, 709 words in the vocabulary
epoch   0  log-loss 0.6931
epoch 100  log-loss 0.1525
epoch 200  log-loss 0.1204
epoch 300  log-loss 0.1134
epoch 400  log-loss 0.1115
TP 18  FP 1  FN 3  TN 32
accuracy 0.926  precision 0.947  recall 0.857
most spammy : anda sekarang now tanpa link nomor to untuk klik dulu
most hammy  : aku sudah jam the pagi on i lupa kita hari
```

The log-loss starts at $\ln 2 = 0.6931$, the loss of answering 0.5 to everything, and falls to 0.11. On the 54 test messages the filter catches 18 of the 21 spam messages (recall 0.857) and wrongly flags one genuine message (precision 0.947). The word lists read like a lesson in Indonesian spam: the formal *anda*, *sekarang*, *tanpa* ("without collateral", "without a test"), *link*, *nomor*, *klik*, and *dulu* (as in "transfer dulu"). The genuine side is informal and personal: *aku*, *sudah*, *jam*, *pagi*, *lupa*, *kita*. **Figure 12.4** draws these weights.

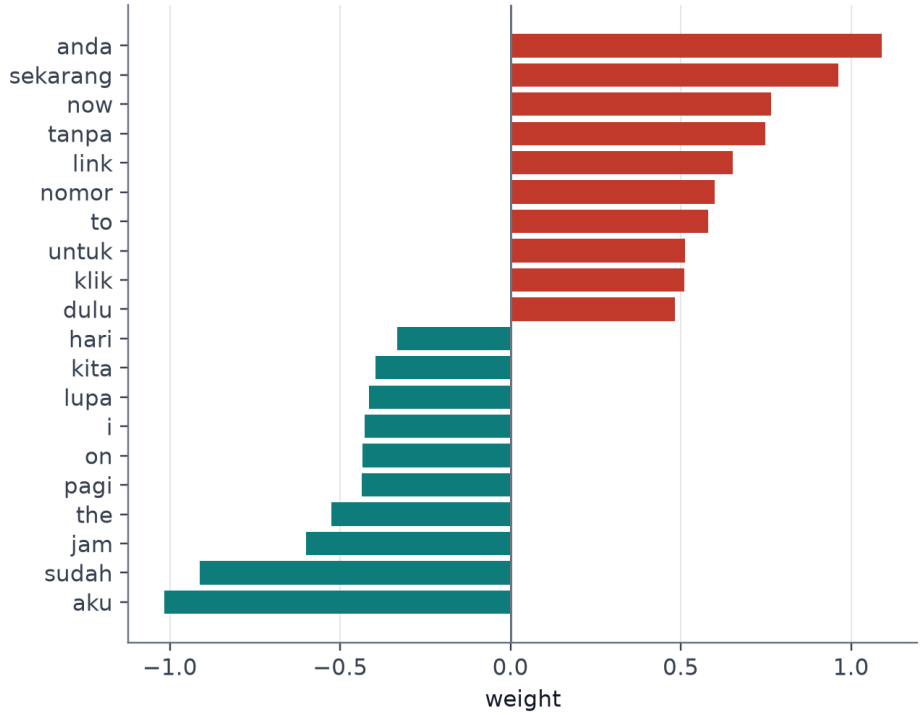

Figure 12.4 The ten most negative and ten most positive word weights learned by `logreg.py`; red words push toward spam, teal words toward a genuine message.

12.4.4 The same filter in scikit-learn

In scikit-learn a vectorizer and a classifier go into one pipeline [8]. **Listing 12.3** compares three ways of turning text into numbers, all feeding the same `LogisticRegression`. `CountVectorizer(binary=True)` is our 0/1 bag of words. `TfidfVectorizer` weights each word by *term frequency–inverse document frequency*: a word counts more when it is frequent in this message and rare across messages,

$$\text{tfidf}(t, m) = \text{tf}(t, m) \cdot \left(\ln \frac{1 + n}{1 + \text{df}(t)} + 1 \right) \tag{12.12}$$

where $\text{tf}(t, m)$ is how often term t occurs in message m, n the number of training messages and $\text{df}(t)$ the number of messages containing t (this is scikit-learn's smoothed default [9]); `ngram_range=(1, 2)` adds word pairs such as "klik link". The third option, `analyzer="char_wb"` with `ngram_range=(3, 5)`, uses pieces of 3 to 5 characters inside word boundaries, so "hadiah", "hadiahnya" and "hadiah2" share most of their pieces.

Listing 12.3 `sklearn_spam.py`: three text representations feeding scikit-learn's `LogisticRegression`.

```
# sklearn_spam.py - the same filter with scikit-learn, plus tf-idf and bigrams
from sklearn.feature_extraction.text import CountVectorizer, TfidfVectorizer
from sklearn.linear_model import LogisticRegression
from sklearn.metrics import confusion_matrix, precision_score, recall_score
from sklearn.pipeline import make_pipeline
from textprep import load, stratified_split

texts, y = load()
tr, te = stratified_split(y)                  # the same split as logreg.py
X_tr, X_te = [texts[i] for i in tr], [texts[i] for i in te]

models = {
    "words, 0/1 counts": make_pipeline(
        CountVectorizer(binary=True), LogisticRegression(C=10)),
    "tf-idf, 1-2 grams": make_pipeline(
        TfidfVectorizer(ngram_range=(1, 2), sublinear_tf=True),
        LogisticRegression(C=10)),
    "tf-idf, char 3-5": make_pipeline(
        TfidfVectorizer(analyzer="char_wb", ngram_range=(3, 5)),
        LogisticRegression(C=10)),
}
for name, model in models.items():
    model.fit(X_tr, y[tr])
    pred = model.predict(X_te)
    (tn, fp), (fn, tp) = confusion_matrix(y[te], pred)
    print(f"{name:18s} TP {tp:2d} FP {fp} FN {fn} TN {tn}  "
          f"precision {precision_score(y[te], pred):.3f}  "
          f"recall {recall_score(y[te], pred):.3f}")
```

```
words, 0/1 counts  TP 19 FP 1 FN 2 TN 32  precision 0.950  recall 0.905
tf-idf, 1-2 grams  TP 19 FP 2 FN 2 TN 31  precision 0.905  recall 0.905
tf-idf, char 3-5   TP 20 FP 2 FN 1 TN 31  precision 0.909  recall 0.952
```

In scikit-learn the penalty strength is given as `C`, the *inverse* of our λ (roughly $C = 1/(n\lambda)$), so `C=10` means a light penalty. Since version 1.8 the old `penalty=` argument is deprecated: the amount of L2 is set with `C` alone, and `l1_ratio` chooses between L2 and L1 [10]. Examples you find online that pass `penalty="l2"` still work in 1.9 with a warning and will break in 1.10.

Character n-grams give the best recall, 20 of 21, and all three are close in precision. With only 54 test messages, one message is almost two percentage points; differences of one or two messages are not evidence that one method is better. Chapter 20 shows how cross-validation gives steadier comparisons.

12.4.5 The app

Listing 12.4 is what Bu Dewi would run. It trains on all 181 messages (for a deployed model we use every labeled example we have; the test split was only for measuring), scores one message, and explains the verdict. The explanation uses Equation (12.1) directly: the contribution of word j is $w_j x_j$, so for a message it is simply the weight of each word present.

Listing 12.4 `spam_app.py`: the spam filter as a command-line app that explains its verdict.

```python
# spam_app.py - score one message and show which words pushed it
import argparse
import numpy as np
from sklearn.feature_extraction.text import CountVectorizer
from sklearn.linear_model import LogisticRegression
from sklearn.pipeline import make_pipeline
from textprep import load

def train():
    texts, y = load()
    model = make_pipeline(CountVectorizer(binary=True), LogisticRegression(C=10))
    return model.fit(texts, y)                    # the app learns from all 181

def explain(model, text, k=4):
    vec, clf = model[0], model[-1]
    x = vec.transform([text]).toarray()[0]
    names = vec.get_feature_names_out()
    contrib = x * clf.coef_[0]                    # w_j * x_j for present words
    order = np.argsort(contrib)
    up = [f"{names[j]} (+{contrib[j]:.2f})" for j in order[::-1][:k]
          if contrib[j] > 0]
    down = [f"{names[j]} ({contrib[j]:.2f})" for j in order[:k] if contrib[j] < 0]
    return up, down

def main():
    ap = argparse.ArgumentParser(description="Indonesian/English SMS spam filter")
    ap.add_argument("message")
    ap.add_argument("--threshold", type=float, default=0.5)
    a = ap.parse_args()
    model = train()
    p = model.predict_proba([a.message])[0, 1]
    verdict = "SPAM" if p >= a.threshold else "not spam"
    print(f"P(spam) = {p:.3f}  ->  {verdict} (threshold {a.threshold})")
    up, down = explain(model, a.message)
    print("pushed toward spam :", ", ".join(up) or "-")
    print("pushed toward ham  :", ", ".join(down) or "-")

if __name__ == "__main__":
    main()
```

12.5 Running It

A classic prize scam:

```
python spam_app.py "Selamat! Anda menang undian 50 juta, klik link ini untuk klaim
hadiah"
```

```
P(spam) = 1.000  ->  SPAM (threshold 0.5)
pushed toward spam : anda (+2.51), link (+1.76), untuk (+1.03), klik (+0.98)
pushed toward ham  : -
```

A customer message about laundry:

```
python spam_app.py "Cucian kamu sudah selesai, nanti sore aku antar ke rumah ya"
```

```
P(spam) = 0.000  ->  not spam (threshold 0.5)
pushed toward spam : ke (+0.25), rumah (+0.01)
pushed toward ham  : aku (-2.01), sudah (-1.79), cucian (-0.53), kamu (-0.48)
```

And a hard case, a genuine message full of promotional words:

```
python spam_app.py "Promo gratis ongkir di toko langganan kita sampai besok"
```

```
P(spam) = 0.030  ->  not spam (threshold 0.5)
pushed toward spam : ongkir (+0.61), gratis (+0.56), promo (+0.27)
pushed toward ham  : kita (-1.17), sampai (-0.46), besok (-0.43), toko (-0.30)
```

The words *ongkir*, *gratis* and *promo* do push toward spam, but *kita*, *sampai*, *besok* and *toko* push back harder: a friend talking about "our" shop tomorrow does not sound like a stranger selling. That is the difference between a keyword blacklist, which would have blocked this message, and a learned model, which weighs all the evidence together. Each run takes one to two and a half seconds on the build machine, almost all of it spent importing scikit-learn; the training itself takes a few milliseconds.

The probabilities printed are extreme (1.000 and 0.000) because `C=10` applies only a light penalty and the vocabulary separates our training messages easily. A model this sure of itself is confident, not necessarily right; with more varied real data the probabilities would be more modest.

12.6 Improving It

The easiest improvement costs no new data: choose the threshold on purpose. The default of 0.5 treats both mistakes as equally bad. **Listing 12.5** uses the character n-gram model and counts, for seven thresholds, how much spam is caught and how many genuine messages are flagged.

Listing 12.5 `threshold.py`: spam caught against genuine messages flagged, as the threshold moves.

```
# threshold.py - trade missed spam against good messages lost, by moving the cut
import numpy as np
from sklearn.feature_extraction.text import TfidfVectorizer
from sklearn.linear_model import LogisticRegression
from sklearn.pipeline import make_pipeline
from textprep import load, stratified_split

texts, y = load()
tr, te = stratified_split(y)
model = make_pipeline(TfidfVectorizer(analyzer="char_wb", ngram_range=(3, 5)),
                      LogisticRegression(C=10))
model.fit([texts[i] for i in tr], y[tr])
p = model.predict_proba([texts[i] for i in te])[:, 1]
yt = y[te]
print("threshold  spam caught  good messages flagged")
for t in [0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8]:
    flag = p >= t
    caught = np.sum(flag & (yt == 1))
    lost = np.sum(flag & (yt == 0))
    print(f"   {t:.1f}       {caught:2d} / {yt.sum()}          {lost:2d} / "
          f"{(yt == 0).sum()}")
```

```
threshold  spam caught  good messages flagged
   0.2       21 / 21          13 / 33
   0.3       21 / 21           5 / 33
   0.4       21 / 21           4 / 33
   0.5       20 / 21           2 / 33
   0.6       13 / 21           1 / 33
   0.7        9 / 21           1 / 33
   0.8        2 / 21           1 / 33
```

Figure 12.5 draws the same trade-off for every threshold between 0.05 and 0.95. At 0.5 the filter catches 20 of 21 spam messages and flags 2 of 33 genuine ones. Raising the threshold to 0.6 cuts the flagged genuine messages to 1 but lets 8 spam messages through. Lowering it to 0.3 catches everything but flags 5 genuine messages. There is no free lunch; there is only a choice, and it

belongs to whoever pays for each kind of mistake. For Bu Dewi's front desk a good design is two thresholds: above 0.8 goes straight to the spam folder, between 0.3 and 0.8 is shown with a warning, below 0.3 is delivered normally.

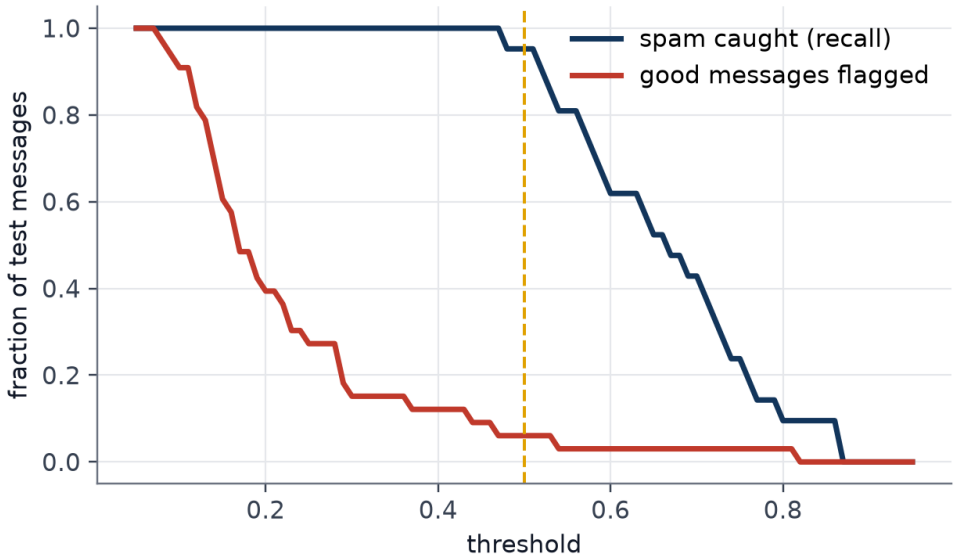

Figure 12.5 Fraction of spam caught (recall) and fraction of genuine messages flagged, against the decision threshold, for the character n-gram model on the 54 test messages.

Three further improvements are worth knowing. More and fresher data beats everything else: spammers change their wording every month, so a real filter is retrained regularly on newly reported messages. Features beyond words help: the presence of a link, a phone number, an amount of money, or a message from an unknown number are strong signals. And the character n-grams of **Listing 12.3** already defend against the misspellings spammers use to dodge filters ("h4diah", "gr4tis").

Finally the tests. **Listing 12.6** checks that the sigmoid is symmetric, that the tokenizer behaves as documented, that the model learns a tiny separable problem, and that unknown words are ignored.

Listing 12.6 `test_logreg.py`: four tests for the spam filter's building blocks.

```python
# test_logreg.py - run with:  python -m pytest -q
import numpy as np
from logreg import LogisticRegressionGD, log_loss, sigmoid
from textprep import BagOfWords, tokens

def test_sigmoid_is_symmetric():
    z = np.array([-3.0, 0.0, 3.0])
    assert np.allclose(sigmoid(z) + sigmoid(-z), 1.0)
    assert sigmoid(np.array(0.0)) == 0.5

def test_tokens_lowercase_and_split():
    expected = ["klik", "bit", "ly", "hadiah", "2026"]
    assert tokens("KLIK bit.ly/Hadiah-2026!") == expected

def test_learns_a_separable_toy_problem():
    X = np.array([[1, 0], [1, 0], [0, 1], [0, 1]], dtype=float)
    y = np.array([1, 1, 0, 0])
    m = LogisticRegressionGD(lr=1.0, epochs=200, lam=0.0).fit(X, y, report=0)
    assert (m.predict(X) == y).all()
    assert log_loss(y, m.predict_proba(X)) < 0.1

def test_unknown_words_are_ignored():
    bow = BagOfWords().fit(["halo dunia"])
    assert bow.transform(["dunia baru"]).tolist() == [[1.0, 0.0]]
```

```
....                                                                     [100%]
4 passed in 0.26s
```

12.7 Common Mistakes, and How to Avoid Them

Building the vocabulary from all messages. If the test messages help build the vocabulary, their words get columns even though, in real use, a new message may contain words never seen before. Fit the vectorizer on training messages only; a scikit-learn pipeline enforces this.

Judging by accuracy alone. With 111 genuine and 70 spam messages, a "filter" that never flags anything scores 61 percent accuracy and catches nothing. Always look at the confusion matrix, precision and recall.

Using the test set to pick the threshold or λ. Every choice tuned on the test set makes its score optimistic. Tune on a separate validation set or by cross-validation (Chapter 20), then report the test score once.

Reading weights of rare words as meaningful. A word seen once in one spam message can get a sizeable weight by chance. Trust weights of words that occur in many messages, and keep the penalty on.

Forgetting the sigmoid's saturation. Very large scores make e^{-z} underflow and p become exactly 1.0 in floating point, and $\ln(1-p)$ becomes $-\infty$. Clip probabilities before logarithms, as `log_loss` does, or use a library routine that works with scores directly.

Passing `penalty="l2"` from old tutorials. In scikit-learn 1.8 and later, the `penalty` argument is deprecated; use `C` (and `l1_ratio` if you want L1) [10].

Assuming the filter understands language. It counts words. "Tidak ada hadiah" (there is no prize) contains *hadiah*. Chapter 15 shows a simple way to handle negation, and Part 9 moves to models that read whole sentences.

12.8 Chapter Summary

- A bag of words turns a message into a 0/1 vector over a vocabulary built from training messages.
- Logistic regression computes a linear score (Equation (12.1)) and turns it into a probability with the sigmoid (Equation (12.2), Equation (12.3)). Each weight adds to the log-odds of spam (Equation (12.4)).
- Log-loss (Equation (12.5)) punishes confident wrong probabilities without limit and is the right cost for probabilities; the training cost adds an L2 penalty (Equation (12.6)) so rare words cannot be memorized.
- The gradient reduces to "prediction minus truth" per message (Equation (12.7), Equation (12.8)), and gradient descent (Equation (12.9)) finds the single minimum of the convex cost.
- Precision (Equation (12.10)) and recall (Equation (12.11)) measured on held-out messages describe a classifier better than accuracy; the threshold trades one against the other.
- scikit-learn pipelines combine a vectorizer (0/1 counts, tf-idf of Equation (12.12), character n-grams) with `LogisticRegression`, whose penalty is set by `C` since the `penalty` argument was deprecated.
- A linear model explains itself: the contribution of each word to a verdict is its weight.

12.9 Exercises

1. Using the toy filter of the example in Section 12.3.2, compute the probability of spam for "klik hadiah aku" and for "halo". What does the second answer tell you about b?
2. Show that $\sigma'(z) = \sigma(z)(1-\sigma(z))$, and then that $\partial \ell_i / \partial z_i = p_i - y_i$.
3. A mailbox receives 1,000 messages a day, 20 of them spam. Filter A flags nothing. Filter B flags 25 messages, 18 of which are spam. Compute accuracy, precision and recall for both, and say which you would deploy.
4. Run the app on the English message "Your parcel is waiting, confirm your address at this link today" with threshold 0.3, and on "Mama sudah sampai rumah, nanti mama telepon ya". Explain both verdicts from the word contributions.
5. Train `LogisticRegressionGD` for 1,000 epochs with $\lambda = 0, 0.001, 0.01, 0.1, 1$. Report the weight size $\| \mathbf{w} \|$, the training and test log-loss, and the test accuracy, and explain the pattern.
6. The spammer's trick "k1ik l1nk" defeats the word model. Explain why, and why the character n-gram model is harder to fool.

12.10 Solutions to the Exercises

Exercise 12.1. "klik hadiah aku": $z = -0.8 + 1.2 + 0.9 - 1.5 = -0.2$, so $p = 1/(1+e^{0.2}) = 1/(1+1.221) = 0.450$: not spam, narrowly; the personal *aku* outweighs the bias toward spam that *klik* and *hadiah* bring. "halo" contains no known word, so $z = b = -0.8$ and $p = 1/(1+e^{0.8}) = 0.310$. The bias alone sets the probability of a message about which the words say nothing; it reflects how common spam is in the training data.

Exercise 12.2. Write $\sigma(z) = (1+e^{-z})^{-1}$. By the chain rule, $\sigma'(z) = -(1+e^{-z})^{-2} \cdot (-e^{-z}) = \frac{e^{-z}}{(1+e^{-z})^2}$. Since $1 - \sigma(z) = \frac{e^{-z}}{1+e^{-z}}$, this equals $\sigma(z)(1-\sigma(z))$. Now $\ell = -[y \ln p + (1-y)\ln(1-p)]$ with $p = \sigma(z)$, so $\frac{\partial \ell}{\partial z} = -\left[\frac{y}{p} - \frac{1-y}{1-p}\right] p(1-p) = -[y(1-p) - (1-y)p] = p - y$.

Exercise 12.3. Filter A: TP 0, FP 0, FN 20, TN 980; accuracy $980/1000 = 0.98$, precision undefined (it flags nothing; we report 0), recall $0/20 = 0$. Filter B: TP 18, FP 7, FN 2, TN 973; accuracy $991/1000 = 0.991$, precision $18/25 = 0.72$, recall $18/20 = 0.90$. The accuracies look almost the same; the confusion matrix shows that A is useless. Deploy B, but look at the 7 genuine messages it flags: if they matter, raise the threshold.

Exercise 12.4.

```
python spam_app.py "Your parcel is waiting, confirm your address at this link today" --
threshold 0.3
```

```
P(spam) = 0.899  ->  SPAM (threshold 0.3)
pushed toward spam : link (+1.76), your (+0.74), today (+0.54), this (+0.40)
pushed toward ham  : is (-0.11), at (-0.11)
```

```
python spam_app.py "Mama sudah sampai rumah, nanti mama telepon ya"
```

```
P(spam) = 0.015  ->  not spam (threshold 0.5)
pushed toward spam : telepon (+0.35), mama (+0.22), rumah (+0.01)
pushed toward ham  : sudah (-1.79), sampai (-0.46), nanti (-0.33), ya (-0.03)
```

The first message contains *link*, *your*, *today* and *this*, all learned from English scams in the training set; only the tiny weights of *is* and *at* push back. It would be spam even at 0.5. The second contains *mama* and *telepon*, which appear in the "Mama minta pulsa" scam, but the strongly personal *sudah*, *sampai* and *nanti* outweigh them. The model has learned that the scam and the real mother use some of the same words, and that the rest of the sentence decides.

Exercise 12.5. Listing 12.7 trains five models.

Listing 12.7 `solutions/ex_lambda.py`: the effect of the L2 penalty strength.

```
# ex_lambda.py - Exercise 12.5: how the L2 penalty changes weights and accuracy
import sys
from pathlib import Path
import numpy as np
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from logreg import LogisticRegressionGD, log_loss
from textprep import BagOfWords, load, stratified_split

texts, y = load()
tr, te = stratified_split(y)
bow = BagOfWords().fit([texts[i] for i in tr])
X_tr = bow.transform([texts[i] for i in tr])
X_te = bow.transform([texts[i] for i in te])
for lam in [0.0, 0.001, 0.01, 0.1, 1.0]:
    m = LogisticRegressionGD(lam=lam, epochs=1000).fit(X_tr, y[tr], report=0)
    acc = np.mean(m.predict(X_te) == y[te])
    print(f"lambda {lam:5.3f}: |w| = {np.linalg.norm(m.w):6.2f}  "
          f"train loss {log_loss(y[tr], m.predict_proba(X_tr)):.3f}  "
          f"test loss {log_loss(y[te], m.predict_proba(X_te)):.3f}  "
          f"test accuracy {acc:.3f}")
```

```
lambda 0.000: |w| =   9.96  train loss 0.012  test loss 0.192  test accuracy 0.944
lambda 0.001: |w| =   8.28  train loss 0.024  test loss 0.212  test accuracy 0.944
lambda 0.010: |w| =   4.55  train loss 0.110  test loss 0.306  test accuracy 0.907
lambda 0.100: |w| =   1.48  train loss 0.379  test loss 0.496  test accuracy 0.796
lambda 1.000: |w| =   0.23  train loss 0.612  test loss 0.637  test accuracy 0.611
```

As λ grows the weights shrink ($\|\mathbf{w}\|$ from 9.96 to 0.23), the training loss rises (the model is not allowed to fit as closely) and, beyond a point, the test loss rises too, because a heavily penalized model cannot use its evidence. With these 127 clean training messages the lightest penalties do best on the test set. That is a property of this small, tidy data set, not a law: with noisier or larger

vocabularies a moderate penalty usually wins. The right λ is chosen on validation data, never on the test set.

Exercise 12.6. The word model sees `k1ik` and `l1nk` as unknown tokens and ignores them, so the message loses its two strongest spam signals. The character model breaks words into 3- to 5-character pieces within word boundaries: “k1ik” still contains the piece “ik” (and “l1nk” still has “nk”), and the rest of the message (“hadiah”, “anda”, “sekarang”) keeps its pieces untouched. To dodge a character model a spammer must mangle almost every word, which also makes the message unreadable to the person being fooled.

Chapter 13

Iris Flower Classifier: k-Nearest Neighbors

The two models of the previous chapters learned a formula: weights and a bias. This chapter meets a method that learns no formula at all. To name a new flower, *k-nearest neighbors* (k-NN) simply finds the flowers it remembers that look most like the new one and lets them vote. It is the most intuitive learning method there is, and it teaches three ideas that stay with us for the rest of the book: that "looking alike" must be defined as a distance; that the units of the features can quietly decide the answer; and that a model's single most important setting, here the number k, is chosen by cross-validation, never by peeking at the test set. By the end of the chapter you will be able to compute Euclidean and Manhattan distances by hand; implement k-NN from scratch with a proper tie-break; explain why $k = 1$ overfits and a huge k underfits; choose k by cross-validation with scikit-learn's `GridSearchCV`; standardize features and show why it matters; and run a small app that names an iris from four measurements and shows the flowers it resembles.

13.1 Why an Iris Classifier?

In 1935 the botanist Edgar Anderson measured flowers of three kinds of iris growing in the Gaspé Peninsula in Canada: *Iris setosa*, *Iris versicolor* and *Iris virginica* [1]. For each flower he recorded four numbers, the length and width of the *sepal* (the outer, leaf-like part of the flower) and of the *petal* (the colored inner part). A year later the statistician Ronald Fisher used Anderson's 150 flowers to demonstrate a method for telling species apart from measurements [2]. Ninety years on, the table is still the first data set most people meet in machine learning, and it ships inside scikit-learn, so it works with no download at all [3].

Why begin a learning method with flowers instead of something more practical? Because iris is small enough to see. With 150 rows and 4 columns we can print every neighbor of a query, draw the whole data set on one page, and check every answer by eye. The method we build here, though, is exactly the one used in practical systems that must say "this new thing is like those old things": recommending a laundry service to a customer whose history resembles other customers' histories, flagging a transaction that looks like past frauds, or finding a similar product in a catalog. Part 6 builds several of those on the same idea.

The app we build takes four measurements in centimeters:

```
python iris_app.py 6.3 2.8 4.9 1.6
```

and answers with a species, the votes behind it, and the seven flowers from Anderson's collection that it resembles most.

13.2 The Idea in Plain Words

Imagine you move to a new neighborhood in Surabaya and want to guess which football club people support. You do not need a theory of football loyalty. You knock on the doors of your seven

nearest neighbors, ask each one, and go with the majority. If five say Persebaya and two say something else, you guess Persebaya. That is k-NN with $k = 7$.

For flowers, "nearest" means "most similar in measurements". Put every flower on a map whose directions are its measurements: petal length east–west, petal width north–south, and, in directions we cannot draw, the two sepal measurements. Similar flowers land close together. **Figure 13.1** shows the two petal measurements of all 150 flowers. The three species form three clouds; setosa sits far off by itself, while versicolor and virginica touch and overlap a little. The star is a new flower. Its seven nearest neighbors (circled) are a mix: four virginica and three versicolor. So k-NN says virginica, but only just, and that "only just" is honest information.

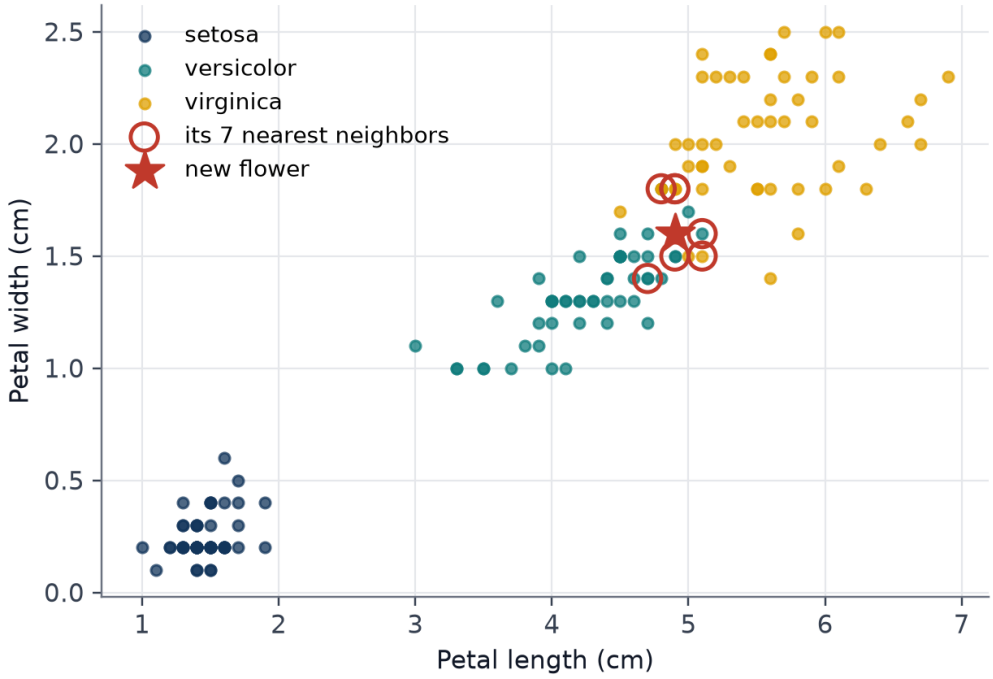

Figure 13.1 Petal length and width of the 150 iris flowers. The star is the new flower (6.3,2.8,4.9,1.6); the circles mark its seven nearest neighbors, measured with all four features.

Notice what k-NN does *not* do. It does not summarize the data in weights. "Training" is just remembering every flower. All the work happens when a question arrives: measure the distance to every remembered flower, sort, take the k closest, count votes. For this reason k-NN is called a *lazy* learner, or an *instance-based* method: the model *is* the data. The idea goes back to a 1951 report by Fix and Hodges [4], and Cover and Hart proved in 1967 that, with enough data, even the single nearest neighbor makes at most twice as many mistakes as the best possible classifier [5].

Two choices decide how well it works. The first is what "distance" means, and in particular what happens when one measurement is recorded in centimeters and another in millimeters. The second is k. With $k = 1$ every flower in the training set is its own little kingdom, so a single oddly shaped flower creates an island of the wrong species around itself. With k enormous, say all 150, every question gets the same answer, the majority species. Somewhere between lies the right amount of smoothing.

> **KEY INSIGHT:** k-NN has no formula to fit, but it still has a setting to choose, k, and that choice is where it can overfit or underfit. Picking a model's settings on data it was not trained on is the same discipline for every method in this book.

13.3 The Mathematics, Gently

13.3.1 Distance between two flowers

Describe a flower by its four measurements, a vector $\mathbf{x} = (x_1, x_2, x_3, x_4)$. The distance between two flowers $\mathbf{x}$ and $\mathbf{q}$ that everyone knows from school is the straight-line one, measured with a ruler on the map. With two features this is Pythagoras; with d features it is the same rule with more terms:

$$\text{dist}(\mathbf{x}, \mathbf{q}) = \sqrt{\sum_{j=1}^{d} (x_j - q_j)^2} \tag{13.1}$$

This is the *Euclidean distance*. Another common choice is to walk along the grid, like a becak that must follow the streets of a city laid out in blocks, adding the differences without squaring:

$$\text{dist}_1(\mathbf{x}, \mathbf{q}) = \sum_{j=1}^{d} |x_j - q_j| \tag{13.2}$$

This is the *Manhattan* or *city-block distance*. Both are special cases of the *Minkowski distance* with a power p ($p = 2$ for Equation (13.1), $p = 1$ for Equation (13.2)), which is scikit-learn's default family [6].

> **EXAMPLE.** New flower $\mathbf{q}$ = (6.3,2.8,4.9,1.6) and flower number 133 of the data set, $\mathbf{x}$ = (6.3,2.8,5.1,1.5).
>
> Differences: 0,0, −0.2,0.1. Squares: 0,0,0.04,0.01. Sum 0.05. Euclidean distance $\sqrt{0.05} = 0.224$.
>
> Manhattan distance: $0 + 0 + 0.2 + 0.1 = 0.3$.
>
> Flower number 72 is (6.3,2.5,4.9,1.5): differences 0,0.3,0,0.1, Euclidean $\sqrt{0.09 + 0.01} = 0.316$. So 133 is nearer than 72. These are the first and fourth neighbors printed by the app in Section 13.5.

13.3.2 The vote

Let $N_k(\mathbf{q})$ be the set of the k training flowers nearest to $\mathbf{q}$, and let y_i be the species of flower i. The predicted species is the one with most votes:

$$\hat{y}(\mathbf{q}) = \underset{c}{\text{argmax}} \sum_{i \in N_k(\mathbf{q})} [y_i = c] \tag{13.3}$$

The bracket $[y_i = c]$ is 1 if flower i belongs to species c and 0 otherwise, so the sum counts the votes for c, and argmax_c means "the c that makes this largest". When two species tie, we need a rule. Ours gives the win to the tied species whose member is nearest to $\mathbf{q}$: the closest witness breaks the tie.

A refinement lets closer neighbors count more. With *distance weighting* each vote is worth the inverse of its distance:

$$\hat{y}(\mathbf{q}) = \operatorname*{argmax}_{c} \sum_{i \in N_k(\mathbf{q})} \frac{[y_i = c]}{\operatorname{dist}(\mathbf{x}_i, \mathbf{q})} \tag{13.4}$$

A neighbor at distance 0.2 then counts twice as much as one at 0.4. (If a training flower sits at distance exactly 0, it simply decides the answer.)

13.3.3 Units matter: standardization

Equation (13.1) adds squared differences from different features as if they were in the same currency. They may not be. If sepal width is recorded in millimeters instead of centimeters, every difference in that feature becomes ten times larger, its square a hundred times larger, and suddenly sepal width decides almost every distance. Nothing about the flowers changed; only a unit did. The cure, as in Chapter 11, is to put every feature on the same footing with the z-score

$$z_j = \frac{x_j - \mu_j}{\sigma_j} \tag{13.5}$$

where μ_j and σ_j are the mean and standard deviation of feature j over the training flowers. After Equation (13.5) a difference of 1 means "one typical spread" in every feature, whatever its unit. Section 13.6 measures the effect.

13.3.4 How much work is a prediction?

To answer one question, k-NN computes the distance to all n training flowers, each costing about d subtractions, squarings and additions, and then selects the k smallest. The cost C_{query} of one query is about

$$C_{\text{query}} \approx n \cdot d \tag{13.6}$$

operations, which is nothing for $n = 150$ and $d = 4$ (600 operations) but a real concern for a million customers with a hundred features each. Tree-shaped indexes such as the k-d tree avoid measuring every point when d is small [7]; scikit-learn chooses such an index automatically [6].

13.3.5 Choosing k honestly: cross-validation

Which k is best? We cannot ask the test set, because a score used for choosing is no longer an honest score for reporting. Instead we split the *training* data itself. In m-fold *cross-validation*, the training rows are cut into m equal folds. Each fold in turn is held out, the model is trained on the other $m - 1$ folds and scored on the held-out one, and the m scores are averaged:

$$\mathrm{CV}(k) = \frac{1}{m} \sum_{f=1}^{m} \text{accuracy}_f\,(k) \tag{13.7}$$

We compute $\mathrm{CV}(k)$ for every candidate k, keep the k with the highest average, retrain on all training rows with that k, and only then look at the test set, once [8]. With $m = 5$ each flower is held out exactly once. Chapter 20 studies cross-validation in depth.

13.4 Building It Step by Step

13.4.1 A first look at the data

The folder `Chapter013` uses the same `requirements.txt` as Chapter 11. The data needs no file: `load_iris` returns the 150 flowers bundled inside scikit-learn. **Listing 13.1** prints how many flowers each species has and the average of each measurement per species.

Listing 13.1 `explore_iris.py`: counting the flowers and averaging each measurement per species.

```
# explore_iris.py - first look at the 150 iris flowers that ship with scikit-learn
import pandas as pd
from sklearn.datasets import load_iris

iris = load_iris(as_frame=True)
df = iris.frame
df["species"] = iris.target_names[iris.target]
print(df.shape[0], "flowers,", len(iris.feature_names), "measurements (cm)")
print(df["species"].value_counts().to_string())
print()
means = df.drop(columns="target").groupby("species").mean().round(2)
means.columns = ["sepal_len", "sepal_wid", "petal_len", "petal_wid"]
print(means.to_string())
```

```
150 flowers, 4 measurements (cm)
species
setosa        50
versicolor    50
virginica     50

            sepal_len  sepal_wid  petal_len  petal_wid
species
setosa           5.01       3.43       1.46       0.25
versicolor       5.94       2.77       4.26       1.33
virginica        6.59       2.97       5.55       2.03
```

The table already tells the story of **Figure 13.1**. Setosa's petals are tiny (1.46 cm long on average) and nothing like the others; versicolor and virginica differ mostly in petal size, and their ranges overlap. We should expect k-NN to be perfect on setosa and to make its few mistakes between the other two.

13.4.2 k-NN from scratch

Listing 13.2 is the whole method in about forty lines.

Listing 13.2 `knn.py`: k-nearest neighbors from scratch, with a stratified split and test accuracy for several values of *k*.

```
# knn.py - k-nearest neighbors from scratch
from collections import Counter
import numpy as np
from sklearn.datasets import load_iris

def distances(A, q):
    return np.sqrt(((A - q) ** 2).sum(axis=1))      # Euclidean, to every row

class KNN:
    def __init__(self, k=5):
        self.k = k

    def fit(self, X, y):
        self.X, self.y = np.asarray(X, float), np.asarray(y)
        return self                                  # "training" = remembering

    def kneighbors(self, q):
        d = distances(self.X, q)
        idx = np.argsort(d, kind="stable")[: self.k]
        return idx, d[idx]

    def predict_one(self, q):
        idx, _ = self.kneighbors(q)
        votes = Counter(self.y[idx])
        best = max(votes.values())
        for i in idx:                                # tie: nearest winner wins
            if votes[self.y[i]] == best:
                return self.y[i]

    def predict(self, Q):
        return np.array([self.predict_one(q) for q in np.asarray(Q, float)])

def stratified_split(y, test_frac=0.3, seed=13):
    rng = np.random.default_rng(seed)
    test = []
    for c in np.unique(y):
        idx = rng.permutation(np.flatnonzero(y == c))
        test.extend(idx[: int(round(len(idx) * test_frac))])
    test = np.sort(np.array(test))
    return np.setdiff1d(np.arange(len(y)), test), test
```

Listing 13.2 (Continued) *knn.py: k-nearest neighbors from scratch, with a stratified split and test accuracy for several values of k.*

```
if __name__ == "__main__":
    X, y = load_iris(return_X_y=True)
    tr, te = stratified_split(y)
    print(f"{len(tr)} training flowers, {len(te)} test flowers")
    for k in [1, 3, 5, 7, 9, 15, 25, 51]:
        model = KNN(k).fit(X[tr], y[tr])
        acc = np.mean(model.predict(X[te]) == y[te])
        print(f"k = {k:2d}   test accuracy {acc:.3f}")
```

The function `distances` is Equation (13.1) applied to every row of `A` at once: `A - q` subtracts the query from every row (NumPy *broadcasting*), the squares are summed across each row with `axis=1`, and the square root is taken. `KNN.fit` only stores the data, which is the "lazy" part. `kneighbors` sorts the distances and keeps the first k; the option `kind="stable"` makes equally distant flowers keep their original order, so results are reproducible. `predict_one` is Equation (13.3): a `Counter` tallies the species among the neighbors, and the loop walks the

neighbors from nearest to farthest and returns the first one whose species has the top vote count, which is exactly the tie-break of Section 13.3.2. `stratified_split` holds out 30 percent of each species, 15 flowers each, so the test set is balanced.

```
105 training flowers, 45 test flowers
k =  1   test accuracy 0.933
k =  3   test accuracy 0.933
k =  5   test accuracy 0.933
k =  7   test accuracy 0.933
k =  9   test accuracy 0.933
k = 15   test accuracy 0.933
k = 25   test accuracy 0.889
k = 51   test accuracy 0.911
```

Every k from 1 to 15 gets 42 of the 45 test flowers right (0.933). Only very large k does worse: with $k = 25$ the neighborhood of a borderline flower reaches deep into the other species. On a test set this small, one flower is 2.2 percentage points, so the flat run from 1 to 15 means "all about equally good", not "all exactly equal". To choose k we need something steadier than one test split.

13.4.3 Choosing k with scikit-learn

Listing 13.3 builds a pipeline of `StandardScaler` and `KNeighborsClassifier`, and hands it to `GridSearchCV`, which runs the 5-fold cross-validation of Equation (13.7) for every odd k from 1 to 31 on the 105 training flowers.

Listing 13.3 `sklearn_knn.py`: choosing k by 5-fold cross-validation, then testing once.

```
# sklearn_knn.py - choose k by cross-validation, then test once
from sklearn.datasets import load_iris
from sklearn.metrics import confusion_matrix
from sklearn.model_selection import GridSearchCV, StratifiedKFold
from sklearn.neighbors import KNeighborsClassifier
from sklearn.pipeline import make_pipeline
from sklearn.preprocessing import StandardScaler
from knn import stratified_split

X, y = load_iris(return_X_y=True)
tr, te = stratified_split(y)                    # the same split as knn.py
pipe = make_pipeline(StandardScaler(), KNeighborsClassifier())
grid = {"kneighborsclassifier__n_neighbors": list(range(1, 32, 2))}
cv = StratifiedKFold(n_splits=5, shuffle=True, random_state=0)
search = GridSearchCV(pipe, grid, cv=cv).fit(X[tr], y[tr])

scores = search.cv_results_["mean_test_score"]
for k, s in zip(grid["kneighborsclassifier__n_neighbors"], scores):
    print(f"k = {k:2d}  cross-validated accuracy {s:.3f}")
best = search.best_params_["kneighborsclassifier__n_neighbors"]
print("best k:", best)
pred = search.predict(X[te])
print(f"test accuracy with k = {best}: {(pred == y[te]).mean():.3f}")
print(confusion_matrix(y[te], pred))
```

```
k =  1  cross-validated accuracy 0.924
k =  3  cross-validated accuracy 0.943
k =  5  cross-validated accuracy 0.952
k =  7  cross-validated accuracy 0.962
k =  9  cross-validated accuracy 0.952
k = 11  cross-validated accuracy 0.943
k = 13  cross-validated accuracy 0.943
k = 15  cross-validated accuracy 0.933
k = 17  cross-validated accuracy 0.914
k = 19  cross-validated accuracy 0.895
k = 21  cross-validated accuracy 0.905
k = 23  cross-validated accuracy 0.895
k = 25  cross-validated accuracy 0.886
k = 27  cross-validated accuracy 0.895
k = 29  cross-validated accuracy 0.886
k = 31  cross-validated accuracy 0.886
best k: 7
test accuracy with k = 7: 0.911
[[15  0  0]
 [ 0 12  3]
 [ 0  1 14]]
```

The pipeline's parameters are named by joining the step name and the parameter name with a double underscore, hence `kneighborsclassifier__n_neighbors`. `StratifiedKFold` keeps the three species in equal proportions in every fold; `shuffle=True` with a fixed `random_state` mixes the rows reproducibly. **Figure 13.2** plots the cross-validated accuracy together with the accuracy on the training folds themselves.

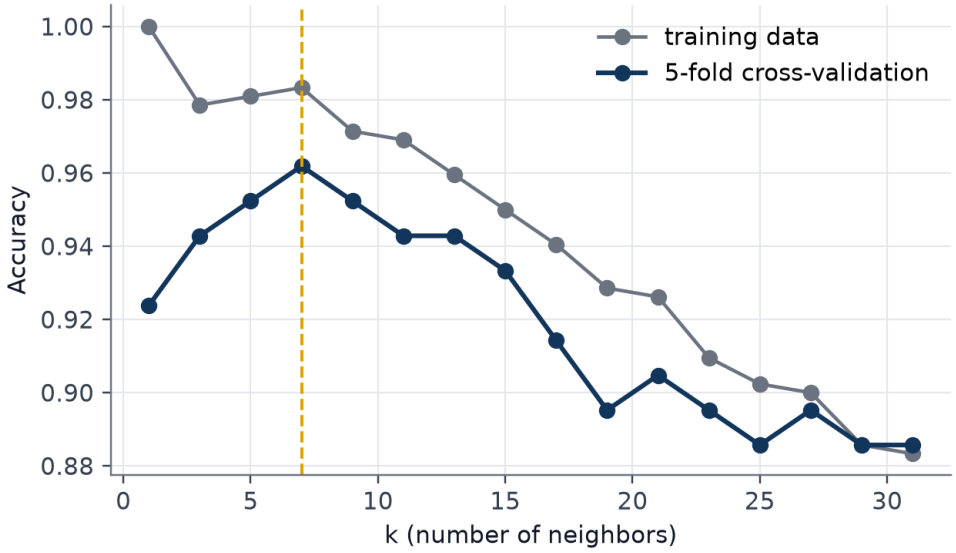

Figure 13.2 Accuracy against k on the training folds and under 5-fold cross-validation, for standardized features. The dashed line marks the chosen $k = 7$.

The shape is the classic one. At $k = 1$ training accuracy is perfect, because every training flower is its own nearest neighbor, while cross-validated accuracy is lower (0.924): the model has memorized, noise included. As k grows, the training score drops and the cross-validated score rises to a peak of 0.962 at $k = 7$, then falls again as the neighborhoods become too wide. Small k means high *variance* (answers swing with every individual flower); large k means high *bias* (answers are pulled toward the overall majority). The chosen $k = 7$ scores 0.911 on the test set, 41 of 45. The confusion matrix shows where the four mistakes are: all 15 setosa correct, 3 versicolor called virginica, 1 virginica called versicolor, exactly the overlap visible in **Figure 13.1**.

That the test score (0.911) is a little below the cross-validated one (0.962) is normal on 45 flowers and is precisely why we report the test score rather than the score we optimized.

13.4.4 The app

Listing 13.4 wraps the scratch `KNN` in a command-line app. It learns from all 150 flowers, predicts the species of the four measurements given, prints the votes, and lists the neighbors with their row numbers, measurements, species and distances. Being able to show the evidence is k-NN's great strength: the answer is not a number from a formula but "these seven real flowers".

Listing 13.4 `iris_app.py`: the iris classifier as a command-line app that shows its neighbors.

```
# iris_app.py - measure a flower, get its species and the flowers it resembles
import argparse
import numpy as np
from sklearn.datasets import load_iris
from knn import KNN

def main():
    ap = argparse.ArgumentParser(description="Iris species by k-nearest neighbors")
    for name in ["sepal_length", "sepal_width", "petal_length", "petal_width"]:
        ap.add_argument(name, type=float, help="centimeters")
    ap.add_argument("-k", type=int, default=7)
    a = ap.parse_args()
    iris = load_iris()
    q = np.array([a.sepal_length, a.sepal_width, a.petal_length, a.petal_width])
    model = KNN(a.k).fit(iris.data, iris.target)
    idx, d = model.kneighbors(q)
    names = iris.target_names
    print(f"prediction: {names[model.predict_one(q)]}  (k = {a.k})")
    votes = {names[c]: int(np.sum(iris.target[idx] == c)) for c in range(3)}
    print("votes:", ", ".join(f"{s} {v}" for s, v in votes.items() if v))
    print("nearest flowers (row, measurements, species, distance):")
    for i, di in zip(idx, d):
        print(f"  #{i:3d}  {iris.data[i]}  {names[iris.target[i]]:10s}  {di:.3f}")

if __name__ == "__main__":
    main()
```

The app uses the raw centimeter measurements without scaling. All four iris features are lengths in the same unit and of similar size, so here the raw distances are sensible; Section 13.6 shows when that assumption breaks.

13.5 Running It

A flower in the middle of the versicolor cloud:

```
python iris_app.py 5.8 2.8 4.3 1.4
```

```
prediction: versicolor  (k = 7)
votes: versicolor 7
nearest flowers (row, measurements, species, distance):
  # 96  [5.7 2.9 4.2 1.3]  versicolor  0.200
  # 55  [5.7 2.8 4.5 1.3]  versicolor  0.245
  # 99  [5.7 2.8 4.1 1.3]  versicolor  0.245
  # 94  [5.6 2.7 4.2 1.3]  versicolor  0.265
  # 61  [5.9 3.  4.2 1.5]  versicolor  0.265
  # 95  [5.7 3.  4.2 1.2]  versicolor  0.316
  # 78  [6.  2.9 4.5 1.5]  versicolor  0.316
```

The vote is unanimous and every neighbor is within 0.32 cm. Now the flower of **Figure 13.1**, on the border:

```
python iris_app.py 6.3 2.8 4.9 1.6
```

```
prediction: virginica  (k = 7)
votes: versicolor 3, virginica 4
nearest flowers (row, measurements, species, distance):
  #133  [6.3 2.8 5.1 1.5]  virginica   0.224
  #123  [6.3 2.7 4.9 1.8]  virginica   0.224
  #126  [6.2 2.8 4.8 1.8]  virginica   0.245
  # 72  [6.3 2.5 4.9 1.5]  versicolor  0.316
  #127  [6.1 3.  4.9 1.8]  virginica   0.346
  # 63  [6.1 2.9 4.7 1.4]  versicolor  0.361
  # 83  [6.  2.7 5.1 1.6]  versicolor  0.374
```

Four to three. The first and fourth neighbors are the flowers of the worked example in Section 13.3.1. An honest app should pass this doubt on to its user: "virginica, but three of the seven closest flowers are versicolor" is much more useful than "virginica". Each run takes about a second, nearly all of it importing scikit-learn for `load_iris`.

Figure 13.3 shows the whole map of decisions for two values of k, using only the two petal features so that it can be drawn. With $k = 1$ the border is jagged and small islands appear around individual flowers that sit inside the other species' cloud; with $k = 15$ the border is smooth and the islands are gone.

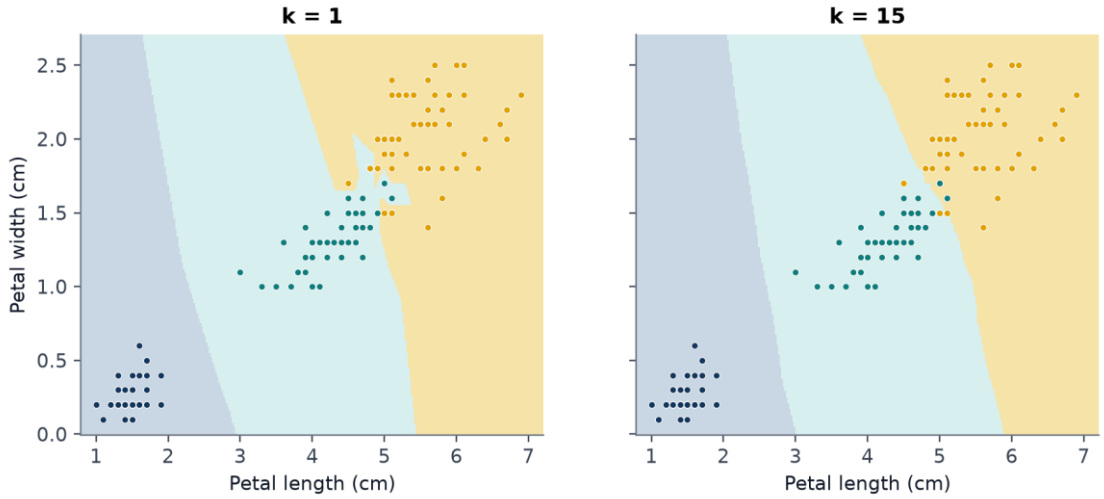

Figure 13.3 Decision regions of k-NN on petal length and width, for $k = 1$ (left) and $k = 15$ (right). Small k follows every individual flower; larger k smooths the border.

The picture also shows why the question "which species?" is sometimes the wrong question. Near the border between versicolor and virginica the honest answer is a mixture, and the vote counts are a rough estimate of it: four of seven neighbors is about 57 percent virginica. scikit-learn's `predict_proba` returns exactly these vote shares. They are not carefully calibrated probabilities, but they are far better than a bare label when a person must decide what to do next, for example whether to look at the flower more closely.

13.6 Improving It

Listing 13.5 measures four possible improvements with 10-fold cross-validation on all 150 flowers, reporting the mean accuracy and its standard deviation across the ten folds.

Listing 13.5 `improve.py`: the effect of units, scaling, distance weighting and feature choice on k-NN.

```
# improve.py - what helps k-NN: scaling, distance weights, fewer features
import numpy as np
from sklearn.datasets import load_iris
from sklearn.model_selection import StratifiedKFold, cross_val_score
from sklearn.neighbors import KNeighborsClassifier
from sklearn.pipeline import make_pipeline
from sklearn.preprocessing import StandardScaler

X, y = load_iris(return_X_y=True)
X_mm = X.copy()
X_mm[:, 1] *= 10                    # sepal width recorded in millimeters
cv = StratifiedKFold(n_splits=10, shuffle=True, random_state=1)

def score(model, data, label):
    s = cross_val_score(model, data, y, cv=cv)
    print(f"{label:38s} {s.mean():.3f} +/- {s.std():.3f}")

knn = KNeighborsClassifier(n_neighbors=7)
score(knn, X, "raw cm, all four features")
score(knn, X_mm, "sepal width in mm, no scaling")
scaled = make_pipeline(StandardScaler(), knn)
score(scaled, X_mm, "sepal width in mm, standardized")
weighted = KNeighborsClassifier(n_neighbors=7, weights="distance")
score(weighted, X, "raw cm, distance-weighted votes")
score(knn, X[:, 2:], "petal length and width only")
```

```
raw cm, all four features              0.967 +/- 0.045
sepal width in mm, no scaling          0.933 +/- 0.067
sepal width in mm, standardized        0.953 +/- 0.060
raw cm, distance-weighted votes        0.967 +/- 0.045
petal length and width only            0.960 +/- 0.044
```

Line by line:

- On the raw centimeter data, $k = 7$ reaches 0.967.
- Record one feature, sepal width, in millimeters, and accuracy drops to 0.933. The flowers are the same; only a unit changed, and sepal width, the least useful measurement, now dominates every distance.
- Standardize with Equation (13.5) and most of the loss comes back (0.953). It does not return exactly to 0.967 because standardization is not the same as "the original centimeters": it gives every feature equal spread, whereas in centimeters the petal features, which vary most and separate the species best, naturally had more say.
- Distance-weighted votes (Equation (13.4)) change nothing here (0.967), because the neighborhoods of iris flowers are compact.
- Using only the two petal features loses almost nothing (0.960). Fewer features means faster distances and pictures you can draw, and it guards against irrelevant features diluting the distance, a problem that grows quickly as the number of features rises (the *curse of dimensionality*).

The spreads of $$0.04 to 0.07 across folds are a reminder that differences of one or two points on 150 flowers are within the noise. The robust lessons are qualitative: units can silently hurt k-NN, scaling protects you, and the choice of features matters as much as the choice of k.

The tests in **Listing 13.6** pin down the distance, check that $k = 1$ reproduces the training labels, and check the majority vote and the nearest-neighbor tie-break.

Listing 13.6 `test_knn.py`: tests for the distance, the vote and the tie-break.

```
# test_knn.py - run with:  python -m pytest -q
import numpy as np
from knn import KNN, distances

def test_distance_is_pythagoras():
    assert np.allclose(distances(np.array([[3.0, 4.0]]), np.array([0.0, 0.0])), 5)

def test_one_neighbor_reproduces_training_labels():
    X = np.array([[0, 0], [1, 1], [5, 5]], dtype=float)
    y = np.array([0, 0, 1])
    assert (KNN(1).fit(X, y).predict(X) == y).all()

def test_majority_vote_and_tie_break():
    X = np.array([[0.0], [1.0], [2.0], [3.0]])
    y = np.array(["a", "b", "b", "a"])
    assert KNN(3).fit(X, y).predict_one(np.array([1.2])) == "b"
    assert KNN(2).fit(X, y).predict_one(np.array([0.1])) == "a"   # tie: nearest
```

```
...                                                                  [100%]
3 passed in 2.84s
```

13.6.1 From flowers to laundry customers

Everything in this chapter carries over to Profitina Laundry unchanged except the meaning of the columns. Suppose each customer is described by four numbers: how many orders they placed in the last three months, their average bill in thousands of rupiah, the share of their orders that were express service, and the number of days since their last visit. A new customer arrives and has placed two orders. Which services should the cashier suggest? k-NN answers: find the seven existing customers whose four numbers are closest, and suggest the services those seven use most. No formula about laundry habits is needed, no weights have to be trained, and a new customer joins the pool of neighbors the moment their data is stored, and the suggestion comes with its own explanation, “customers like you usually add ironing”.

The three lessons of this chapter become sharper with such data. First, units: an average bill of 45 (thousand rupiah) and a share of 0.2 live on completely different scales, so without standardization the bill alone would decide who is “similar”. Second, the choice of k: with $k = 1$ the suggestion depends on a single customer who might be unusual; with k in the hundreds every new customer gets the same popular suggestion. Third, cost: a chain with a few hundred thousand customers pays Equation (13.6) on every question, which is why real recommenders precompute neighbors overnight. Chapter 16 groups the same laundry customers into segments with k-means, and Part 6 builds full recommenders on this idea of similarity.

13.7 Common Mistakes, and How to Avoid Them

Mixing units without scaling. Centimeters with millimeters, rupiah with kilograms, age with income: the feature with the largest numbers wins every distance. Standardize, inside a pipeline, fitted on training rows only.

Choosing k on the test set. Trying $k = 1,3,5, \ldots$ and reporting the best test score reports luck. Choose k by cross-validation on training data (Equation (13.7)), then test once.

Evaluating with k = 1 on the training data. Every training point is its own nearest neighbor, so training accuracy is always 100 percent and tells you nothing.

Forgetting ties. With two classes an even k can split 3–3; with three classes even an odd k can split 3–3–1. Decide the tie-break (nearest neighbor, or distance weighting) rather than leaving it to whatever order your code happens to see.

Using k-NN on huge data without an index. The cost of Equation (13.6) per query adds up. For large data use scikit-learn's tree indexes or an approximate nearest-neighbor library, and reduce the number of features first (Chapter 17 shows how with PCA).

Including useless features. A feature unrelated to the answer adds noise to every distance. k-NN has no weights to switch it off; you must leave it out yourself.

13.8 Chapter Summary

- k-NN classifies a new point by a vote among the k training points nearest to it (Equation (13.3)); "training" is only storing the data.
- Nearness is a distance: Euclidean (Equation (13.1)) or Manhattan (Equation (13.2)). Votes can be weighted by inverse distance (Equation (13.4)).
- Distances are only meaningful when features share a scale; standardization (Equation (13.5)) removes the arbitrary effect of units.
- Small k overfits (jagged borders, high variance); large k underfits (everything drifts toward the majority, high bias).
- k is chosen by cross-validation on training data (Equation (13.7)) and the test set is used once, at the end. On iris, $k = 7$ reached 0.962 in cross-validation and 0.911 on the test set.
- A prediction costs about $n \cdot d$ operations (Equation (13.6)), so large data sets need an index or fewer features.
- k-NN explains itself by showing its neighbors, which makes it a natural first model whenever "similar cases" is a meaningful answer.

13.9 Exercises

1. By hand, compute the Euclidean distances from $\mathbf{q} = (5.0,3.4,1.6,0.3)$ to the flowers $A = (5.0,3.4,1.6,0.4)$, $B = (5.1,3.5,1.4,0.3)$ and $C = (5.9,3.0,4.2,1.5)$. Which is the single nearest neighbor?
2. Compute the Manhattan distances for the same three pairs. Do Euclidean and Manhattan agree on the order? Construct two points for which they disagree.
3. Three classes, $k = 7$, and the neighbors, nearest first, have the classes B, A, A, C, B, C, B. Which class wins by Equation (13.3)? Now take four classes and the neighbors B, A, A, C, B, C, D. Which class does `knn.py` predict, and why?
4. Run the app for $\mathbf{q}$ of Exercise 13.1 with $k = 5$ and compare with your hand computation.
5. A laundry has 250,000 customer records with 40 features each and must answer 100 "similar customer" questions per second. Estimate the work per second with Equation (13.6) and suggest two ways to reduce it.
6. *Leave-one-out* cross-validation is m-fold cross-validation with $m = n$: every flower is held out once and classified by all the others. Implement it with the scratch `KNN` for $k = 1,3,5,7,9,11,15$ and compare with **Figure 13.2**.

13.10 Solutions to the Exercises

Exercise 13.1. To A: differences $0,0,0,-0.1$; distance $\sqrt{0.01} = 0.100$. To B: differences $-0.1,-0.1,0.2,0$; squares $0.01 + 0.01 + 0.04 = 0.06$; distance 0.245. To C: differences $-0.9,0.4,-2.6,-1.2$; squares $0.81 + 0.16 + 6.76 + 1.44 = 9.17$; distance 3.028. The nearest neighbor is A, a setosa (C is a versicolor far away).

Exercise 13.2. Manhattan: A 0.1, B $0.1 + 0.1 + 0.2 = 0.4$, C $0.9 + 0.4 + 2.6 + 1.2 = 5.1$. Same order. They can disagree: from the origin, $P = (3,0)$ has Euclidean 3 and Manhattan 3, while $Q = (2,2)$ has Euclidean $\sqrt{8} = 2.83$ and Manhattan 4. Euclidean says Q is nearer, Manhattan says P is. Euclidean distance favors points that differ a little in many features; Manhattan favors points that differ in few.

Exercise 13.3. In the first case the votes are B 3, A 2, C 2, so B wins outright. In the second the votes are A 2, B 2, C 2, D 1: a three-way tie. `knn.py` walks the neighbors from nearest to farthest and returns the first whose class has the top count. The nearest neighbor is a B, and B has 2 votes, equal to the top count, so B is predicted. The nearest witness breaks the tie; with distance weighting (Equation (13.4)) the tie would almost never arise at all.

Exercise 13.4.

```
python iris_app.py 5.0 3.4 1.6 0.3 -k 5
```

```
prediction: setosa  (k = 5)
votes: setosa 5
nearest flowers (row, measurements, species, distance):
  # 26  [5.  3.4 1.6 0.4]  setosa      0.100
  #  7  [5.  3.4 1.5 0.2]  setosa      0.141
  # 39  [5.1 3.4 1.5 0.2]  setosa      0.173
  # 11  [4.8 3.4 1.6 0.2]  setosa      0.224
  # 17  [5.1 3.5 1.4 0.3]  setosa      0.245
```

The nearest neighbor is row 26, (5.0,3.4,1.6,0.4), at 0.100, exactly flower A of Exercise 13.1. All five neighbors are setosa.

Exercise 13.5. Per query about $250{,}000 \times 40 = 10^7$ operations; at 100 queries per second, 10^9 operations per second, which is a whole CPU core busy with arithmetic alone. Reductions: (a) reduce the features, for example from 40 to 8 with PCA (Chapter 17), a factor of 5; (b) use an index (k-d tree or ball tree for moderate dimensions, or an approximate nearest-neighbor library for large ones) so that most customers are never measured; (c) precompute answers for frequent questions.

Exercise 13.6. **Listing 13.7** holds each flower out in turn.

Listing 13.7 `solutions/ex_loo.py`: leave-one-out accuracy of the scratch k-NN on raw centimeters.

```python
# ex_loo.py - Exercise 13.6: leave-one-out accuracy of the from-scratch k-NN
import sys
from pathlib import Path
import numpy as np
from sklearn.datasets import load_iris
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from knn import KNN

X, y = load_iris(return_X_y=True)
for k in [1, 3, 5, 7, 9, 11, 15]:
    hits = 0
    for i in range(len(y)):
        keep = np.arange(len(y)) != i            # every flower but number i
        hits += KNN(k).fit(X[keep], y[keep]).predict_one(X[i]) == y[i]
    print(f"k = {k:2d}  leave-one-out accuracy {hits / len(y):.3f}"
          f"  ({len(y) - hits} mistakes)")
```

```
k =  1  leave-one-out accuracy 0.960  (6 mistakes)
k =  3  leave-one-out accuracy 0.960  (6 mistakes)
k =  5  leave-one-out accuracy 0.967  (5 mistakes)
k =  7  leave-one-out accuracy 0.967  (5 mistakes)
k =  9  leave-one-out accuracy 0.967  (5 mistakes)
k = 11  leave-one-out accuracy 0.973  (4 mistakes)
k = 15  leave-one-out accuracy 0.973  (4 mistakes)
```

Leave-one-out uses all 150 flowers and raw centimeters, so its numbers are not identical to **Figure 13.2** (105 training flowers, standardized), but the pattern agrees: $k = 1$ and $k = 3$ make the most mistakes, and moderate k does better. On raw centimeters the best values continue up to 11 and 15 with 4 mistakes. The differences between 4, 5 and 6 mistakes out of 150 are small; any k from 5 to 15 is a sound choice for iris.

Chapter 14

Loan Approval Advisor: An Explainable Decision Tree

Some decisions must come with reasons. When a bank, a cooperative or a buy-now-pay-later app turns down a loan, the applicant deserves to hear why, and the people who run the system must be able to check that the reasons are sensible and fair. This chapter builds a loan advisor on the most readable model in machine learning, the *decision tree*: a short list of yes-or-no questions, learned from past decisions, that anyone can follow with a finger. By the end of the chapter you will be able to measure how mixed a group of cases is with Gini impurity and entropy; find the best question to ask by trying every split; grow a tree recursively and print it as plain rules; explain one decision as the path through the tree; see a tree overfit as it grows deeper and stop it in time; turn domain knowledge into a feature (the debt-service ratio) and watch the tree shrink and improve; and produce "what would change the answer" suggestions for a rejected applicant. The data and the approval policy in this chapter are invented for teaching; the app shows how such models work and is not a credit policy or financial advice.

14.1 Why a Loan Advisor?

Mas Rizal repairs motorcycles in Wiyung and earns about 8 million rupiah a month. He wants to borrow 60 million over two years to buy a second lift. His cooperative's loan officer, Bu Ani, has seen hundreds of applications. She knows, without writing it down, that what matters most is whether the monthly installment eats too much of the income, that a history of missed payments is a red flag, and that someone who started their job last month is a greater risk than someone who has worked for ten years. She also knows that the number of children an applicant has is none of her business unless it genuinely changes their ability to pay.

We want an advisor that learns Bu Ani's way of deciding from her past decisions, and then does two things a spreadsheet formula cannot: it tells Mas Rizal *why*, in the same terms Bu Ani would use, and it tells him *what would change the answer* ("a loan of 55 million would pass", "the same loan over three years would pass").

A decision tree is the natural model for this. It was developed in the 1980s by statisticians (the CART method of Breiman and colleagues [1]) and by computer scientists (Quinlan's ID3 [2]) independently, precisely because its output is a set of rules that people can read. Rudin argued in 2019 that for high-stakes decisions about people, interpretable models like this one should be preferred to black boxes with explanations bolted on afterwards [3]. And trees are the building blocks of random forests and gradient boosting, the strongest methods for tables of data, which Chapter 19 builds from them.

14.2 The Idea in Plain Words

Think of the game "twenty questions". One player thinks of an animal; the other may ask yes-or-no questions. A good player does not start with "is it a pangolin?"; she starts with "does it live in water?", because whatever the answer, it rules out about half of the possibilities. Each good

question splits the remaining possibilities into two groups that are each *purer*, more dominated by one kind of answer, than before.

A decision tree plays this game with the loan applications. At the start all 450 training applications sit in one pile, about half approved and half rejected: as mixed as a pile can be. The tree tries every question of the form "is feature ≤ some value?" (is the income at most 6.5 million? is the tenor at most 18 months?) and keeps the one that splits the pile into the two purest sub-piles. Then it does the same inside each sub-pile, and again inside theirs, until the piles are pure or a depth limit is reached. The final piles are the *leaves*. A new application is answered by walking it down the questions to a leaf and reading off the majority decision in that leaf, together with how many past cases landed there.

The walk is the explanation. "Your installment would be 35 percent of your income, which is above the 33 percent at which past loans started being refused" is a sentence built directly from the path.

Two warnings are part of the idea. First, a tree that keeps asking questions until every leaf is pure will end up with leaves of one or two applications each, memorizing every odd decision in the past, including the mistakes. Depth must be limited. Second, a tree can only ask questions about the features it is given, one feature at a time. If the real rule is about a *ratio* of two features, the tree has to approximate it with a staircase of many questions. Giving it the ratio directly is often the single best improvement, and Section 14.6 does exactly that.

> **KEY INSIGHT:** A decision tree learns by repeatedly choosing the one question that makes the groups purest. Its explanations are exact, because the path *is* the model; but it is only as good as the questions its features allow it to ask.

14.3 The Mathematics, Gently

14.3.1 How mixed is a pile? Gini impurity and entropy

Take a pile of cases in which a fraction p were approved and $1 - p$ rejected. We want a number that is 0 when the pile is pure ($p = 0$ or $p = 1$) and largest when it is evenly mixed ($p = 0.5$). The *Gini impurity* is

$$G = 1 - p^2 - (1 - p)^2 \tag{14.1}$$

It has a friendly meaning: pick two cases from the pile at random, with replacement; G is the probability that they have different decisions. A pure pile gives $G = 0$; an even pile gives $1 - 0.25 - 0.25 = 0.5$. With more than two classes the rule is the same: $G = 1 - \sum_c p_c^2$, the sum running over the classes.

The other classic measure is *entropy*, from Shannon's information theory [4]:

$$H = -p\log_2 p - (1 - p)\log_2(1 - p) \tag{14.2}$$

measured in *bits*: 0 for a pure pile, 1 bit for an even one (with $0\log_2 0$ taken as 0). Entropy is the average number of yes-or-no questions still needed to learn a case's decision. **Figure 14.1** shows that the two curves have almost the same shape; in practice they choose nearly the same splits, and scikit-learn uses Gini by default [5].

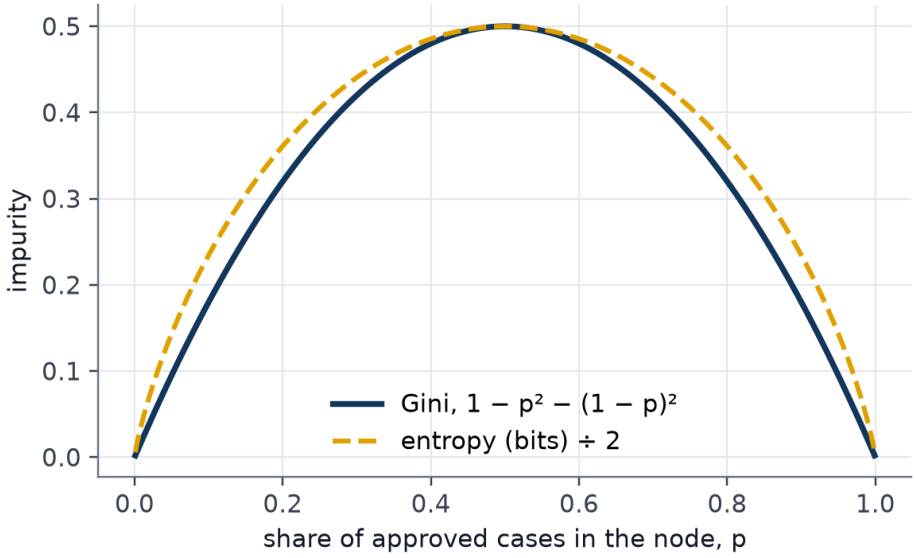

Figure 14.1 Gini impurity (Equation (14.1)) and entropy (Equation (14.2), halved to share the scale) as functions of the share p of approved cases. Both are zero for pure piles and largest for an even mix.

14.3.2 How good is a question? Weighted impurity and gain

A question "is feature j at most t?" splits a pile of n cases into a left pile of n_L cases (answer yes) and a right pile of n_R cases (answer no). The impurity after the split is the average of the two piles' impurities, each weighted by its size:

$$G_{\text{split}} = \frac{n_L}{n} G_L + \frac{n_R}{n} G_R \tag{14.3}$$

The improvement, or *gain*, is how much impurity the question removes:

$$\Delta = G - G_{\text{split}} \tag{14.4}$$

The tree chooses the feature j and the threshold t with the largest gain, which is the same as the smallest G_{split}. For a numeric feature only a few thresholds need trying: the midpoints between consecutive distinct values in the pile, since any threshold between the same two values splits the pile identically.

EXAMPLE. A pile of 10 applications, 6 approved and 4 rejected: $p = 0.6$, so $G = 1 - 0.36 - 0.16 = 0.48$ and $H = -(0.6\log_2 0.6 + 0.4\log_2 0.4) = 0.442 + 0.529 = 0.971$ bits.

The question "installment ratio at most 0.33?" sends 6 applications left (5 approved, 1 rejected) and 4 right (1 approved, 3 rejected).

Left: $p = 5/6$, $G_L = 1 - 25/36 - 1/36 = 10/36 = 0.278$. Right: $p = 1/4$, $G_R = 1 - 1/16 - 9/16 = 6/16 = 0.375$.

Weighted: $G_{\text{split}} = 0.6 \times 0.278 + 0.4 \times 0.375 = 0.167 + 0.150 = 0.317$. Gain: $0.48 - 0.317 = 0.163$.

A question that sent 5 approved and 3 rejected left and 1 and 1 right would give $G_{\text{split}} = 0.8 \times 0.469 + 0.2 \times 0.5 = 0.475$, a gain of only 0.005: a nearly useless question.

14.3.3 Growing the tree, and stopping

Growing is recursion: find the best question for the pile; split; grow a tree for the left pile and a tree for the right pile in exactly the same way. The recursion stops at a node when the pile is pure, when no split leaves at least a minimum number of cases on each side (`min_leaf`), or when the node sits at the maximum depth. A leaf holding m cases, a of them approved, predicts with the share of approved cases in it,

$$\hat{p}_{\text{leaf}} = \frac{a}{m} \tag{14.5}$$

and approves when $\hat{p}_{\text{leaf}} \geq 0.5$. The leaf's size and share are the evidence behind the answer: "92 percent of 224 similar cases were approved" is much stronger than "100 percent of 1".

Why a depth limit? Each extra level roughly doubles the number of leaves and halves the cases in each. Deep leaves hold so few cases that their majority is decided by chance and by the occasional unusual human decision in the data. The tree then fits the training data better and new data worse: *overfitting*, which Section 14.6 measures. James and colleagues give a gentle treatment of growing and pruning trees [6].

14.3.4 The feature a loan officer uses

A loan of P million rupiah repaid over n months at a monthly interest rate r has a fixed monthly installment given by the annuity formula

$$A = P \cdot \frac{r}{1 - (1 + r)^{-n}} \tag{14.6}$$

For $P = 50$, $n = 24$ and $r = 0.01$ (12 percent a year): $(1.01)^{-24} = 0.7876$, so $A = 50 \times 0.01 / 0.2124 = 2.354$ million a month. Lenders compare that installment with the monthly income I through the *debt-service ratio*

$$\text{DSR} = \frac{A}{I} \tag{14.7}$$

A DSR of 0.35 means that 35 percent of the monthly income goes to this loan. Our invented policy approves applicants with a good history up to a DSR of 0.35 and those with a fair history up to 0.25, never approves a bad history, requires at least a year in the current job unless the history is good, and then has 5 percent of decisions flipped to imitate the judgment calls every real officer makes. The tree is never told this policy; it must discover what it can from the 450 training decisions.

14.4 Building It Step by Step

14.4.1 The data

The folder `Chapter014` has the same `requirements.txt` as Chapter 11. **Listing 14.1** generates 600 applications with a fixed seed.

Listing 14.1 `make_loans.py`: 600 invented loan applications and the hidden policy that decided them.

```python
# make_loans.py - generate 600 loan applications with a hidden approval policy
from pathlib import Path
import numpy as np
import pandas as pd

rng = np.random.default_rng(14)
n = 600
income = np.clip(rng.lognormal(np.log(7), 0.5, n), 2.5, 40).round(1)  # million/mo
amount = np.clip(rng.lognormal(np.log(40), 0.8, n), 5, 300).round()   # million
tenor = rng.choice([6, 12, 24, 36, 48, 60], n)                          # months
history = rng.choice(["good", "fair", "bad"], n, p=[0.6, 0.28, 0.12])
years = rng.integers(0, 26, n)                                          # at job
dependents = rng.integers(0, 6, n)

def installment(p, months, rate=0.01):
    return p * rate / (1 - (1 + rate) ** -months)    # 12% a year, monthly

dsr = installment(amount, tenor) / income                # debt-service ratio
limit = np.where(history == "good", 0.35, 0.25)
steady = (years >= 1) | (history == "good")
approved = (history != "bad") & (dsr <= limit) & steady
flip = rng.random(n) < 0.05                              # 5% human judgment calls
approved = approved ^ flip
df = pd.DataFrame({"income": income, "amount": amount, "tenor": tenor,
                   "history": history, "years": years, "dependents": dependents,
                   "approved": approved.astype(int)})
df.to_csv(Path(__file__).parent / "data" / "loans.csv", index=False)
print(df.head().to_string())
print(f"{n} applications, {df.approved.mean():.0%} approved")
```

```
   income  amount  tenor history  years  dependents  approved
0     9.9     5.0     24    fair     20           3         1
1     4.3    51.0     12    good      9           5         0
2     3.2    21.0     36    fair      6           3         1
3     2.5    47.0     60     bad      5           2         0
4     5.9    38.0      6    fair     22           0         0
600 applications, 50% approved
```

Income is drawn from a log-normal distribution (most incomes modest, a few large), and so is the loan amount. Credit history is one of three words. Notice what the table does *not* contain: no name, no gender, no religion, no ethnicity, no address. A model cannot discriminate on a feature it never sees, although it can still discriminate through features that stand in for one (Exercise 14.6). Under Indonesia's Personal Data Protection Law, UU No. 27 of 2022, collecting personal data must also have a lawful basis and a stated purpose [7]; data a model does not need should not be collected at all. Chapter 99 returns to fairness and data protection in depth.

14.4.2 A tree from scratch

Listing 14.2 implements Section 14.3 in about ninety lines, with the tree stored as nested Python dictionaries.

Listing 14.2 `tree.py`: a decision tree from scratch, with Gini impurity, exhaustive split search and recursive growth.

```python
# tree.py - a decision tree from scratch: Gini impurity, best split, recursion
from pathlib import Path
import numpy as np
import pandas as pd

HISTORY = {"bad": 0, "fair": 1, "good": 2}          # ordered, so "<=" makes sense
RAW = ["income", "amount", "tenor", "history", "years", "dependents"]

def load(extra=False):
    df = pd.read_csv(Path(__file__).parent / "data" / "loans.csv")
    df["history"] = df["history"].map(HISTORY)
    cols = list(RAW)
    if extra:                                       # engineered feature, Section 14.6
        r, n = 0.01, df["tenor"]
        df["dsr"] = df["amount"] * r / (1 - (1 + r) ** -n) / df["income"]
        cols.append("dsr")
    return df[cols].to_numpy(float), df["approved"].to_numpy(), cols

def gini(y):
    if len(y) == 0:
        return 0.0
    p = np.mean(y)
    return 1.0 - p ** 2 - (1 - p) ** 2

def best_split(X, y, min_leaf):
    best = (None, None, gini(y))                # (feature, threshold, impurity)
    n = len(y)
    for j in range(X.shape[1]):
        values = np.unique(X[:, j])
        for t in (values[:-1] + values[1:]) / 2:      # midpoints between values
            left = X[:, j] <= t
            nl = left.sum()
            if nl < min_leaf or n - nl < min_leaf:
                continue
            imp = (nl * gini(y[left]) + (n - nl) * gini(y[~left])) / n
            if imp < best[2] - 1e-12:
                best = (j, t, imp)
    return best
```

Listing 14.2 (Continued) *tree.py: a decision tree from scratch, with Gini impurity, exhaustive split search and recursive growth.*

```
def grow(X, y, depth=0, max_depth=3, min_leaf=5):
    node = {"n": len(y), "p": float(np.mean(y)), "gini": gini(y)}
    if depth < max_depth and node["gini"] > 0:
        j, t, _ = best_split(X, y, min_leaf)
        if j is not None:
            left = X[:, j] <= t
            d = depth + 1
            node.update(feature=j, threshold=float(t),
                        left=grow(X[left], y[left], d, max_depth, min_leaf),
                        right=grow(X[~left], y[~left], d, max_depth, min_leaf))
    return node

def predict_one(node, x, names=None, path=None):
    while "feature" in node:
        j, t = node["feature"], node["threshold"]
        go_left = x[j] <= t
        if path is not None:
            op = "<=" if go_left else ">"
            path.append(f"{names[j]} = {x[j]:.4g} {op} {t:.4g}")
        node = node["left"] if go_left else node["right"]
    return int(node["p"] >= 0.5), node

def show(node, names, indent=""):
    if "feature" not in node:
        verdict = "APPROVE" if node["p"] >= 0.5 else "reject"
        share = f"{node['n']} cases, {node['p']:.0%} approved"
        return f"{indent}-> {verdict}  ({share})\n"
    j, t = node["feature"], node["threshold"]
    return (f"{indent}if {names[j]} <= {t:g}:\n"
            + show(node["left"], names, indent + "    ")
            + f"{indent}else:  # {names[j]} > {t:g}\n"
            + show(node["right"], names, indent + "    "))

def split_rows(n, test_frac=0.25, seed=41):
    idx = np.random.default_rng(seed).permutation(n)
    k = int(n * test_frac)
    return idx[k:], idx[:k]
```

Listing 14.2 (Continued) *tree.py: a decision tree from scratch, with Gini impurity, exhaustive split search and recursive growth.*

```
if __name__ == "__main__":
    X, y, names = load()
    tr, te = split_rows(len(y))
    root = grow(X[tr], y[tr], max_depth=3)
    print(show(root, names), end="")
    acc = np.mean([predict_one(root, x)[0] for x in X[te]] == y[te])
    print(f"test accuracy (depth 3, raw features): {acc:.3f}")
```

Walking through it:

- `load` reads the CSV and turns the credit history into numbers, bad 0, fair 1, good 2. The order matters: "history $\leq$ 0.5" then means "bad", and "history $\leq$ 1.5" means "bad or fair". With `extra=True` it adds the DSR column of Equation (14.7); we use that in Section 14.6.
- `gini` is Equation (14.1); `np.mean(y)` is p because the labels are 0 and 1.

- `best_split` tries every feature and every midpoint threshold, computes the weighted impurity of Equation (14.3), and remembers the best. It skips splits that would leave fewer than `min_leaf` cases on one side.
- `grow` builds a node dictionary with the case count `n`, the approval share `p` of Equation (14.5) and the impurity; if the node may still split, it finds the best split and calls itself on the two halves.
- `predict_one` walks from the root to a leaf. If it is given a list `path`, it records each question and answer: that list is the explanation.
- `show` prints the tree as nested `if`/`else` rules.
- `split_rows` keeps 150 applications (25 percent) aside for testing.

The search is exhaustive: for each node it tries every threshold of every feature, recomputing impurities from scratch. That is slow in principle (scikit-learn sorts each feature once and updates counts incrementally) but for 450 rows it runs in well under a second.

```
if tenor <= 18:
    if amount <= 22.5:
        if income <= 6.5:
            -> reject  (12 cases, 25% approved)
        else:  # income > 6.5
            -> APPROVE  (18 cases, 89% approved)
    else:  # amount > 22.5
        if income <= 11.5:
            -> reject  (100 cases, 6% approved)
        else:  # income > 11.5
            -> reject  (17 cases, 35% approved)
else:  # tenor > 18
    if history <= 0.5:
        if dependents <= 0.5:
            -> reject  (8 cases, 25% approved)
        else:  # dependents > 0.5
            -> reject  (26 cases, 0% approved)
    else:  # history > 0.5
        if amount <= 61.5:
            -> APPROVE  (193 cases, 84% approved)
        else:  # amount > 61.5
            -> reject  (76 cases, 38% approved)
test accuracy (depth 3, raw features): 0.840
```

This tree, grown on the six raw features with depth 3, is already readable. Its first question is about the tenor, then about the amount and the income, and one branch asks about credit history. It scores 0.840 on the 150 test applications. But the rules look odd to a loan officer: “tenor at most 18 months and amount above 22.5 million: reject” is a clumsy stand-in for “the installment is too large for the income”. The tree is approximating a ratio with a staircase of single-feature questions.

14.4.3 The app

Listing 14.3 is the advisor. It computes the installment and DSR for the application, grows the tree on all 600 cases using the DSR feature of Section 14.6, walks the application down the tree recording the path, and, for a rejection, searches for the smallest change that would flip the decision: first smaller amounts in steps of 5 million over the same tenor, then longer tenors for the same amount. Such “what would have to change” answers are called *counterfactual explanations* [8], and they are often the most useful thing an applicant can hear.

Listing 14.3 `loan_app.py`: the explainable loan advisor, with the decision path and counterfactual suggestions.

```
# loan_app.py - a loan advisor that explains itself (teaching model, not a policy)
import argparse
import numpy as np
from tree import HISTORY, grow, load, predict_one

def installment(amount, tenor, rate=0.01):
    return amount * rate / (1 - (1 + rate) ** -tenor)

def row(a, amount, tenor):
    dsr = installment(amount, tenor) / a.income
    return np.array([a.income, amount, tenor, HISTORY[a.history], a.years,
                     a.dependents, dsr], float)

def main():
    ap = argparse.ArgumentParser(description="Explainable loan advisor")
    ap.add_argument("--income", type=float, required=True, help="million Rp/month")
    ap.add_argument("--amount", type=float, required=True, help="million Rp")
    ap.add_argument("--tenor", type=int, required=True, help="months")
    ap.add_argument("--history", choices=list(HISTORY), required=True)
    ap.add_argument("--years", type=int, required=True, help="years at the job")
    ap.add_argument("--dependents", type=int, default=0)
    a = ap.parse_args()
    X, y, names = load(extra=True)
    root = grow(X, y, max_depth=3)                  # learn from all 600 cases
    x = row(a, a.amount, a.tenor)
    path = []
    ok, leaf = predict_one(root, x, names, path)
    print(f"installment Rp {installment(a.amount, a.tenor):.2f} million/month, "
          f"dsr {x[6]:.2f}")
    print("decision:", "APPROVE" if ok else "REJECT",
          f"({leaf['n']} similar past cases, {leaf['p']:.0%} approved)")
    print("because:")
    for step in path:
        print("  ", step)
    if not ok:                                      # smallest change that flips it
        for amt in np.arange(a.amount - 5, 4, -5):
            if predict_one(root, row(a, amt, a.tenor))[0]:
                print(f"would pass with an amount of Rp {amt:g} million "
                      f"over {a.tenor} months")
                break
        else:
            print("no smaller amount over the same tenor would pass")
        for ten in [t for t in (12, 24, 36, 48, 60) if t > a.tenor]:
            if predict_one(root, row(a, a.amount, ten))[0]:
                print(f"would pass with the same amount over {ten} months")
                break
        else:
            print("no longer tenor (up to 60 months) would pass")

if __name__ == "__main__":
    main()
```

Listing 14.3 (Continued) *loan_app.py: the explainable loan advisor, with the decision path and counterfactual suggestions.*

14.5 Running It

An application the advisor approves:

```
python loan_app.py --income 8 --amount 50 --tenor 24 --history good --years 3 --
dependents 2
```

```
installment Rp 2.35 million/month, dsr 0.29
decision: APPROVE (298 similar past cases, 92% approved)
because:
   dsr = 0.2942 <= 0.3322
   history = 2 > 0.5
   years = 3 > 0.5
```

The installment of 2.35 million is the one computed by hand in Section 14.3.4. The explanation reads: the DSR of 0.294 is at most 0.332, the history is better than bad (2, good, is above 0.5), and the applicant has worked more than half a year. The leaf holds 298 of the 600 past cases, 92 percent of them approved.

Now Mas Rizal's application, 60 million instead of 50:

```
python loan_app.py --income 8 --amount 60 --tenor 24 --history good --years 3 --
dependents 2
```

```
installment Rp 2.82 million/month, dsr 0.35
decision: REJECT (215 similar past cases, 2% approved)
because:
   dsr = 0.3531 > 0.3322
   dsr = 0.3531 > 0.3494
   income = 8 <= 10.2
would pass with an amount of Rp 55 million over 24 months
would pass with the same amount over 36 months
```

His DSR, 0.353, is above both DSR thresholds the tree has learned. The advisor does not stop at "no": 55 million over the same two years would pass, and so would the full 60 million over three years. Those two sentences are worth more to Mas Rizal than the refusal itself.

An applicant with a bad history:

```
python loan_app.py --income 12 --amount 50 --tenor 12 --history bad --years 10
```

```
installment Rp 4.44 million/month, dsr 0.37
decision: REJECT (27 similar past cases, 15% approved)
because:
   dsr = 0.3702 > 0.3322
   dsr = 0.3702 > 0.3494
   income = 12 > 10.2
no smaller amount over the same tenor would pass
no longer tenor (up to 60 months) would pass
```

Here no smaller amount and no longer tenor helps, which is the tree's way of saying that the history, not the size of the loan, is the obstacle: in the left branch of the tree a bad history is refused at any DSR. Notice, though, that the printed path mentions only DSR and income, because this application went right at the first question. A path explains *this* decision; it is not a list of every reason the applicant might be refused. Each run takes about a second.

14.6 Improving It

14.6.1 Give the tree the right question

Figure 14.2 plots the installment against the income for the applicants with a good history. The approved and rejected cases are separated by a diagonal line, installment $= 0.35 \times$ income. A tree can only cut parallel to the axes ("income $\leq$ something", "amount $\leq$ something"), so it needs many cuts to follow a diagonal. One new column, the DSR of Equation (14.7), turns the diagonal into a single cut.

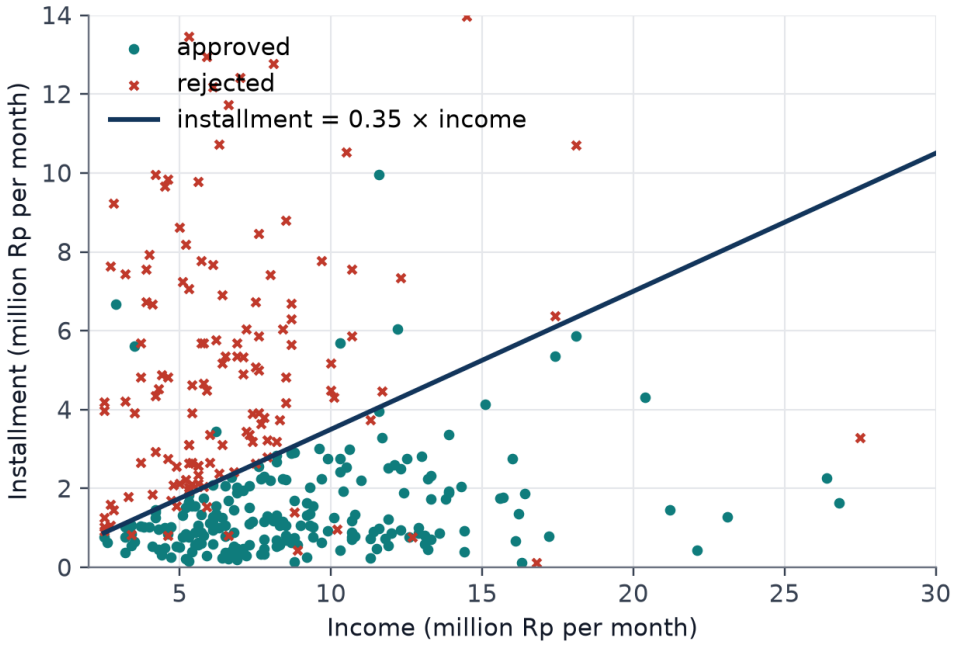

Figure 14.2 Installment against income for the applicants with a good credit history. The policy boundary is a diagonal, which single-feature questions can only approximate with a staircase.

Listing 14.4 grows the scratch tree with the extra column, compares 10-fold cross-validated accuracy with and without it using scikit-learn's `DecisionTreeClassifier`, prints the *feature importances* (the share of the total impurity reduction contributed by each feature), and prints scikit-learn's own view of the tree with `export_text`.

Listing 14.4 `improve.py`: adding the debt-service ratio, and measuring the difference.

```
# improve.py - give the tree the feature a loan officer actually uses
import numpy as np
from sklearn.model_selection import cross_val_score
from sklearn.tree import DecisionTreeClassifier, export_text
from tree import grow, load, predict_one, show, split_rows

X, y, names = load(extra=True)                # adds dsr = installment / income
tr, te = split_rows(len(y))
root = grow(X[tr], y[tr], max_depth=3)
print(show(root, names), end="")
acc = np.mean([predict_one(root, x)[0] for x in X[te]] == y[te])
print(f"test accuracy (depth 3, with dsr): {acc:.3f}\n")

for label, cols in [("raw features", slice(0, 6)), ("with dsr", slice(0, 7))]:
    s = cross_val_score(DecisionTreeClassifier(max_depth=3, random_state=0),
                        X[:, cols], y, cv=10)
    print(f"10-fold CV, depth 3, {label:12s}: {s.mean():.3f} +/- {s.std():.3f}")

clf = DecisionTreeClassifier(max_depth=3, random_state=0).fit(X[tr], y[tr])
imp = sorted(zip(clf.feature_importances_, names), reverse=True)
print("importances:", ", ".join(f"{n} {v:.2f}" for v, n in imp if v > 0))
print(export_text(clf, feature_names=names, decimals=2), end="")
```

```
if dsr <= 0.332663:
    if history <= 0.5:
        if dependents <= 0.5:
            -> reject  (6 cases, 33% approved)
        else:  # dependents > 0.5
            -> reject  (20 cases, 0% approved)
    else:  # history > 0.5
        if years <= 0.5:
            -> reject  (7 cases, 29% approved)
        else:  # years > 0.5
            -> APPROVE  (224 cases, 92% approved)
else:  # dsr > 0.332663
    if dsr <= 0.349351:
        if history <= 1.5:
            -> reject  (9 cases, 0% approved)
        else:  # history > 1.5
            -> APPROVE  (6 cases, 100% approved)
    else:  # dsr > 0.349351
        if income <= 11.5:
            -> reject  (164 cases, 2% approved)
        else:  # income > 11.5
            -> reject  (14 cases, 21% approved)
test accuracy (depth 3, with dsr): 0.927

10-fold CV, depth 3, raw features: 0.797 +/- 0.036
10-fold CV, depth 3, with dsr    : 0.917 +/- 0.026
importances: dsr 0.73, history 0.22, years 0.03, dependents 0.01, income 0.01
|--- dsr <= 0.33
|   |--- history <= 0.50
|   |   |--- dependents <= 0.50
|   |   |   |--- class: 0
|   |   |--- dependents >  0.50
|   |   |   |--- class: 0
|   |--- history >  0.50
|   |   |--- years <= 0.50
|   |   |   |--- class: 0
|   |   |--- years >  0.50
|   |   |   |--- class: 1
|--- dsr >  0.33
|   |--- dsr <= 0.35
|   |   |--- history <= 1.50
|   |   |   |--- class: 0
|   |   |--- history >  1.50
|   |   |   |--- class: 1
|   |--- dsr >  0.35
|   |   |--- income <= 11.50
|   |   |   |--- class: 0
|   |   |--- income >  11.50
|   |   |   |--- class: 0
```

The effect is large. The first question is now “DSR $\leq$ 0.333?”, recovering the policy’s 0.35 almost exactly (the gap is the noise and the few fair-history cases between 0.25 and 0.35). The second level asks about history; one more question finds the 0.349 edge for good histories. Test accuracy rises from 0.840 to 0.927, and cross-validated accuracy from 0.797 to 0.917. The importances say that DSR carries 73 percent of the tree’s decisions and history 22 percent; dependents and income play almost no role. With 5 percent of the labels flipped at random, about 95 percent is the best any model could reach, so the tree is close to the ceiling. scikit-learn’s tree (printed last) asks the same questions as ours, with thresholds rounded to two decimals. **Figure 14.3** draws it.

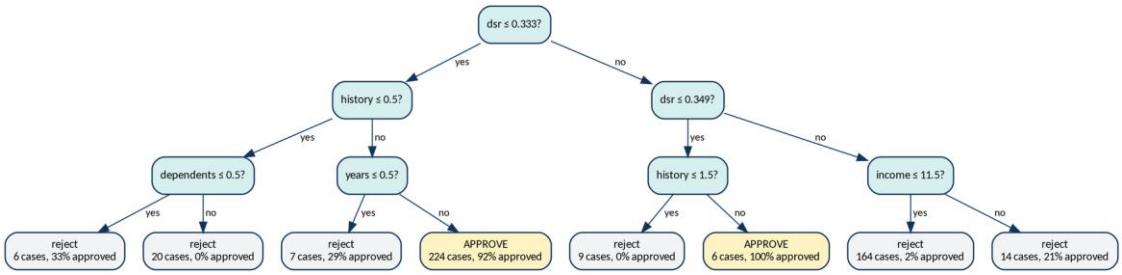

Figure 14.3 The depth-3 tree grown by `tree.py` on the training applications with the DSR feature. Yellow leaves approve; each leaf shows its number of past cases and their approval share.

This is the most important lesson of the chapter, and it holds far beyond trees: *a feature built from domain knowledge beats any amount of algorithmic cleverness*. Bu Ani's way of thinking, "how much of the income goes to the installment", is worth more than extra depth.

14.6.2 How deep should it grow?

Listing 14.5 grows scikit-learn trees of increasing depth, with and without DSR, and prints training and test accuracy.

Listing 14.5 `sklearn_tree.py`: training and test accuracy of trees of increasing depth.

```
# sklearn_tree.py - how deep should the tree grow? train versus test accuracy
from sklearn.tree import DecisionTreeClassifier
from tree import load, split_rows

for extra in (False, True):
    X, y, names = load(extra=extra)
    tr, te = split_rows(len(y))                # the same split as tree.py
    print("features:", ", ".join(names))
    print("depth  leaves  train   test")
    for depth in [1, 2, 3, 4, 6, 8, None]:
        clf = DecisionTreeClassifier(max_depth=depth, random_state=0)
        clf.fit(X[tr], y[tr])
        print(f"{str(depth):>5s}  {clf.get_n_leaves():6d}  "
              f"{clf.score(X[tr], y[tr]):.3f}  {clf.score(X[te], y[te]):.3f}")
```

```

    4      13  0.947  0.927
    6      24  0.980  0.913
    8      30  0.989  0.900
 None      39  1.000  0.893
```

On the raw features the test accuracy keeps creeping up with depth, to 0.880 for an unlimited tree of 68 leaves: the tree needs many leaves to build its staircase. With DSR the picture is the textbook one, drawn in **Figure 14.4**: test accuracy reaches 0.927 at depth 2 and stays there to depth 4, then falls (0.913, 0.900, 0.893) while training accuracy climbs to 1.000. The deeper leaves are memorizing the 5 percent of flipped decisions. A depth of 2 to 4 is right; in practice

choose it by cross-validation, exactly as k was chosen in Chapter 13. scikit-learn also offers *cost-complexity pruning* (the `ccp_alpha` parameter), which grows a full tree and then cuts back the branches that add least [5].

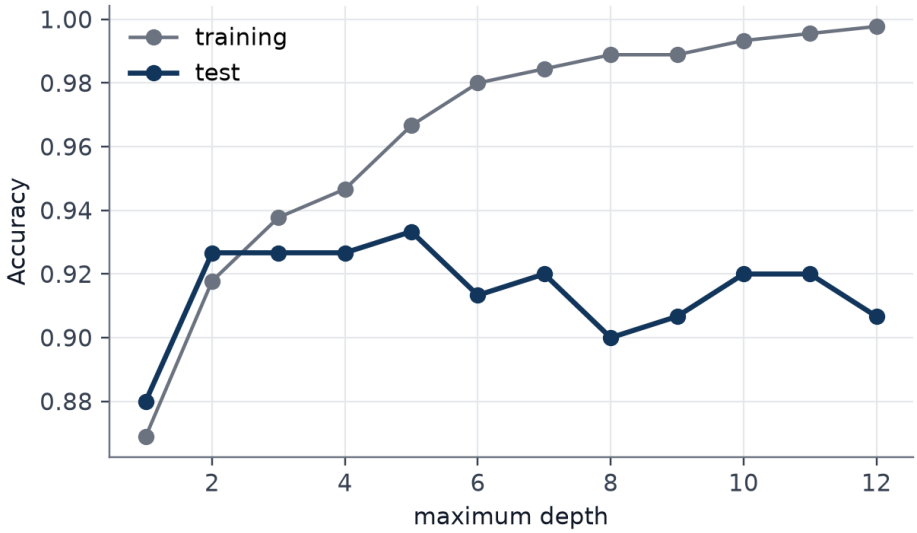

Figure 14.4 Training and test accuracy of trees with the DSR feature, by maximum depth. Beyond depth 4 the tree fits the training set better and the test set worse.

Finally the tests of **Listing 14.6**: Gini on pure and even piles, the best split on an obvious example, and a depth-2 tree that must learn logical OR exactly.

Listing 14.6 `test_tree.py`: tests for the impurity, the split search and the growth of the tree.

```
# test_tree.py - run with:  python -m pytest -q
import numpy as np
from tree import best_split, gini, grow, predict_one

def test_gini_pure_and_even():
    assert gini(np.array([1, 1, 1])) == 0.0
    assert gini(np.array([0, 1, 0, 1])) == 0.5

def test_best_split_finds_the_obvious_threshold():
    X = np.array([[1.0], [2.0], [3.0], [10.0], [11.0], [12.0]])
    y = np.array([0, 0, 0, 1, 1, 1])
    j, t, imp = best_split(X, y, min_leaf=1)
    assert (j, t, imp) == (0, 6.5, 0.0)

def test_tree_fits_training_data_it_can_separate():
    X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)
    y = np.array([0, 1, 1, 1])                          # logical OR
    root = grow(X, y, max_depth=2, min_leaf=1)
    assert [predict_one(root, x)[0] for x in X] == [0, 1, 1, 1]
```

```
...                                                                  [100%]
3 passed in 0.45s
```

14.7 Common Mistakes, and How to Avoid Them

Letting the tree grow without limit. A tree with pure leaves has memorized the training data. Limit `max_depth` or `min_samples_leaf`, or prune with `ccp_alpha`, and choose the setting by cross-validation.

Encoding categories as arbitrary numbers. Mapping bad/fair/good to 0/1/2 works because the categories are ordered. Mapping districts such as Rungkut, Wiyung and Keputih to 0/1/2 would invent an order that does not exist; use one column per category instead (*one-hot encoding*).

Reading a path as the complete set of reasons. A path explains why this case landed in this leaf. A different application with the same problem may be refused by a different path. For the applicant, counterfactuals ("what would change it") are usually more useful than the path.

Trusting feature importances too much. Importances are shares of impurity reduction on the training data. When two features carry the same information (amount and DSR, for instance), the tree picks one and the other looks unimportant, even though it matters.

Forgetting that trees are unstable. A small change in the training data can change the first question and so the whole tree. Chapter 19 turns this weakness into a strength by averaging hundreds of trees.

Including features that stand in for protected ones. Leaving out gender or religion is not enough if another feature (a neighborhood, a school, a first name) predicts them. Check the model's decisions across groups, not only its inputs.

14.8 Chapter Summary

- Gini impurity (Equation (14.1)) and entropy (Equation (14.2)) measure how mixed a pile of cases is; both are zero for pure piles.
- A split is judged by the size-weighted impurity of its two sides (Equation (14.3)) and the gain over the parent (Equation (14.4)); the tree tries every feature and every midpoint threshold and keeps the best.
- Growing is recursion with stopping rules; a leaf predicts with its approval share (Equation (14.5)), and its case count is the evidence.
- A decision tree explains a decision exactly by its path, and a search over small changes gives counterfactual advice.
- Deep trees overfit: training accuracy rises to 1 while test accuracy falls. Choose the depth by cross-validation or prune.
- The engineered feature DSR (Equation (14.6), Equation (14.7)) turned a clumsy staircase of rules into a three-question tree and raised cross-validated accuracy from 0.797 to 0.917. Domain knowledge in a feature beats extra depth.
- A table without protected attributes is a start, not a guarantee, of a fair model; data protection law requires a purpose for every piece of personal data collected.

14.9 Exercises

1. A node holds 8 approved and 12 rejected applications. Compute its Gini impurity and its entropy. A question splits it into (7 approved, 2 rejected) and (1 approved, 10 rejected). Compute the weighted Gini impurity and the gain.

2. Using Equation (14.6), compute the monthly installment for 60 million over 24 months and over 36 months at 1 percent a month, and the DSR for an income of 8 million. Check your answers against the app's suggestions in Section 14.5.
3. Why does the tree of **Figure 14.3** ask about DSR twice on its right side, with thresholds 0.333 and 0.349? What part of the hidden policy is it approximating?
4. Run the app for an applicant with a *fair* history: income 6, amount 40, tenor 24, 4 years at the job, 1 dependent. Compare the decision with the hidden policy of `make_loans.py` and explain the disagreement.
5. Grow the scratch tree with DSR at depths 3, 4 and 5. For the applicants with a fair history and a DSR between 0.25 and 0.35 (whom the policy always rejects), count how many each tree approves, and report the test accuracy.
6. The feature `dependents` appears in the tree of **Figure 14.3**. Should a lender use it? Give one argument for and one against, and name a feature that could act as a hidden stand-in for a protected attribute in an Indonesian loan data set.

14.10 Solutions to the Exercises

Exercise 14.1. $p = 8/20 = 0.4$: $G = 1 - 0.16 - 0.36 = 0.48$; $H = -(0.4\log_2 0.4 + 0.6\log_2 0.6) = 0.529 + 0.442 = 0.971$ bits. Left pile: $p = 7/9$, $G_L = 1 - 49/81 - 4/81 = 28/81 = 0.346$. Right pile: $p = 1/11$, $G_R = 1 - 1/121 - 100/121 = 20/121 = 0.165$. Weighted: $\frac{9}{20} \times 0.346 + \frac{11}{20} \times 0.165 = 0.156 + 0.091 = 0.247$. Gain: $0.48 - 0.247 = 0.233$.

Exercise 14.2. Over 24 months: $(1.01)^{-24} = 0.7876$, $A = 60 \times 0.01/0.2124 = 2.825$ million, DSR $2.825/8 = 0.353$: above the learned 0.333, rejected, as the app printed. Over 36 months: $(1.01)^{-36} = 0.6989$, $A = 0.6/0.3011 = 1.993$ million, DSR 0.249: approved, as suggested. For 55 million over 24 months: $A = 0.55/0.2124 = 2.590$, DSR 0.324: just under 0.333, approved.

Exercise 14.3. For applicants with a good history the policy's limit is 0.35, but the root threshold 0.333 is a compromise between good histories (limit 0.35) and fair ones (limit 0.25) plus noise. On the right side, the second DSR question, "at most 0.349?", catches the band between 0.333 and 0.349 where good-history applicants are still approved; the next question, "history $\leq$ 1.5?", separates them from fair ones. Together they approximate "good history: up to 0.35".

Exercise 14.4.

```
python loan_app.py --income 6 --amount 40 --tenor 24 --history fair --years 4 --
dependents 1
```

```
installment Rp 1.88 million/month, dsr 0.31
decision: APPROVE (298 similar past cases, 92% approved)
because:
   dsr = 0.3138 <= 0.3322
   history = 1 > 0.5
   years = 4 > 0.5
```

The tree approves, but the hidden policy rejects: for a fair history the limit is 0.25, and this DSR is 0.314. The depth-3 tree has no question that separates fair from good below 0.333, because only 18 of the 600 applications fall in that band (fair history, DSR between 0.25 and 0.35), too few to earn a split near the root. An explainable model makes this gap visible: a loan officer reading **Figure 14.3** would spot at once that fair histories are treated like good ones below 0.333.

Exercise 14.5. **Listing 14.7** grows three trees and inspects the contested band.

Listing 14.7 `solutions/ex_depth4.py`: how deeper trees treat fair-history applicants with a DSR between 0.25 and 0.35.

```
# ex_depth4.py - Exercise 14.5: does a deeper tree find the stricter "fair" rule?
import sys
from pathlib import Path
import numpy as np
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from tree import grow, load, predict_one, split_rows

X, y, names = load(extra=True)
tr, te = split_rows(len(y))
fair = X[:, 3] == 1
for depth in (3, 4, 5):
    root = grow(X[tr], y[tr], max_depth=depth)
    pred = np.array([predict_one(root, x)[0] for x in X])
    zone = fair & (X[:, 6] > 0.25) & (X[:, 6] <= 0.35)    # the contested band
    print(f"depth {depth}: test accuracy {np.mean(pred[te] == y[te]):.3f}, "
          f"'fair' with dsr 0.25-0.35 approved by tree: "
          f"{pred[zone].sum()} of {zone.sum()} (policy: 0)")
```

```
depth 3: test accuracy 0.927, 'fair' with dsr 0.25-0.35 approved by tree: 12 of 18 (policy:
0)
depth 4: test accuracy 0.907, 'fair' with dsr 0.25-0.35 approved by tree: 12 of 18 (policy:
0)
depth 5: test accuracy 0.920, 'fair' with dsr 0.25-0.35 approved by tree: 2 of 18 (policy:
0)
```

Depths 3 and 4 approve 12 of the 18 applicants in the band; depth 5 finally learns the stricter rule and approves only 2. Yet test accuracy hardly moves (0.927, 0.907, 0.920), because only a handful of test cases fall in the band and the extra depth also adds noise elsewhere. Overall accuracy can hide a systematic error on a small group; checking the model on meaningful subgroups is part of evaluating it.

Exercise 14.6. For: more dependents can mean higher fixed expenses, so the same DSR is riskier. Against: it penalizes families, it can correlate with age, religion or region, and the DSR already captures ability to pay; in **Figure 14.3** the split on dependents only separates two rejecting leaves, so it changes no decision and should be removed. Possible hidden stand-ins in Indonesian data: the district or *kelurahan* of the address (which can correlate with ethnicity or income group), the name of a school or a place of worship in the address, or the applicant's first name.

Chapter 15

Sentiment Analyzer: Naive Bayes in Indonesian and English

Customers say what they think, in reviews, chat messages and comment boxes, and they say it in whatever language comes naturally: in Surabaya that is often Indonesian, sometimes English, and sometimes both in one sentence. This chapter builds an app that reads a short review and says whether it is positive or negative, with a probability and the words that decided it. The method is *naive Bayes*, a classifier built directly on the rules of probability. It trains by counting, predicts by multiplying, and is still, after sixty years, one of the best first models for short texts [1]. By the end of the chapter you will be able to state Bayes' theorem and read it as "update a belief with evidence"; explain the "naive" independence assumption and why it works anyway; estimate word probabilities by counting and repair them with Laplace smoothing; compute a prediction in logarithms so that long texts do not underflow; turn scores back into probabilities with the log-sum-exp trick; handle negation such as *tidak bagus* and *not bad*; and judge honestly what a model trained on 240 reviews can and cannot do.

15.1 Why a Sentiment Analyzer?

Profitina Laundry receives dozens of short reviews every week, through the order app, through chat and on the map listing of each outlet: "Cuciannya wangi dan rapi, kurirnya ramah", "Pesanan terlambat tiga hari tanpa kabar", "Not bad at all, fast and friendly". The owner, Pak Hendra, cannot read them all every day, but he wants to know at once when an outlet's reviews turn sour, and he wants to find the angry ones quickly so that someone can call the customer back before the problem spreads.

Sorting reviews into positive and negative is called *sentiment analysis*. It is a classification problem like the spam filter of Chapter 12, and we could use logistic regression again. We use naive Bayes instead, for three reasons. It learns from very little data, which matters because every review in our training set had to be read and labeled by a person. It trains in a single pass of counting, so retraining every night on the latest reviews is effortless. And it teaches the most important idea in all of probabilistic machine learning, Bayes' theorem, in its simplest useful form [2].

The app works in both languages with one model:

```
python sentiment_app.py "Cuciannya wangi dan rapi, kurirnya ramah"
```

answers POSITIVE with a probability, guesses the language, and lists every known word with how strongly it leaned toward positive or negative.

15.2 The Idea in Plain Words

Imagine two jars of word tiles. Into the first jar we pour every word of every positive review we have; into the second, every word of every negative review. The positive jar is full of *bersih*, *rapi*,

ramah, *clean*, *friendly*; the negative jar of *bau*, *kotor*, *lambat*, *dirty*, *slow*. Common words like *dan*, *yang*, *the*, *and* are plentiful in both.

Now someone hands us a new review, "rapi dan ramah", and asks which jar it more probably came from. We ask: if I drew three tiles from the positive jar, how likely is it that I would draw *rapi*, *dan* and *ramah*? And the same for the negative jar. *Rapi* and *ramah* are much more common in the positive jar, *dan* about equally common in both, so the positive jar is far more likely to have produced this review. If one jar is simply bigger (if we had seen more negative reviews than positive ones in general), we also take that into account: a bigger jar is a more likely source to begin with.

That is naive Bayes. "Bayes" because turning "how likely is this review, given the jar" into "how likely is the jar, given this review" is exactly what Bayes' theorem does. "Naive" because we pretend that the tiles are drawn independently of each other, as if the chance of *ramah* did not depend on whether *rapi* had just been drawn. Real language is not like that: *tidak* changes the meaning of the next word completely. The pretense is wrong, and yet the classifier works surprisingly well, because to classify we only need to know which jar is *more* likely, not by exactly how much [3].

> **KEY INSIGHT:** Naive Bayes learns by counting how often each word appears in each class, and classifies by asking which class would most probably have produced the words it sees. Every number in the model is a frequency you can check by hand.

15.3 The Mathematics, Gently

15.3.1 Bayes' theorem

Write c for a class (positive or negative) and d for a document, here a review. We want $P(c \mid d)$, "the probability of class c given the review d". Bayes' theorem expresses it through quantities we can estimate:

$$P(c \mid d) = \frac{P(d \mid c)\,P(c)}{P(d)} \tag{15.1}$$

$P(c)$ is the *prior*: how probable the class is before we read anything. $P(d \mid c)$ is the *likelihood*: how probable this exact review is if it came from class c. $P(d)$ is the probability of the review at all; it is the same for every class, so for deciding between classes it only rescales, and we can ignore it until the very end. The result $P(c \mid d)$ is the *posterior*, the belief after seeing the evidence. Equation (15.1) follows in one line from the definition of conditional probability: $P(c \mid d)P(d)$ and $P(d \mid c)P(c)$ are both equal to $P(c \text{ and } d)$.

The prior is estimated from the training set as a simple share:

$$P(c) = \frac{N_c}{N} \tag{15.2}$$

where N_c is the number of training reviews in class c and N the number of all training reviews. Our data are balanced, so both priors are 0.5.

15.3.2 The naive step

A review is a sequence of words $w_1, w_2, \ldots, w_m$. Its likelihood $P(w_1, \ldots, w_m \mid c)$ is hopeless to estimate directly: almost every review is unique, so we have never seen the exact sequence before. The naive assumption says that, within a class, each word is drawn independently, so the probability of the sequence is the product of the probabilities of its words:

$$P(d \mid c) \approx \prod_{i=1}^{m} P(w_i \mid c) \tag{15.3}$$

The capital pi $\prod$ means "multiply together", as $\sum$ means "add together". Now we need only one number per word and class, $P(w \mid c)$, and those we can count. This version, where a review is a bag of word draws and repeated words count repeatedly, is called *multinomial* naive Bayes [4].

15.3.3 Estimating word probabilities by counting

The natural estimate of $P(w \mid c)$ is the share of word tiles in jar c that are w:

$$P(w \mid c) = \frac{\text{count}(w, c)}{\sum_{v \in V} \text{count}(v, c)} \tag{15.4}$$

where $\text{count}(w, c)$ is how many times w occurs in the training reviews of class c, and the sum in the denominator runs over the whole vocabulary V, giving the total number of word tiles in the jar.

Equation (15.4) has a fatal flaw. If a word never appeared in the positive training reviews, its estimated probability there is exactly 0, and by Equation (15.3) the whole product is 0: a single unseen word vetoes the class, however positive the rest of the review is. *Laplace smoothing* (also called add-one or additive smoothing) pretends we have seen every vocabulary word α extra times in every class:

$$P(w \mid c) = \frac{\text{count}(w, c) + \alpha}{\sum_{v \in V} \text{count}(v, c) + \alpha |V|} \tag{15.5}$$

where $|V|$ is the size of the vocabulary and $\alpha > 0$ is the smoothing strength ($\alpha = 1$ is classic add-one). The $\alpha|V|$ in the denominator keeps the probabilities of each class summing to 1. Words never seen in *any* training review are simply skipped when predicting, since they carry no evidence either way.

> **EXAMPLE.** Four training reviews. Positive: "enak murah", "bersih enak". Negative: "mahal kotor", "kotor lambat".
>
> Counts. Positive jar: *enak* 2, *murah* 1, *bersih* 1, total 4. Negative jar: *mahal* 1, *kotor* 2, *lambat* 1, total 4. Vocabulary V = {enak, murah, bersih, mahal, kotor, lambat}, $|V| = 6$. Priors 0.5 each.
>
> With $\alpha = 1$ each denominator is $4 + 6 = 10$. $P(\text{enak} \mid \text{pos}) = 3/10$, $P(\text{mahal} \mid \text{pos}) = 1/10$, $P(\text{enak} \mid \text{neg}) = 1/10$, $P(\text{mahal} \mid \text{neg}) = 2/10$.
>
> New review "enak tapi mahal". *Tapi* is not in the vocabulary and is skipped.
>
> Positive: $0.5 \times 0.3 \times 0.1 = 0.015$. Negative: $0.5 \times 0.1 \times 0.2 = 0.010$. Posterior: $P(\text{pos} \mid d) = 0.015/(0.015 + 0.010) = 0.6$. A mild positive.
>
> Without smoothing, $P(\text{mahal} \mid \text{pos}) = 0/4 = 0$, the positive score is 0, and the review is called negative with certainty, only because *mahal* never happened to appear in a positive training review.

15.3.4 Working in logarithms

A review of 20 words multiplies 20 probabilities, each perhaps around 0.005. The product, about 10^{-46}, is still representable, but a long document of 400 words would give 10^{-920}, far below the smallest number a computer's floating point can hold (10^{-308}); it *underflows* to exactly 0 for both classes. The cure is to add logarithms instead of multiplying probabilities, since $\log(ab) = \log a + \log b$. The *score* of class c is

$$s_c = \log P(c) + \sum_{i=1}^{m} \log P(w_i \mid c) \tag{15.6}$$

and the predicted class is the one with the larger score. Logarithms of probabilities are negative numbers of modest size (for example $\log 0.005 \approx -5.3$), so their sums never underflow.

To report a probability we must undo the logarithms and divide by the total, as in the example: $P(c \mid d) = e^{s_c} / \sum_{c'} e^{s_{c'}}$. Computing e^{s_c} directly would underflow again. The *log-sum-exp trick* subtracts the largest score $s_{\max}$ first:

$$\log \sum_{c'} e^{s_{c'}} = s_{\max} + \log \sum_{c'} e^{s_{c'} - s_{\max}} \tag{15.7}$$

Every exponent on the right is at most 0, and the largest is exactly $e^0 = 1$, so nothing underflows to a total of zero. The posterior is then $P(c \mid d) = \exp(s_c - \log \sum_{c'} e^{s_{c'}})$.

15.3.5 Which words matter

For two classes, the difference between the scores is a sum of one number per word:

$$s_{\text{pos}} - s_{\text{neg}} = \log \frac{P(\text{pos})}{P(\text{neg})} + \sum_{i=1}^{m} r(w_i), \qquad r(w) = \log \frac{P(w \mid \text{pos})}{P(w \mid \text{neg})} \tag{15.8}$$

The *log-ratio* $r(w)$ is positive for words more common in positive reviews, negative for words more common in negative ones, and near zero for words like *dan*. It plays exactly the role of a weight in logistic regression (Equation (15.8) is a linear model in the word counts), which is why the app can explain its verdicts word by word. The difference is how the weights are found: naive Bayes computes them from counts in one pass; logistic regression searches for them by gradient descent, which lets it correct for words that always appear together.

15.4 Building It Step by Step

15.4.1 The data

The folder `Chapter015` has the same `requirements.txt` as Chapter 11 and a data file `data/reviews.csv` with 240 short reviews written for this book: 140 in Indonesian and 100 in English, half positive and half negative in each language, about laundries, restaurants, shops, apps, hotels and rides. Public Indonesian sentiment data sets exist, such as the SmSA collection in the IndoNLU benchmark [5], but they must be downloaded; ours ships with the code. The first lines:

```
lang,label,text
id,neg,Buku ini membingungkan dan banyak salah ketik
en,neg,"Awful, the ironing is all wrinkled"
id,neg,Harganya mahal tapi hasilnya biasa saja
id,neg,"Kusut, bau, telat, buruk sekali"
en,pos,The food was delicious and the portion was generous
```

Some reviews are deliberately hard: “Tidak mengecewakan” (not disappointing) is positive although *mengecewakan* is a negative word, “Not good” is negative although *good* is positive, and a few reviews mix a complaint with praise.

15.4.2 Naive Bayes from scratch

Listing 15.1 is the whole classifier. It needs nothing beyond NumPy and Python’s `Counter`.

Listing 15.1 `nb.py`: multinomial naive Bayes from scratch, with Laplace smoothing and log-space prediction.

```
# nb.py - multinomial naive Bayes from scratch, with Laplace smoothing
import csv
import re
from collections import Counter
from pathlib import Path
import numpy as np

TOKEN = re.compile(r"[a-z]+(?:-[a-z]+)?")
CLASSES = ["neg", "pos"]

def tokens(text):
    return TOKEN.findall(text.lower())

NEGATORS = {"tidak", "bukan", "kurang", "belum", "jangan",
            "not", "no", "never", "nothing", "without"}

def tokens_neg(text):
    out, negate = [], False                          # "tidak bagus" -> not_bagus
    for w in tokens(text):
        if w in NEGATORS:
            negate = True
            continue
        out.append("not_" + w if negate else w)
        negate = False
    return out

def load(path=None):
    path = path or Path(__file__).parent / "data" / "reviews.csv"
    with open(path, encoding="utf8") as f:
        rows = list(csv.DictReader(f))
    return ([r["text"] for r in rows], np.array([r["label"] for r in rows]),
            np.array([r["lang"] for r in rows]))
```

Listing 15.1 (Continued) *nb.py: multinomial naive Bayes from scratch, with Laplace smoothing and log-space prediction.*

```
def split(labels, langs, test_frac=0.25, seed=5):
    rng = np.random.default_rng(seed)                 # stratify by label and lang
    test = []
    for key in set(zip(labels, langs)):
        idx = np.flatnonzero((labels == key[0]) & (langs == key[1]))

    print("most negative:", " ".join(ranked[:10]))
    print("most positive:", " ".join(ranked[::-1][:10]))
```

Walking through it:

- `tokens` lower-cases the text and keeps runs of letters, allowing one hyphen inside a word so that *asal-asalan* stays whole. `tokens_neg` is the negation-aware version used in Section 15.6.
- `load` reads the CSV; `split` holds out a quarter of each (label, language) group, so that the test set has the same mix of languages and sentiments as the whole.
- `log_sum_exp` is Equation (15.7).
- `NaiveBayes.fit` counts words per class with one `Counter` per class, builds the vocabulary as the union of all words seen, and stores the log-priors of Equation (15.2) and the log of each class's smoothed denominator.
- `log_lik` is the logarithm of Equation (15.5).
- `predict_proba` drops words not in the vocabulary, computes the two scores of Equation (15.6), and normalizes them with log-sum-exp. It returns the pair $[P(\text{neg}), P(\text{pos})]$.
- `ratio` is the log-ratio $r(w)$ of Equation (15.8).

Training is a single pass of counting: on 180 reviews it takes about a millisecond.

```
180 training and 60 test reviews, 558 words in the vocabulary
accuracy on id: 0.694  (36 reviews)
accuracy on en: 0.750  (24 reviews)
overall accuracy: 0.717
most negative: bau slow tidak smelly kusut of mahal rude buruk salah
most positive: bersih fast rapi friendly clean bagus puas mantap membantu fresh
```

On the 60 test reviews the model is right 72 percent of the time: 69 percent in Indonesian and 75 percent in English. The two word lists are revealing. The positive side reads like a good review: *bersih*, *fast*, *rapi*, *friendly*, *clean*, *bagus*, *puas*, *mantap*. The negative side contains *bau*, *slow*, *smelly*, *kusut*, *mahal*, *rude*, *buruk*, but also *tidak* and *of*. *Tidak* is there because most of our reviews that contain it are complaints ("tidak enak", "tidak sesuai janji"), and *of* because of phrases like "a waste of money". The model has no idea what *tidak* means; it only knows where it appeared. Section 15.6 does something about that.

Is 72 percent good? For a model trained on 180 short reviews that share few words, it is about what to expect, and Section 15.6 shows how it rises with more data. But it is far from the 93 percent of the spam filter, and the reason is instructive: spam has a strong, repeated vocabulary

(*klik*, *hadiah*, *link*), whereas a laundry review and a restaurant review may share no content words at all.

15.4.3 The same model in scikit-learn

scikit-learn's `MultinomialNB` implements Equation (15.5) and Equation (15.6) exactly [6]. **Listing 15.2** feeds it word counts from a `CountVectorizer` that uses our own tokenizer, so that the two implementations see identical words, and then uses 10-fold cross-validation to compare smoothing strengths and a logistic regression.

Listing 15.2 `sklearn_nb.py`: `MultinomialNB` on the same split, the smoothing strength α by cross-validation, and logistic regression for comparison.

```
# sklearn_nb.py - the same classifier in scikit-learn, and the smoothing alpha
from sklearn.feature_extraction.text import CountVectorizer
from sklearn.linear_model import LogisticRegression
from sklearn.model_selection import StratifiedKFold, cross_val_score
from sklearn.naive_bayes import MultinomialNB
from sklearn.pipeline import make_pipeline
from nb import load, split, tokens

texts, labels, langs = load()
tr, te = split(labels, langs)                       # the same split as nb.py
vec = CountVectorizer(analyzer=tokens)              # our tokenizer, for a fair match
model = make_pipeline(vec, MultinomialNB(alpha=1.0))
model.fit([texts[i] for i in tr], labels[tr])
acc = model.score([texts[i] for i in te], labels[te])
print(f"scikit-learn MultinomialNB, test accuracy {acc:.3f}")

cv = StratifiedKFold(n_splits=10, shuffle=True, random_state=0)
for alpha in [0.01, 0.1, 0.5, 1.0, 2.0]:
    m = make_pipeline(CountVectorizer(analyzer=tokens), MultinomialNB(alpha=alpha))
    s = cross_val_score(m, texts, labels, cv=cv)
    print(f"alpha {alpha:4.2f}: 10-fold accuracy {s.mean():.3f} +/- {s.std():.3f}")
lr = make_pipeline(CountVectorizer(analyzer=tokens), LogisticRegression(C=10))
s = cross_val_score(lr, texts, labels, cv=cv)
print(f"logistic regression : 10-fold accuracy {s.mean():.3f} +/- {s.std():.3f}")
```

```
scikit-learn MultinomialNB, test accuracy 0.717
alpha 0.01: 10-fold accuracy 0.688 +/- 0.075
alpha 0.10: 10-fold accuracy 0.688 +/- 0.073
alpha 0.50: 10-fold accuracy 0.717 +/- 0.067
alpha 1.00: 10-fold accuracy 0.742 +/- 0.061
alpha 2.00: 10-fold accuracy 0.754 +/- 0.068
logistic regression : 10-fold accuracy 0.742 +/- 0.058
```

scikit-learn gives the same 0.717 as our code on the same split, as it must. Cross-validation over all 240 reviews then shows two things. Very little smoothing ($\alpha = 0.01$) is worst, 0.688: rare words get extreme log-ratios and a single one can swing a review. More smoothing helps up to $\alpha = 2$ (0.754), because with so little data every count is uncertain and pulling the estimates toward "equally likely in both classes" is wise. **Figure 15.1** plots the whole curve. And logistic regression, the model of Chapter 12, is no better here (0.742): with this little data the simpler counting model holds its own, which matches the classic comparison of Ng and Jordan, who showed that naive Bayes approaches its best accuracy with fewer examples than logistic regression [7].

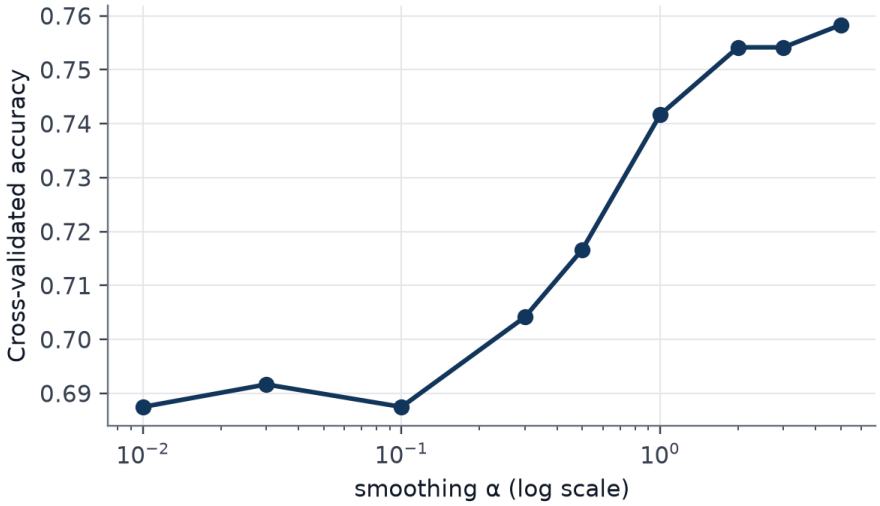

Figure 15.1 Ten-fold cross-validated accuracy of multinomial naive Bayes against the smoothing strength α on the 240 reviews.

The standard deviations of about 0.06 across folds are a warning: with 24 reviews per fold, one review is 4 percentage points. Differences of two or three points between settings are not reliable here.

15.4.4 The app

Listing 15.3 trains on all 240 reviews with the negation-aware tokenizer of Section 15.6, predicts, makes a rough guess at the language by counting a few very common Indonesian and English words, and prints every known word of the review with its log-ratio, sorted from most negative to most positive.

Listing 15.3 `sentiment_app.py`: the sentiment analyzer as a command-line app that explains its verdict.

```
# sentiment_app.py - positive or negative, in Indonesian or English, with reasons
import argparse
from nb import NaiveBayes, load, tokens, tokens_neg

ID_HINTS = {"dan", "yang", "tidak", "sangat", "sekali", "saya", "tapi", "sudah",
            "masih", "banget", "nya", "ini", "itu", "di", "ke", "dengan"}
EN_HINTS = {"the", "and", "not", "very", "was", "is", "my", "but", "it", "i",
            "a", "of", "to", "with", "this", "at"}

def language(text):
    words = tokens(text)
    ind = sum(w in ID_HINTS for w in words)
    eng = sum(w in EN_HINTS for w in words)
    return "Indonesian" if ind > eng else "English" if eng > ind else "unsure"

def main():
    ap = argparse.ArgumentParser(description="Naive Bayes sentiment analyzer")
    ap.add_argument("review")
    a = ap.parse_args()
    texts, labels, _ = load()
    nb = NaiveBayes(tokenize=tokens_neg).fit(texts, labels)   # all 240 reviews
    p_neg, p_pos = nb.predict_proba(a.review)
    verdict = "POSITIVE" if p_pos >= 0.5 else "NEGATIVE"
    print(f"{verdict}  P(positive) = {p_pos:.3f}   language: {language(a.review)}")
    known = [w for w in tokens_neg(a.review) if w in nb.vocab]
    unknown = [w for w in tokens_neg(a.review) if w not in nb.vocab]
    for w in sorted(set(known), key=nb.ratio):
        print(f"  {w:18s} {nb.ratio(w):+.2f}")
    if unknown:
        print("  not in vocabulary:", ", ".join(unknown))

if __name__ == "__main__":
    main()
```

15.5 Running It

A happy Indonesian customer:

```
python sentiment_app.py "Cuciannya wangi dan rapi, kurirnya ramah"
```

```
POSITIVE  P(positive) = 0.998   language: Indonesian
  dan                -0.12
  kurirnya           -0.06
  cuciannya          +0.23
  wangi              +1.73
  ramah              +2.13
  rapi               +2.34
```

Rapi, *ramah* and *wangi* carry the verdict; *dan* is almost neutral; *kurirnya* appears once in a positive and once in a negative review, and its slightly negative value only reflects that the positive jar holds a few more word tiles in total (828 against 738), so each of its tiles is a slightly smaller share. The probability of 0.998 is naive Bayes being overconfident, a known habit: because it treats the three positive words as independent pieces of evidence, it multiplies their effects even though they tend to come together.

An unhappy English one:

```
python sentiment_app.py "The ironing was not good and the delivery was late"
```

```
NEGATIVE  P(positive) = 0.051   language: English
  late               -1.45
  not_good           -1.16
  ironing            -0.47
  was                -0.18
  the                -0.06
  and                +0.01
  delivery           +0.63
```

The token `not_good` is the negation handling at work: without it, the word *good* would have pushed toward positive. *Delivery* leans positive because it appears once in the training reviews, in a positive one ("Fast delivery and a polite courier"); one appearance is thin evidence, which is exactly why smoothing keeps its log-ratio modest.

And a mixed review, the kind that shows the model's limits:

```
python sentiment_app.py "Harganya agak mahal tapi hasilnya tidak mengecewakan"
```

```
NEGATIVE  P(positive) = 0.268   language: Indonesian
  mahal              -1.67
  tapi               -0.76
  hasilnya           +0.34
  harganya           +0.45
  not_mengecewakan   +0.63
  not in vocabulary: agak
```

A person reads "a bit expensive, but the result is not disappointing" as mildly positive: the part after *tapi* (but) matters more. The model sees *mahal* (strongly negative) and *tapi* (negative, because complaints in our data often contain "mahal tapi hasilnya biasa saja"), outweighing `not_mengecewakan`. It has no notion that *tapi* shifts the weight to what follows, and *agak* (a bit) is not even in its vocabulary. Each run takes one to two seconds, mostly Python start-up and importing NumPy.

Figure 15.2 shows the words with the strongest log-ratios among those seen at least three times.

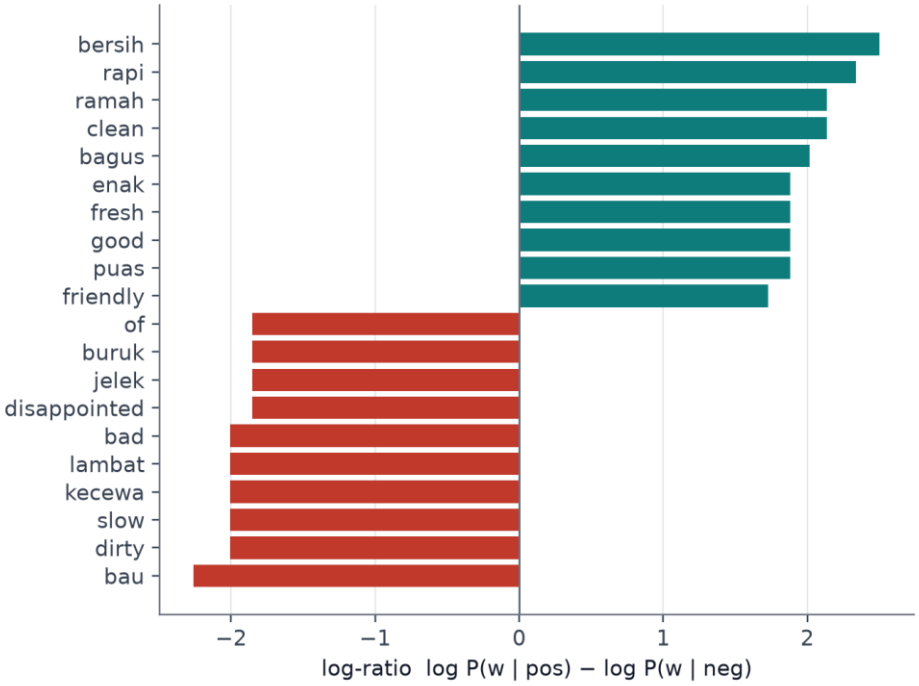

Figure 15.2 Log-ratios $r(w)$ of Equation (15.8) for the ten most negative and ten most positive words that occur at least three times in the 240 reviews, with negation marked.

15.6 Improving It

15.6.1 Negation

The simplest useful treatment of negation, used in early sentiment research by Pang, Lee and Vaithyanathan [8], rewrites the word after a negator as a new token: *tidak bagus* becomes `not_bagus`, *not bad* becomes `not_bad`. The model then learns separate statistics for "bagus" and "not bagus". Our `tokens_neg` does this for the Indonesian negators *tidak*, *bukan*, *kurang*, *belum*, *jangan* and the English *not*, *no*, *never*, *nothing*, *without*, and drops the negator itself. **Listing 15.4** shows it on two reviews and measures the effect.

Listing 15.4 `negation.py`: marking the word after a negator, and its effect on accuracy and on individual words.

```
# negation.py - "tidak bagus" is not "bagus": mark the word after a negator
import numpy as np
from sklearn.feature_extraction.text import CountVectorizer
from sklearn.model_selection import StratifiedKFold, cross_val_score
from sklearn.naive_bayes import MultinomialNB
from sklearn.pipeline import make_pipeline
from nb import NaiveBayes, load, tokens, tokens_neg

texts, labels, langs = load()
print(tokens_neg("Tidak bagus, hasil cucian masih kotor"))
print(tokens_neg("Not bad at all, the clothes were clean"))

cv = StratifiedKFold(n_splits=10, shuffle=True, random_state=0)
for name, tok in [("plain words", tokens), ("negation marked", tokens_neg)]:
    m = make_pipeline(CountVectorizer(analyzer=tok), MultinomialNB())
    s = cross_val_score(m, texts, labels, cv=cv)
    print(f"{name:16s}: 10-fold accuracy {s.mean():.3f} +/- {s.std():.3f}")

nb = NaiveBayes(tokenize=tokens_neg).fit(texts, labels)
for w in ["mengecewakan", "not_mengecewakan", "good", "not_good"]:
    print(f"{w:18s} log-ratio {nb.ratio(w):+.2f}  "
          f"(pos {nb.counts['pos'][w]}, neg {nb.counts['neg'][w]})")
```

```
['not_bagus', 'hasil', 'cucian', 'masih', 'kotor']
['not_bad', 'at', 'all', 'the', 'clothes', 'were', 'clean']
plain words     : 10-fold accuracy 0.742 +/- 0.061
negation marked : 10-fold accuracy 0.779 +/- 0.081
mengecewakan       log-ratio -1.45  (pos 0, neg 3)
not_mengecewakan   log-ratio +0.63  (pos 1, neg 0)
good               log-ratio +1.88  (pos 6, neg 0)
not_good           log-ratio -1.16  (pos 0, neg 2)
```

Cross-validated accuracy rises from 0.742 to 0.779. The word statistics show why. *Mengecewakan* is now clearly negative (−1.45, seen only in negative reviews), and `not_mengecewakan` is positive (+0.63). *Good* is now strongly positive (+1.88): previously its two appearances in "Not good" had made it look almost neutral. Negation marking is crude (it affects only the next word, so "tidak terlalu bagus" marks *terlalu*, not *bagus*), but it fixes the commonest pattern at no cost.

15.6.2 More data

Figure 15.3 is a *learning curve*: cross-validated accuracy as the number of training reviews grows, with and without negation marking. With 19 training reviews the model is barely better than a coin (0.56); with 192 it reaches 0.75. The curve is still rising at the right edge, which is the clearest possible message: this model is starved of data, and the best improvement is to label more reviews. A few hundred more reviews from Profitina Laundry's own customers, labeled by

the staff during quiet hours, would be worth more than any change to the algorithm. Exercise 15.5 prints the numbers behind the curve.

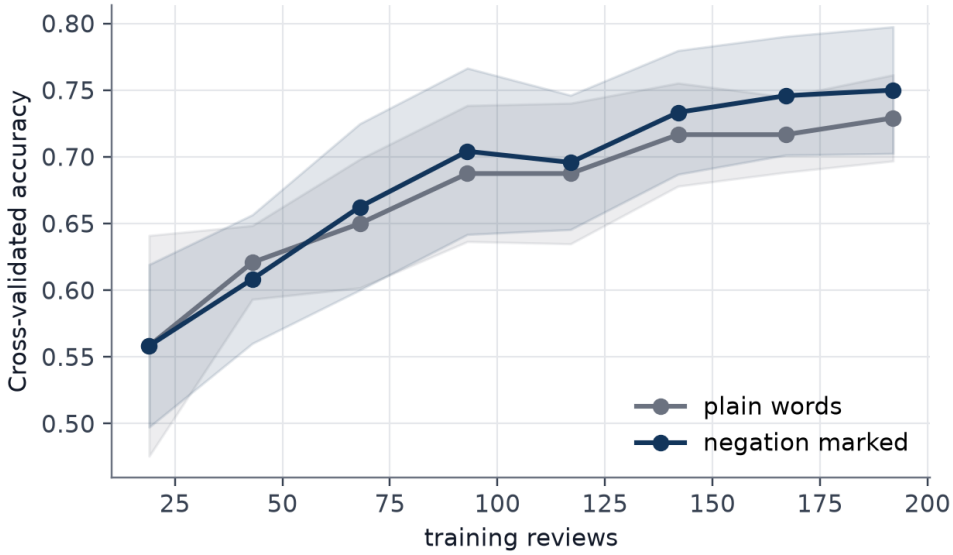

Figure 15.3 Learning curves of naive Bayes on the review data: 5-fold cross-validated accuracy against the number of training reviews, for plain words and with negation marked. Shaded bands show one standard deviation across folds.

15.6.3 Knowing the limits

Three further improvements are standard. Treating *agak*, *sedikit*, *a bit* and *slightly* as softeners, and *tapi*, *namun* and *but* as shifting weight to the clause that follows, handles mixed reviews like the one in Section 15.5. Normalizing the informal spellings of Indonesian chat (*bgt* for *banget*, *gak* and *ga* for *tidak*, *mantul* for *mantap betul*) lets one word's evidence count once instead of being spread over five spellings. And models that read whole sentences, from the neural networks of Part 4 to the language models of Part 9, handle negation, contrast and sarcasm far better, at a much higher cost in data and computation. For a quick nightly dashboard of hundreds of reviews, naive Bayes with negation marking is a sensible, transparent start.

The tests in **Listing 15.5** check that log-sum-exp survives very negative scores, that negation marks exactly one word, and that the smoothed probabilities match a calculation done by hand.

Listing 15.5 `test_nb.py`: tests for log-sum-exp, negation marking and Laplace smoothing.

```python
# test_nb.py - run with:  python -m pytest -q
import numpy as np
from nb import NaiveBayes, log_sum_exp, tokens_neg

def test_log_sum_exp_is_stable():
    a = np.array([-1000.0, -1000.0])
    assert np.isclose(log_sum_exp(a), -1000.0 + np.log(2))

def test_negation_marks_only_the_next_word():
    assert tokens_neg("tidak bagus tapi murah") == ["not_bagus", "tapi", "murah"]

def test_laplace_smoothing_by_hand():
    nb = NaiveBayes(alpha=1.0).fit(["enak enak", "basi"], np.array(["pos", "neg"]))
    # vocabulary {enak, basi}: P(enak|pos) = (2+1)/(2+2), P(enak|neg) = 1/3
    assert np.isclose(np.exp(nb.log_lik("enak", "pos")), 3 / 4)
    assert np.isclose(np.exp(nb.log_lik("enak", "neg")), 1 / 3)
    assert nb.predict("enak") == "pos"
```

```
...                                                                  [100%]
3 passed in 0.29s
```

15.7 Common Mistakes, and How to Avoid Them

Forgetting smoothing. One word seen only in the other class sets a probability to zero and vetoes the class. Always smooth; choose α by cross-validation.

Multiplying probabilities instead of adding logs. Long documents underflow to zero for every class, and the prediction becomes whatever `argmax` returns for a tie. Work with Equation (15.6) and normalize with Equation (15.7).

Trusting the probabilities. Naive Bayes counts correlated words as independent evidence and so pushes probabilities toward 0 and 1. Use its ranking and its verdicts; if calibrated probabilities matter, calibrate them on held-out data (scikit-learn's `CalibratedClassifierCV`).

Ignoring negation. "Tidak bagus" contains *bagus*. Without negation handling, negated praise looks like praise.

Mixing up the vocabulary of training and prediction. Words that appear only in a new review have no counts; they must be skipped, not smoothed into one class. Our `predict_proba` filters them, and `CountVectorizer` ignores them automatically.

Over-reading small test sets. With 60 test reviews, one review is 1.7 percentage points. Report cross-validated accuracy with its spread, and prefer learning curves to single numbers when data are scarce.

15.8 Chapter Summary

- Bayes' theorem (Equation (15.1)) turns "how likely is this review from this class" into "how likely is this class given this review", combining a prior (Equation (15.2)) with a likelihood.
- The naive assumption (Equation (15.3)) treats the words of a review as independent draws, so only one probability per word and class is needed.
- Word probabilities are counted (Equation (15.4)) and smoothed (Equation (15.5)) so that an unseen word cannot veto a class.

- Predictions add log-probabilities (Equation (15.6)); the log-sum-exp trick (Equation (15.7)) turns scores back into probabilities without underflow.
- Each word's log-ratio (Equation (15.8)) is its weight toward positive or negative, which makes every verdict explainable.
- On 240 bilingual reviews, naive Bayes reached about 0.74 cross-validated accuracy, and 0.78 with negation marking; the learning curve shows that more labeled data is the best next step.
- Naive Bayes is fast, transparent and data-efficient, but overconfident, blind to word order and easily confused by contrast ("mahal tapi…").

15.9 Exercises

1. Using the four-review example of Section 15.3.3 with $\alpha = 1$, compute the posterior probability of positive for "kotor tapi murah" and for "enak enak lambat".
2. Show that Equation (15.5) gives probabilities that sum to 1 over the vocabulary for each class.
3. A 300-word review has, in each class, word probabilities of about 0.002. Compute $\log_{10}$ of the product of the 300 probabilities, and explain what happens if the program multiplies them directly in double precision.
4. Run the app on "Not bad at all, fast and friendly" and explain the output word by word.
5. Draw your own learning curve: compute 5-fold cross-validated accuracy with negation marking for 10, 25, 50, 75 and 100 percent of the available training data, and say what you would expect with 1,000 reviews.
6. Is one bilingual model better than one model per language? Train a model on the Indonesian training reviews only and another on the English ones only, and compare each with the bilingual model on its own language's test reviews.

15.10 Solutions to the Exercises

Exercise 15.1. "kotor tapi murah" (*tapi* is skipped). Positive: $0.5 \times P(\text{kotor} \mid \text{pos}) \times P(\text{murah} \mid \text{pos}) = 0.5 \times 1/10 \times 2/10 = 0.010$. Negative: $0.5 \times 3/10 \times 1/10 = 0.015$. Posterior positive $0.010/0.025 = 0.4$. "enak enak lambat": positive $0.5 \times 0.3 \times 0.3 \times 0.1 = 0.0045$; negative $0.5 \times 0.1 \times 0.1 \times 0.2 = 0.0010$; posterior positive $0.0045/0.0055 = 0.818$. The repeated *enak* counts twice, which is what "multinomial" means.

Exercise 15.2. For class c, write $T_c = \sum_{v \in V} \text{count}(v, c)$. Then $\sum_{w \in V} \frac{\text{count}(w,c)+\alpha}{T_c+\alpha|V|} = \frac{T_c+\alpha|V|}{T_c+\alpha|V|} = 1$, because adding α for each of the $|V|$ words adds $\alpha|V|$ to the numerator's total.

Exercise 15.3. $\log_{10}(0.002) = -2.699$, so the product has $\log_{10} = 300 \times (-2.699) = -809.7$, that is about 10^{-810}. Double precision can represent numbers down to about 10^{-308} (and, with reduced precision, 10^{-324}); below that the result becomes exactly 0. Both class scores become 0, the comparison is a tie, and the prediction is meaningless. Adding logarithms gives about -1864 for each class (natural logarithms), perfectly representable.

Exercise 15.4.

```
python sentiment_app.py "Not bad at all, fast and friendly"
```

```
POSITIVE  P(positive) = 0.984   language: English
  and                 +0.01
  all                 +0.23
  at                  +0.34
  not_bad             +0.63
  fast                +1.19
  friendly            +1.73
```

Friendly and *fast* are strongly positive; `not_bad` is positive because "Not bad at all" appeared in a positive training review; *at*, *all* and *and* are nearly neutral. Without negation marking, *bad* (strongly negative) would have fought against *fast* and *friendly*.

Exercise 15.5. Listing 15.6 uses scikit-learn's `learning_curve`, which trains on growing subsets of each training fold.

Listing 15.6 `solutions/ex_curve.py`: cross-validated accuracy for growing amounts of training data.

```
# ex_curve.py - Exercise 15.5: does more data help? a learning curve
import sys
from pathlib import Path
import numpy as np
from sklearn.feature_extraction.text import CountVectorizer
from sklearn.model_selection import StratifiedKFold, learning_curve
from sklearn.naive_bayes import MultinomialNB
from sklearn.pipeline import make_pipeline
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from nb import load, tokens_neg

texts, labels, _ = load()
model = make_pipeline(CountVectorizer(analyzer=tokens_neg), MultinomialNB())
cv = StratifiedKFold(n_splits=5, shuffle=True, random_state=0)
sizes, _, test = learning_curve(model, np.array(texts, dtype=object), labels,
                                train_sizes=[0.1, 0.25, 0.5, 0.75, 1.0], cv=cv)
for n, s in zip(sizes, test):
    print(f"{n:3d} training reviews: accuracy {s.mean():.3f} +/- {s.std():.3f}")
```

```
 19 training reviews: accuracy 0.558 +/- 0.061
 48 training reviews: accuracy 0.608 +/- 0.069
 96 training reviews: accuracy 0.704 +/- 0.074
144 training reviews: accuracy 0.733 +/- 0.057
192 training reviews: accuracy 0.750 +/- 0.048
```

Accuracy climbs steadily from 0.558 to 0.750 and has not levelled off. Learning curves of text classifiers typically keep rising, ever more slowly, for thousands of examples; with 1,000 reviews of similar style one could reasonably expect accuracy well above 0.8, but the only way to know is to label them and measure.

Exercise 15.6. Listing 15.7 trains the three models on the same training split.

Listing 15.7 `solutions/ex_by_lang.py`: one bilingual model against one model per language.

```
# ex_by_lang.py - Exercise 15.6: one bilingual model or one model per language?
import sys
from pathlib import Path
import numpy as np
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from nb import NaiveBayes, load, split, tokens_neg

texts, labels, langs = load()
tr, te = split(labels, langs)
both = NaiveBayes(tokenize=tokens_neg).fit([texts[i] for i in tr], labels[tr])
for lang in ["id", "en"]:
    tr_l = tr[langs[tr] == lang]
    te_l = te[langs[te] == lang]
    own = NaiveBayes(tokenize=tokens_neg)
    own.fit([texts[i] for i in tr_l], labels[tr_l])
    a_both = np.mean([both.predict(texts[i]) == labels[i] for i in te_l])
    a_own = np.mean([own.predict(texts[i]) == labels[i] for i in te_l])
    print(f"{lang}: bilingual model {a_both:.3f}, {lang}-only model {a_own:.3f}"
          f"  ({len(tr_l)} training, {len(te_l)} test)")
```

```
id: bilingual model 0.750, id-only model 0.750  (104 training, 36 test)
en: bilingual model 0.833, en-only model 0.833  (76 training, 24 test)
```

The accuracies are identical. That is not a coincidence: Indonesian and English reviews share almost no words, so inside the bilingual model the Indonesian words' counts are exactly those of the Indonesian-only model; the English reviews only add their own words, which never appear in an Indonesian test review. The priors are the same because both languages are balanced. One bilingual model is therefore as good as two, and simpler to run. The bilingual model would suffer only if the languages shared words with different meanings, or if one language had far more positive than negative reviews.

Chapter 16

Customer Segmentation: k-Means on Laundry Data

Every model so far learned from examples that came with answers: a price, a spam label, a species, a loan decision, a sentiment. This chapter meets *unsupervised learning*, where there are no answers at all, only data, and the task is to find structure nobody has labeled. We take a year of real-looking orders from Profitina Laundry's three outlets in Surabaya, describe each customer by three numbers (how recently they came, how often, and how much they spent), and let the *k-means* algorithm sort the customers into groups that behave alike. By the end of the chapter you will be able to build an RFM table from raw transactions; explain why skewed features need a logarithm and why every feature needs a common scale; run k-means by hand on a handful of points; implement it from scratch with the k-means++ start; choose the number of groups with the elbow of inertia and the silhouette score; check that the groups are stable; and turn clusters into named segments with a concrete action for each, in a small app that the laundry's staff could use on Monday morning.

16.1 Why Customer Segmentation?

Profitina Laundry has 253 customers who placed 2,953 orders between October 2025 and September 2026 across its outlets in Rungkut, Keputih and Wiyung. Pak Hendra has a small marketing budget: some vouchers, a loyalty card he could print, and the time his staff can spend sending personal WhatsApp messages. Giving every customer the same treatment wastes all three. A voucher is wasted on someone who comes every week anyway; a "thank you, loyal customer" card is odd for someone who came once; a win-back message makes sense only for someone who has stopped coming.

What he needs is a small number of groups, each homogeneous enough that one action fits all its members, and different enough from the others that the actions differ. Marketing people call these *segments*. They used to be drawn by hand ("customers who spent more than a million this year"), with thresholds chosen by instinct. Clustering finds them from the data instead, and a classic, remarkably effective description of customers for this purpose is *RFM*: *recency* (days since the last order), *frequency* (number of orders) and *monetary* value (total spend) [1].

The data are the sample database that ships with the Profitina Laundry application: realistic but invented customers, bills and payments, so we can use them freely. We use only the bills table and only the columns we need: bill number, date, amount, customer number, service and outlet. No name, phone number or address is needed to segment customers, so none is loaded.

The app we build prints the segments with a suggested action for each, and looks up a single customer:

```
python segment_app.py --customer C0047
```

16.2 The Idea in Plain Words

Imagine the 253 customers as people standing in a large hall, where a person's position is given by their three numbers. People who come often and spend a lot stand together in one corner; people who came once long ago stand in another. We want to put up four flagpoles so that everyone can walk to the nearest flag and the walks are, overall, as short as possible. The groups around the flags are the clusters.

Where should the flags go? k-means answers with a simple dance of two steps, repeated:

1. **Assign.** Everyone walks to the nearest flag.
2. **Update.** Each flag moves to the middle (the average position) of the people now standing at it.

Moving a flag to the middle of its group makes that group's walks shorter; walking to the nearest flag makes each person's walk shorter. Neither step can make the total longer, so the dance settles down, usually within a few rounds. The only choice left to us is where to plant the flags at the start, and how many flags to use.

Two things can spoil the result before the dance begins, and both are about the hall's floor. The first is *scale*: if spend is measured in rupiah (hundreds of thousands) and frequency in orders (tens), the hall is stretched a thousandfold in the spend direction, and "nearest flag" means "flag with the most similar spend", ignoring everything else. The second is *skew*: a few customers spend ten times the median, and on a linear floor they stand so far away that they drag a flag to themselves. We fix both by taking logarithms (which pull in the long tail) and then z-scores (which give every direction the same scale), as Chapters 11 and 13 did for their features.

> **KEY INSIGHT:** k-means repeats two steps, "join the nearest center" and "move each center to the mean of its members", and each step can only lower the total squared distance. What the clusters mean depends entirely on the features and their scaling, which is where the real work lies.

16.3 The Mathematics, Gently

16.3.1 Points, centers and distances

Each customer i is a point $\mathbf{x}_i = (x_{i1}, x_{i2}, x_{i3})$ in three dimensions: transformed recency, frequency and spend. We look for k *centers* (the flags) $\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_k$. The squared Euclidean distance between a customer and a center is

$$\| \mathbf{x}_i - \boldsymbol{\mu}_j \|^2 = \sum_{f=1}^{3} (x_{if} - \mu_{jf})^2 \tag{16.1}$$

the familiar distance of Chapter 13 without the square root. (We keep it squared because the square makes the "middle" in the update step exactly the average.)

16.3.2 What k-means minimizes

Give each customer a label $c_i \in \{1, \ldots, k\}$ saying which center it belongs to. The quality of a clustering is the total squared distance of every customer to its own center:

$$J = \sum_{i=1}^{n} \| \mathbf{x}_i - \boldsymbol{\mu}_{c_i} \|^2 \tag{16.2}$$

scikit-learn calls J the *inertia*. Small inertia means tight groups. Minimizing J exactly is a hard problem (it is NP-hard, which means no known method is fast on every data set), so k-means settles for a very good local answer found by alternating two easy minimizations [2], [3].

16.3.3 The two steps

With the centers held fixed, J is smallest when every customer takes the nearest center:

$$c_i = \operatorname{argmin}_j \| \mathbf{x}_i - \boldsymbol{\mu}_j \|^2 \tag{16.3}$$

With the labels held fixed, J is smallest when every center sits at the mean of its members:

$$\boldsymbol{\mu}_j = \frac{1}{|S_j|} \sum_{i \in S_j} \mathbf{x}_i \tag{16.4}$$

where S_j is the set of customers with label j and $|S_j|$ is how many there are. Why the mean? For one feature, the sum $\sum_{i \in S_j} (x_i - m)^2$ is a parabola in m; its derivative $-2 \sum_{i \in S_j} (x_i - m)$ is zero exactly when m is the average. The same holds for each feature separately.

Each step lowers J or leaves it unchanged, and there are only finitely many ways to label n points, so the alternation must stop. It stops at a clustering where neither step can improve, which is not necessarily the best clustering of all; that is why we restart several times from different starting centers and keep the run with the lowest J.

EXAMPLE. Seven customers on one axis: 1,2,3,10,11,12,20, and $k = 2$ with starting centers $\mu_1 = 1, \mu_2 = 2$.

Round 1. Assign: 1 goes to μ_1; every other point is at least as close to 2, so {2,3,10,11,12,20} go to μ_2. Update: $\mu_1 = 1, \mu_2 = 58/6 = 9.67$.

Round 2. Assign: 2 is 1 away from μ_1 and 7.67 from μ_2, and 3 is 2 away against 6.67, so {1,2,3} go to μ_1 and {10,11,12,20} to μ_2. Update: $\mu_1 = 2, \mu_2 = 53/4 = 13.25$.

Round 3. Assign: 10 is 8 from μ_1 and 3.25 from μ_2; nothing changes. Stop.

Inertia: $(1 + 0 + 1) + (3.25^2 + 2.25^2 + 1.25^2 + 6.75^2) = 2 + 62.75 = 64.75$. A bad start (both centers in the same corner) was repaired in two rounds.

16.3.4 A better start: k-means++

Starting centers chosen purely at random can land two flags in one group and none in another, and the dance may then get stuck. *k-means++* spreads the starting centers out [4]. The first center is a random customer. Each further center is a customer chosen at random with probability proportional to its squared distance $D(\mathbf{x}_i)^2$ from the nearest center already chosen:

$$P(\mathbf{x}_i \text{ is next}) = \frac{D(\mathbf{x}_i)^2}{\sum_{l=1}^{n} D(\mathbf{x}_l)^2} \tag{16.5}$$

Far-away customers are much more likely to be picked, so the starting flags tend to land in different groups. Arthur and Vassilvitskii proved that this start alone guarantees an inertia within

a factor of about $8\ln k$ of the best possible on average, and in practice it is much closer. scikit-learn's `KMeans` uses k-means++ by default.

16.3.5 Preparing the features

Frequency and spend are heavily skewed: the median customer placed 8 orders, the busiest 62; the median spent 407 thousand rupiah, the biggest 3.08 million. Recency is skewed too. We transform each feature x by

$$z = \frac{\ln(1 + x) - m}{s} \tag{16.6}$$

where m and s are the mean and standard deviation of $\ln(1 + x)$ over all customers. The logarithm turns ratios into differences (going from 4 to 8 orders counts as much as going from 20 to 40), and adding 1 keeps a recency of 0 days finite. The z-score then gives the three features equal weight in Equation (16.1). Without this step, spend measured in hundreds of thousands would drown out frequency measured in tens, and recency would hardly be heard at all. Section 16.6 shows the consequence in numbers.

16.3.6 How many clusters? Elbow and silhouette

Inertia always falls as k grows (with $k = n$ it is zero), so we cannot simply minimize it over k. The *elbow* method plots inertia against k and looks for the point where adding a cluster stops buying much. The *silhouette* gives a number to look at instead [5]. For customer i, let $a(i)$ be its average distance to the other members of its own cluster, and $b(i)$ its average distance to the members of the nearest other cluster. Then

$$s(i) = \frac{b(i) - a(i)}{\max\{a(i), b(i)\}} \tag{16.7}$$

is close to 1 when the customer sits snugly in its own cluster and far from the next, near 0 when it lies on a border, and negative when it would fit better elsewhere. The average of $s(i)$ over all customers is the silhouette score of the clustering; we prefer the k that makes it high, as long as the clusters also make business sense.

16.4 Building It Step by Step

16.4.1 From bills to RFM

The folder `Chapter016` has the same `requirements.txt` as Chapter 11 and a data file `data/bills.csv` extracted from the Profitina Laundry sample database. **Listing 16.1** turns bills into one row per customer.

Listing 16.1 `rfm.py`: building the recency–frequency–monetary table and its log-and-z-score features.

```python
# rfm.py - from 2,953 laundry bills to one row per customer: R, F and M
from pathlib import Path
import numpy as np
import pandas as pd

TODAY = pd.Timestamp("2026-10-01")                  # the day after the last bill

def load_bills(path=None):
    path = path or Path(__file__).parent / "data" / "bills.csv"
    return pd.read_csv(path, parse_dates=["arrived"])

def rfm(bills):
    g = bills.groupby("Customer_id")
    table = pd.DataFrame({
        "recency": (TODAY - g["arrived"].max()).dt.days,   # days since last visit
        "frequency": g.size(),                              # number of bills
        "monetary": g["payment"].sum() / 1000,              # thousand rupiah
    })
    return table

def features(table):
    X = np.column_stack([np.log1p(table["recency"]), np.log1p(table["frequency"]),
                         np.log1p(table["monetary"])])
    return (X - X.mean(axis=0)) / X.std(axis=0)             # z-scores of logs

if __name__ == "__main__":
    t = rfm(load_bills())
    print(len(t), "customers")
    print(t.head().to_string())
    print(t.describe().loc[["mean", "50%", "min", "max"]].round(1).to_string())
```

The function `rfm` groups the bills by customer with pandas: recency is the number of days from the customer's last bill to October 1, 2026 (the day after the last bill in the data), frequency is the number of bills, and monetary is the sum of payments in thousands of rupiah. The function `features` is Equation (16.6): `np.log1p` computes $\ln(1 + x)$, then each column is standardized.

```
253 customers
             recency  frequency  monetary
Customer_id
C0001            107         10     463.0
C0002             34         21    1060.0
C0003             32         15     592.0
C0004             94          7     339.0
C0005              6         17     837.0
      recency  frequency  monetary
mean     57.6       11.7     570.0
50%      28.0        8.0     407.0
min       0.0        1.0      12.0
max     344.0       62.0    3079.0
```

The mean and the median tell the story of skew: the average customer spent 570 thousand, but half spent less than 407 thousand, because a few big spenders pull the average up.

16.4.2 k-means from scratch

Listing 16.2 is the algorithm of Section 16.3 in forty lines.

Listing 16.2 `kmeans.py`: k-means from scratch, with k-means++ starts, Lloyd's iterations and several restarts.

```
# kmeans.py - k-means from scratch: k-means++ start, Lloyd iterations, restarts
import numpy as np
from rfm import features, load_bills, rfm

def sq_dist(X, C):
    return ((X[:, None, :] - C[None, :, :]) ** 2).sum(axis=2)   # n x k table

def kmeanspp(X, k, rng):
    centers = [X[rng.integers(len(X))]]
    for _ in range(k - 1):
        d2 = sq_dist(X, np.array(centers)).min(axis=1)
        centers.append(X[rng.choice(len(X), p=d2 / d2.sum())])  # far is likely
    return np.array(centers)

def lloyd(X, C, max_iter=100):
    history = []
    for _ in range(max_iter):
        labels = sq_dist(X, C).argmin(axis=1)                   # assignment step
        history.append(sq_dist(X, C).min(axis=1).sum())
        new = np.array([X[labels == j].mean(axis=0) if np.any(labels == j)
                        else C[j] for j in range(len(C))])      # update step
        if np.allclose(new, C):
            break
        C = new
    return labels, C, history

def kmeans(X, k, n_init=10, seed=0):
    rng = np.random.default_rng(seed)
    best = None
    for _ in range(n_init):
        labels, C, hist = lloyd(X, kmeanspp(X, k, rng))
        if best is None or hist[-1] < best[2][-1]:
            best = (labels, C, hist)
    return best
```

Listing 16.2 (Continued) *kmeans.py: k-means from scratch, with k-means++ starts, Lloyd's iterations and several restarts.*

```
if __name__ == "__main__":
    table = rfm(load_bills())
    X = features(table)
    labels, C, hist = kmeans(X, k=4)
    print("inertia per iteration:", " ".join(f"{h:.1f}" for h in hist))
    table["segment"] = labels
    summary = table.groupby("segment").agg(
        customers=("recency", "size"), recency=("recency", "median"),
        frequency=("frequency", "median"), monetary=("monetary", "median"))
    print(summary.to_string())
```

- `sq_dist` computes Equation (16.1) for every customer and every center at once. The expression `X[:, None, :] - C[None, :, :]` uses NumPy broadcasting to form an $n \times k \times 3$ array of differences; summing the squares over the last axis leaves an $n \times k$ table of squared distances.
- `kmeanspp` is Equation (16.5): after the first random center, it computes each customer's squared distance to the nearest chosen center and passes the normalized distances as the probabilities `p` to `rng.choice`.
- `lloyd` alternates Equation (16.3) (`argmin` over each row of the distance table) and Equation (16.4) (the mean of each cluster's members), recording the inertia of Equation (16.2)

each round, until the centers stop moving. If a cluster ever loses all its members, its center stays where it was. The name honors Stuart Lloyd, who described the method at Bell Labs in 1957 [2]; MacQueen gave it the name "k-means" in 1967 [6].

- `kmeans` runs `lloyd` from ten k-means++ starts and keeps the run with the lowest final inertia.

Running it with $k = 4$ prints the inertia after each assignment step and a summary of the four clusters in the original units:

```
inertia per iteration: 320.5 224.5 213.7 212.4 211.9 211.7 211.7
         customers  recency  frequency  monetary
segment
0               39      5.0        4.0     197.0
1               58    106.0        3.0     153.0
2               89     51.0       10.0     469.0
3               67      6.0       20.0    1057.0
```

The inertia falls from 320.5 to 211.7 in six rounds and stops, exactly as the argument of Section 16.3.3 promised: every number is lower than or equal to the one before. **Figure 16.1** shows the same kind of run on two of the three features, so it can be drawn: four k-means++ starting centers (circles) and the paths they travel to their final positions (crosses).

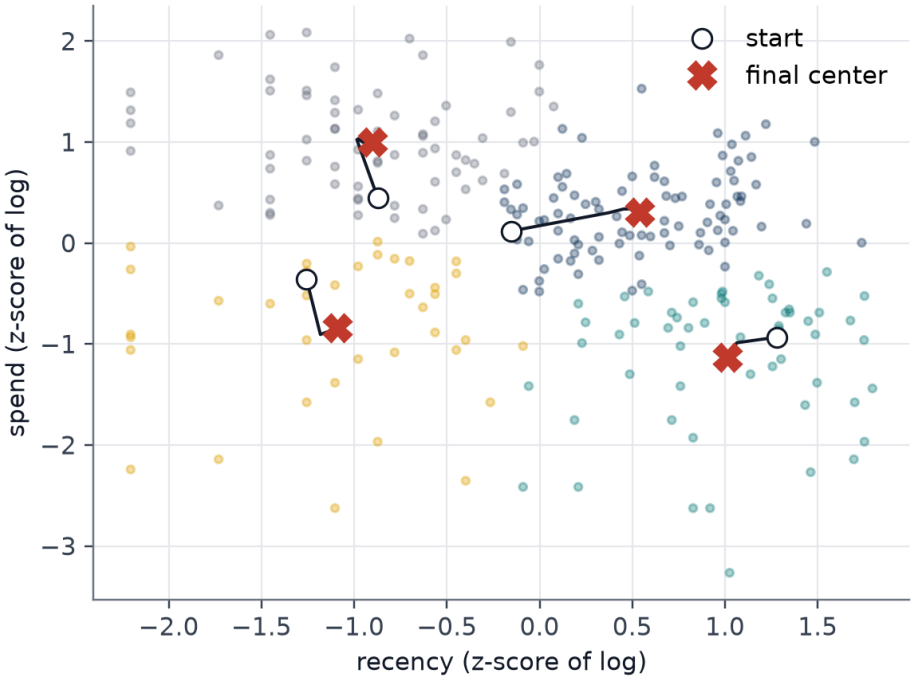

Figure 16.1 Lloyd's iterations on two features (recency and spend, as z-scores of logarithms): each center starts at a k-means++ choice and moves to the mean of its members until nothing changes.

The four clusters are already recognizable in the summary table. Cluster 3 came 6 days ago (median), has 20 orders and spent a million: the core customers. Cluster 0 came 5 days ago but has only 4 orders. Cluster 1 has not come for 106 days and has 3 orders. Cluster 2 sits in between on every count.

16.4.3 How many segments?

We chose $k = 4$ above without justification. **Listing 16.3** runs scikit-learn's `KMeans` [3] for k from 2 to 8 and prints the inertia and the silhouette score of each.

Listing 16.3 `choose_k.py`: inertia and silhouette score for $k = 2$ to 8.

```python
# choose_k.py - how many segments? the elbow of inertia and the silhouette
from sklearn.cluster import KMeans
from sklearn.metrics import silhouette_score
from rfm import features, load_bills, rfm

X = features(rfm(load_bills()))
print(" k   inertia  silhouette")
for k in range(2, 9):
    km = KMeans(n_clusters=k, n_init=10, random_state=0).fit(X)
    print(f"{k:2d}  {km.inertia_:8.1f}  {silhouette_score(X, km.labels_):10.3f}")
```

```
 k   inertia  silhouette
 2     420.6       0.377
 3     304.8       0.334
 4     211.7       0.385
 5     177.8       0.339
 6     148.9       0.334
 7     129.2       0.335
 8     110.8       0.339
```

scikit-learn's inertia for $k = 4$, 211.7, matches our scratch implementation exactly. **Figure 16.2** plots both columns. The inertia curve bends most clearly at $k = 4$: each extra cluster up to four removes about 93 to 116 units of inertia, while the fifth removes only 34, and the silhouette score peaks at $k = 4$ with 0.385. Both methods agree, and four is also a number of segments a small business can actually act on.

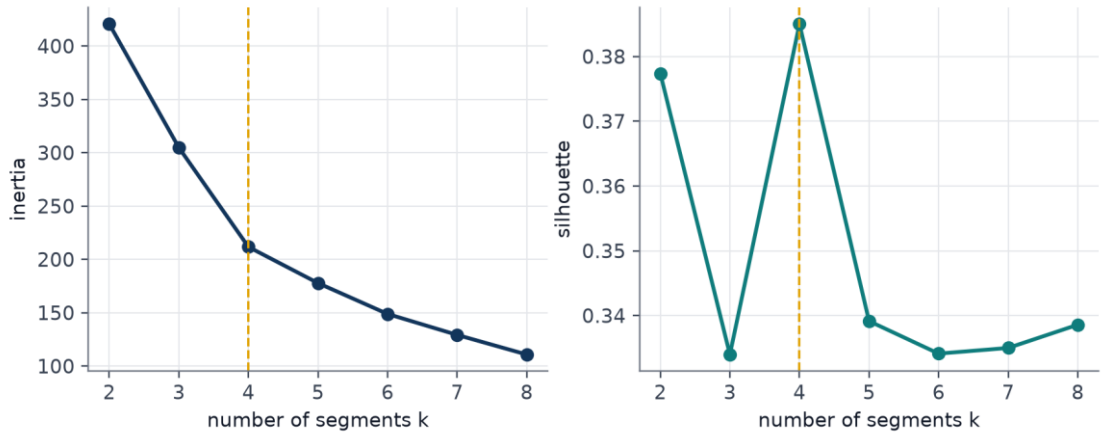

Figure 16.2 Choosing k: inertia (left) falls ever more slowly as k grows, with its clearest bend at $k = 4$; the average silhouette (right) is highest at $k = 4$.

A silhouette of 0.385 is modest. It says the groups are real but their borders are soft: customers form a continuum from "came once" to "comes every week", and any cut through a continuum leaves many people near the edges. That is normal for customer data and is not a reason to distrust the segments, only a reason to treat borderline customers with some judgment.

16.4.4 The app

Listing 16.4 turns cluster numbers into names and actions. Cluster numbers are arbitrary (they depend on which random start won), so the app names the clusters by their properties: the one with the highest median frequency is *loyal*, the one with the highest median recency is *lapsed*, and of the two remaining, the one with fewer orders is *new* and the other *regular*. Each name maps to one action.

Listing 16.4 `segment_app.py`: naming the segments, suggesting actions, and looking up one customer.

```
# segment_app.py - name the four customer segments and look up one customer
import argparse
from kmeans import kmeans
from rfm import features, load_bills, rfm

ACTIONS = {
    "loyal": "thank them: loyalty stamp card, first look at new services",
    "regular": "nudge up: bundle ironing or bed cover with the usual wash",
    "new": "welcome: second-order voucher within two weeks",
    "lapsed": "win back: personal message and a 'we miss you' discount",
}

def name_segments(table):
    med = table.groupby("segment")[["recency", "frequency"]].median()
    names = {med["frequency"].idxmax(): "loyal", med["recency"].idxmax(): "lapsed"}
    rest = med.drop(index=list(names)).sort_values("frequency")
    names[rest.index[0]], names[rest.index[1]] = "new", "regular"
    return names

def main():
    ap = argparse.ArgumentParser(description="Laundry customer segments")
    ap.add_argument("--customer", help="customer id, e.g. C0047")
    a = ap.parse_args()
    table = rfm(load_bills())
    labels, _, _ = kmeans(features(table), k=4)
    table["segment"] = labels
    names = name_segments(table)
    table["name"] = table["segment"].map(names)
    if a.customer:
        row = table.loc[a.customer]
        print(f"{a.customer}: last visit {row.recency} days ago, "
              f"{row.frequency} orders, Rp {row.monetary:,.0f} thousand")
        print(f"segment: {row['name']}  ->  {ACTIONS[row['name']]}")
        return
    s = table.groupby("name").agg(customers=("recency", "size"),
                                  recency=("recency", "median"),
                                  orders=("frequency", "median"),
                                  spend_k=("monetary", "median"))
    print(s.sort_values("orders", ascending=False).to_string())
    for n in s.sort_values("orders", ascending=False).index:
        print(f"{n:8s} {ACTIONS[n]}")
```

Listing 16.4 (Continued) *segment_app.py: naming the segments, suggesting actions, and looking up one customer.*

```
if __name__ == "__main__":
    main()
```

16.5 Running It

The overview for Pak Hendra:

```
python segment_app.py
```

```
          customers  recency  orders  spend_k
name
loyal            67      6.0    20.0   1057.0
regular          89     51.0    10.0    469.0
new              39      5.0     4.0    197.0
lapsed           58    106.0     3.0    153.0
loyal    thank them: loyalty stamp card, first look at new services
regular  nudge up: bundle ironing or bed cover with the usual wash
new      welcome: second-order voucher within two weeks
lapsed   win back: personal message and a 'we miss you' discount
```

Figure 16.3 shows the same four segments on the two most telling axes, recency and spend. The *loyal* customers (67) came within the last week or two, have ordered about 20 times and spent around a million rupiah each; they deserve thanks, not discounts. The *regular* customers (89) come every month or so; the opportunity is to add a service to their usual wash. The *new* customers (39) came recently but only a few times; many of them joined in the last three months (their median first order was 92 days before the end of the data), and a second-order voucher is how they become regulars. The *lapsed* customers (58) have not come for over three months; a personal message is cheap compared with finding a new customer.

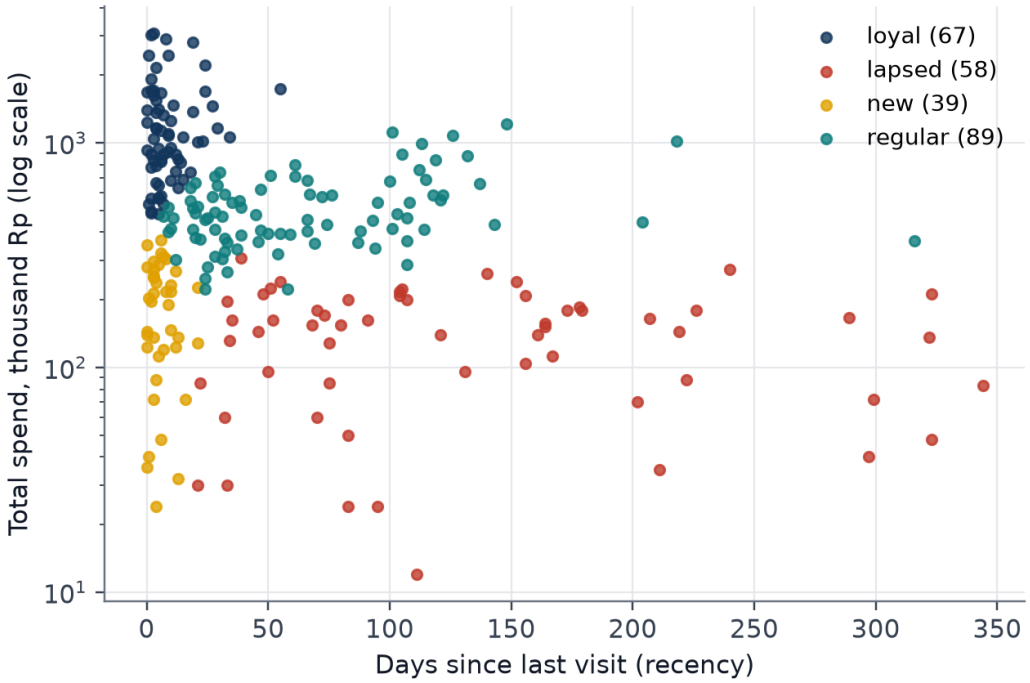

Figure 16.3 The 253 customers by days since their last visit and total spend (log scale), colored by segment, with the size of each segment in the legend.

Looking up one customer:

```
python segment_app.py --customer C0047
```

```
C0047: last visit 101 days ago, 21 orders, Rp 1,111 thousand
segment: regular  ->  nudge up: bundle ironing or bed cover with the usual wash
```

Customer C0047 is interesting. With 21 orders and over a million rupiah, they look like a loyal customer, but they have not come for 101 days, which moved them into *regular*. A good segment app shows the numbers behind the name so that staff notice such cases; a customer drifting out of the loyal group is exactly who deserves a phone call. Chapter 19 builds a model that predicts this drift before it happens. A segment name is a summary, not a verdict. Two customers in the same segment can differ considerably, and a customer near the border of two segments can move with

a single visit. That is why the app always prints the raw numbers beside the segment name, and why staff should read both before sending a customer a message. Each run takes about a second.

16.6 Improving It

Listing 16.5 checks the two decisions that make or break a segmentation: the feature preparation, and the stability of the result.

Listing 16.5 `improve.py`: clustering in raw units, and the stability of k-means with one start versus ten.

```
# improve.py - two things that decide whether segments mean anything
import numpy as np
from sklearn.cluster import KMeans
from sklearn.metrics import adjusted_rand_score
from rfm import features, load_bills, rfm

table = rfm(load_bills())
raw = table[["recency", "frequency", "monetary"]].to_numpy(float)
km = KMeans(n_clusters=4, n_init=10, random_state=0).fit(raw)
print("raw units, no log, no scaling:")
print(table.assign(seg=km.labels_).groupby("seg").median().round(0).assign(
    customers=np.bincount(km.labels_)).to_string())

X = features(table)
for n_init in (1, 10):
    runs = [KMeans(n_clusters=4, n_init=n_init, init="random", random_state=s)
             .fit(X).labels_ for s in range(10)]
    ari = [adjusted_rand_score(runs[0], r) for r in runs[1:]]
    print(f"n_init={n_init:2d}: agreement with seed 0, min {min(ari):.3f}, "
          f"mean {np.mean(ari):.3f}")
```

```
raw units, no log, no scaling:
     recency  frequency  monetary  customers
seg
0       24.0       12.0     588.0         79
1        6.0       50.0    2625.0          8
2        9.0       26.0    1241.0         34
3       46.0        4.0     202.0        132
n_init= 1: agreement with seed 0, min 0.304, mean 0.883
n_init=10: agreement with seed 0, min 0.990, mean 0.995
```

The first table clusters the raw numbers, without logarithms or z-scores. The clusters become spend tiers: 8 customers who spent 2.6 million, 34 around 1.2 million, 79 around 590 thousand, and 132 around 200 thousand. Recency hardly matters any more, because its values (tens of days) are tiny next to spend (hundreds or thousands). The largest cluster lumps together a customer who came yesterday for the first time and one who has not come for ten months; no single action fits both. With Equation (16.6) each feature has an equal say, and the lapsed and new customers separate cleanly.

The second part measures stability with the *adjusted Rand index* (ARI), which compares two clusterings of the same customers: 1 means identical groupings (whatever the cluster numbers), 0 means no more agreement than chance [7]. With purely random starts and a single run (`init="random"`, `n_init=1`), the result depends on the seed: the worst of nine runs agrees with the first only 0.304. With ten restarts, every run agrees at 0.990 or better. Restarts are cheap; always use several.

Other improvements are worth knowing about. A segmentation should be *profiled* after it is found: Exercise 16.5 checks which services and outlets each segment uses. Features beyond RFM,

such as the share of express orders or the preferred outlet, can reveal different kinds of customers rather than different levels of activity. Segments also go stale: rerun the clustering monthly and watch customers move between segments, because the movements (a loyal customer becoming regular) are often the most useful signal of all. When clusters are not round blobs, other methods fit better: DBSCAN finds dense regions of any shape, and Gaussian mixtures allow clusters of different sizes and shapes [3].

The tests of **Listing 16.6** check the distance table, the recovery of two obvious groups, and the promise that inertia never increases.

Listing 16.6 `test_kmeans.py`: tests for the distances, a clear two-group case, and monotone inertia.

```
# test_kmeans.py - run with:  python -m pytest -q
import numpy as np
from kmeans import kmeans, lloyd, sq_dist

def test_squared_distance_table():
    X = np.array([[0.0, 0.0], [3.0, 4.0]])
    C = np.array([[0.0, 0.0]])
    assert sq_dist(X, C).ravel().tolist() == [0.0, 25.0]

def test_finds_two_obvious_groups():
    X = np.array([[0, 0], [0, 1], [1, 0], [10, 10], [10, 11], [11, 10]], float)
    labels, C, _ = kmeans(X, k=2, n_init=3)
    assert len(set(labels[:3])) == 1 and len(set(labels[3:])) == 1
    assert labels[0] != labels[3]

def test_inertia_never_increases():
    rng = np.random.default_rng(1)
    X = rng.normal(size=(60, 2))
    _, _, hist = lloyd(X, X[:3].copy())
    assert all(b <= a + 1e-9 for a, b in zip(hist, hist[1:]))
```

```
...                                                                  [100%]
3 passed in 0.67s
```

16.7 Common Mistakes, and How to Avoid Them

Clustering unscaled features. The feature with the largest numbers decides every distance, as the raw-unit table showed. Transform skewed features and standardize.

Reading cluster numbers as meaningful. “Cluster 3” in one run may be “cluster 0” in the next. Name clusters by their properties, as `name_segments` does.

Choosing k by inertia alone. Inertia always improves with more clusters. Use the elbow, the silhouette, and above all the question “can we act differently on each group?”.

Trusting a single run. k-means finds a local minimum that depends on the start. Use k-means++ and several restarts, and check stability.

Forgetting that k-means assumes round, similar-sized groups. Long, thin or nested clusters are cut badly. Look at the data, and try another method when the shapes are unusual.

Collecting personal data the analysis does not need. Segmentation needs behavior, not identities: an id, dates and amounts suffice. Leave names, phone numbers and addresses out of

the analysis, in the spirit of the data minimization that Indonesia's personal data protection law requires [8].

16.8 Chapter Summary

- Unsupervised learning finds structure without labels; k-means groups points so that the total squared distance to the group centers (Equation (16.1), Equation (16.2)) is small.
- k-means alternates the assignment step (Equation (16.3)) and the update step (Equation (16.4)); each lowers or keeps the inertia, so the algorithm always stops, at a local minimum.
- k-means++ (Equation (16.5)) spreads the starting centers; several restarts make the result stable.
- Skewed features need logarithms and all features need a common scale (Equation (16.6)); otherwise one feature dictates the clusters.
- The elbow of inertia and the silhouette score (Equation (16.7)) help choose k; for the laundry's 253 customers both pointed to four segments.
- Clusters become useful when they are named by their properties, profiled, and tied to actions: loyal, regular, new and lapsed customers each get a different treatment.

16.9 Exercises

1. Run k-means by hand on the points 1,2,3,10,11,12,20 with $k = 2$, starting from $\mu_1 = 10$ and $\mu_2 = 20$. Do you reach the same clustering as the example in Section 16.3.3? Compare the inertias.
2. A customer placed 1 order, another 4, another 16 and another 64. Compute $\ln(1 + x)$ for each. Why does the logarithm make "1 against 4" as important as "16 against 64"?
3. For the example points of Section 16.3.3 in the clustering the example ended with, {1,2,3} and {10,11,12,20}, compute the silhouette $s(i)$ of the point 3 and of the point 20.
4. Look up customers C0002 and C0111 with the app. Explain from their numbers why both are *loyal*, and what distinguishes them.
5. Profile the four segments: for each, compute the share of its bills that are regular wash (S0001), express (S0002) and dry cleaning (S0004 to S0007), and the share of its bills at each outlet. What do you learn?
6. With purely random starting centers, k-means can end with an *empty cluster*. Explain how, what `lloyd` does in that case, and why k-means++ makes it unlikely.

16.10 Solutions to the Exercises

Exercise 16.1. Assign: 1, 2, 3, 10, 11, 12 are closer to 10 (12 is 2 from 10 and 8 from 20); 20 goes to μ_2. Update: $\mu_1 = 39/6 = 6.5$, $\mu_2 = 20$. Assign: 1, 2, 3, 10, 11, 12 still closer to 6.5 (12 is 5.5 from 6.5 and 8 from 20); nothing changes. Final clustering {1,2,3,10,11,12}, {20}, with inertia $(5.5^2 + 4.5^2 + 3.5^2 + 3.5^2 + 4.5^2 + 5.5^2) + 0 = 30.25 + 20.25 + 12.25 + 12.25 + 20.25 + 30.25 = 125.5$. This is a different, worse local minimum than 64.75: the start matters, which is why we restart and keep the lowest inertia.

Exercise 16.2. $\ln 2 = 0.69$, $\ln 5 = 1.61$, $\ln 17 = 2.83$, $\ln 65 = 4.17$. The gaps are 0.92 between 1 and 4 orders and 1.34 between 16 and 64. On the raw scale the gaps are 3 and 48. The logarithm measures *ratios*: four times as many orders is roughly the same step wherever it happens, which

matches how a business thinks (a customer going from 1 to 4 orders has changed as much as one going from 16 to 64).

Exercise 16.3. Point 3: $a = (2 + 1)/2 = 1.5$ (distances to 1 and 2); $b = (7 + 8 + 9 + 17)/4 = 10.25$; $s = (10.25 - 1.5)/10.25 = 0.854$. Point 20: $a = (10 + 9 + 8)/3 = 9$ (distances to 10, 11, 12); $b = (19 + 18 + 17)/3 = 18$; $s = (18 - 9)/18 = 0.5$. Point 20 is an outlier in its own cluster, so its silhouette is lower.

Exercise 16.4.

```
python segment_app.py --customer C0002
```

```
C0002: last visit 34 days ago, 21 orders, Rp 1,060 thousand
segment: loyal  ->  thank them: loyalty stamp card, first look at new services
```

```
python segment_app.py --customer C0111
```

```
C0111: last visit 24 days ago, 46 orders, Rp 2,217 thousand
segment: loyal  ->  thank them: loyalty stamp card, first look at new services
```

Both came within the last five weeks and have far more orders and spend than the median (8 orders, 407 thousand), so both sit with the loyal customers. C0111 is exceptional even there: 46 orders and 2.2 million rupiah, among the very top. The segment does not distinguish them, but the numbers do; a business might reserve special treatment for the top few percent.

Exercise 16.5. **Listing 16.7** joins each bill to its customer's segment and cross-tabulates.

Listing 16.7 `solutions/ex_profile.py`: service mix and outlet mix of each segment.

```
# ex_profile.py - Exercise 16.5: what do the segments actually buy?
import sys
from pathlib import Path
import pandas as pd
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from kmeans import kmeans
from rfm import features, load_bills, rfm
from segment_app import name_segments

bills = load_bills()
table = rfm(bills)
labels, _, _ = kmeans(features(table), k=4)
table["segment"] = labels
names = table["segment"].map(name_segments(table)).rename("name")
b = bills.join(names, on="Customer_id")
kind = pd.Series("other", index=b.index, name="service")
kind[b["Service_id"] == "S0001"] = "regular wash"
kind[b["Service_id"] == "S0002"] = "express"
kind[b["Service_id"].isin(["S0004", "S0005", "S0006", "S0007"])] = "dry clean"
share = pd.crosstab(b["name"], kind, normalize="index").round(2)
print(share.to_string())
print("outlet share:")
outlets = pd.crosstab(b["name"], b["Outlet_id"], normalize="index")
print(outlets.round(2).to_string())
```

```
service  dry clean  express  other  regular wash
name
lapsed        0.10     0.15   0.29          0.46
loyal         0.14     0.14   0.27          0.44
new           0.13     0.09   0.29          0.49
regular       0.11     0.14   0.26          0.49
outlet share:
Outlet_id   O01   O02   O03
name
lapsed     0.38  0.39  0.23
loyal      0.48  0.29  0.23
new        0.48  0.20  0.33
regular    0.39  0.43  0.18
```

The service mix is almost the same in every segment (about 45 percent regular wash, 14 percent express, 11 percent dry cleaning): the segments differ in *how often and how recently* customers come, not in *what* they buy. The outlet mix is more revealing: *new* customers are over-represented at O03, the Wiyung outlet that opened in January 2026 (33 percent of their bills against 18 to 23 percent for the other segments), and *regular* customers are strongest at O02 in Keputih. A welcome campaign for new customers should therefore start in Wiyung.

Exercise 16.6. If a starting center lies far from all points, or two centers start almost on top of each other, the assignment step may give one of them no members at all. The mean of an empty set is undefined; `lloyd` then leaves that center where it was, and it may stay empty for good, wasting one of the k clusters. (scikit-learn instead moves an empty cluster's center onto the point that fits its current cluster worst, the one farthest from its own center.) k-means++ chooses every starting center *at a data point*, and prefers points far from the centers already chosen, so each starting center begins with at least itself as a member and centers rarely start on top of each other.

Chapter 17

Data Explorer with Principal Component Analysis

A table with three columns can be drawn. A table with thirteen, thirty or sixty-four columns cannot, and yet the first thing anyone should do with a new data set is look at it. This chapter builds a data explorer on *principal component analysis* (PCA), the classic way to find the few directions in which a data set varies most, and to draw a many-column table as a picture that keeps as much of its structure as possible. PCA is also a workhorse inside other methods: it compresses images, removes noise, and speeds up models such as k-NN. By the end of the chapter you will be able to center and standardize data and say why; compute a covariance matrix and read it; explain why the directions of greatest variance are the eigenvectors of that matrix; compute PCA twice, from the eigenvectors and from the singular value decomposition, and check that the answers agree; decide how many components to keep from the explained variance; read loadings to name a component; reconstruct data from a few components and measure what was lost; and run a command-line explorer on any of scikit-learn's bundled data sets.

17.1 Why a Data Explorer?

Chemists in Italy once measured 178 wines from three grape cultivars grown in the same region, recording thirteen quantities for each: alcohol, malic acid, ash, magnesium, several kinds of phenols, color intensity, hue, proline and more [1]. The data ship with scikit-learn as `load_wine`. Suppose a wine shop in Surabaya, or a quality-control engineer anywhere, receives such a table. Which measurements matter? Do the three cultivars really differ, and in what way? Are some wines unusual? With thirteen columns there are 78 pairs of columns to plot; nobody can hold them all in their head.

PCA answers with two pictures. The first says how much of the total variation the data can be squeezed into one, two, three directions; for the wines, two directions carry 55 percent of it and five directions 80 percent. The second draws every wine in the two most important directions, and the three cultivars appear as three clouds that barely overlap. We did not tell PCA about the cultivars; it found directions in which the wines differ most, and the cultivars happen to be what makes them differ.

The same tool reappears throughout the book. In Chapter 13, k-NN paid for every feature on every question; PCA can cut the features first. In Chapter 18 we recognize handwritten digits from 64 pixels; PCA shows that most of those pixels are redundant. And the "embeddings" of Parts 4, 6 and 9 are, in spirit, learned versions of the same idea: a few numbers that capture what matters about a thing.

The explorer is one command:

```
python explorer.py --dataset wine --components 3
```

17.2 The Idea in Plain Words

Imagine a swarm of mosquitoes over a rice field at dusk, and you may take only one photograph, from one direction. From directly above, the swarm looks like a round blob. From the side, it may look like a long, thin cloud stretched along the field. The side photograph shows more of the swarm's shape: along its long axis the mosquitoes are spread out, and the photograph keeps that spread. PCA chooses the camera angle for you: it finds the direction along which the points are most spread out, the *first principal component*. Then, among all directions at right angles to the first, it finds the one with the most remaining spread, the *second principal component*, and so on.

Figure 17.1 shows a small cloud of points in two dimensions. The points lie roughly along a tilted line. The first component (the long arrow) points along that line; the second (the short arrow) points across it. Describing each point by its position along the first arrow alone loses little: the spread across the line is small.

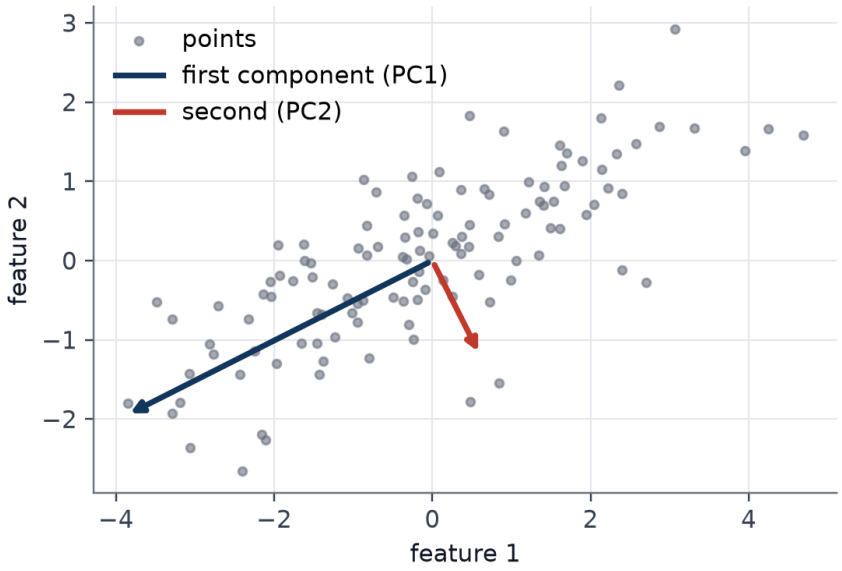

Figure 17.1 A cloud of 120 points and its two principal components. The first points along the direction of greatest spread; the second is at right angles to it. Arrow lengths are proportional to the spread along each direction.

Three things make the picture work in practice. First, we measure spread from the middle of the data, so we *center* every column by subtracting its mean. Second, columns in different units must be put on the same scale, or the column with the biggest numbers wins every time (the same lesson as in Chapters 13 and 16); we *standardize*. Third, the new directions are mixtures of the original columns, and the *loadings* (how much of each original column goes into a component) tell us what a component means: "mostly phenols and flavanoids", "mostly color and alcohol".

> **KEY INSIGHT:** PCA rotates the data so that the first new axis carries as much variance as possible, the second as much of the rest as possible, and so on. Keeping the first few axes keeps most of the information in far fewer numbers.

17.3 The Mathematics, Gently

17.3.1 Centering and the covariance matrix

The data form a table X with n rows (wines) and d columns (measurements). Write $\bar{\mathbf{x}}$ for the row of column means. The *centered* table subtracts it from every row:

$$X_c = X - \mathbf{1}\bar{\mathbf{x}} \tag{17.1}$$

where $\mathbf{1}$ is a column of ones, so that $\mathbf{1}\bar{\mathbf{x}}$ repeats the mean row n times. Every column of X_c has mean zero. The *covariance matrix* collects how each pair of columns varies together:

$$C = \frac{1}{n-1} X_c^\top X_c \tag{17.2}$$

It is a $d \times d$ table. Its diagonal entry C_{jj} is the variance of column j (the average squared distance from the mean, with $n-1$ in the denominator as is usual for samples); its off-diagonal entry C_{jk} is the covariance of columns j and k, positive when they tend to be large together, negative when one tends to be large while the other is small. C is symmetric, since $C_{jk} = C_{kj}$. If the columns were standardized first, C is the *correlation matrix*: its diagonal is all ones.

17.3.2 The variance along a direction

A direction in d dimensions is a vector $\mathbf{w}$ of length 1 ($\mathbf{w}^\top\mathbf{w} = 1$). The position of row i along that direction, its *score*, is the dot product $z_i = \mathbf{x}_{c,i} \cdot \mathbf{w}$. The variance of the scores works out to

$$\mathrm{Var}(z) = \frac{1}{n-1}\sum_{i=1}^{n} z_i^2 = \mathbf{w}^\top C\mathbf{w} \tag{17.3}$$

because $\sum_i z_i^2 = \| X_c\mathbf{w} \|^2 = \mathbf{w}^\top X_c^\top X_c\mathbf{w}$. So the covariance matrix answers the question "how spread out is the data along any direction I choose?" in one formula.

17.3.3 The best direction is an eigenvector

We want the unit vector $\mathbf{w}$ that makes Equation (17.3) as large as possible. The method of Lagrange multipliers (maximize $\mathbf{w}^\top C\mathbf{w} - \lambda(\mathbf{w}^\top\mathbf{w} - 1)$, and set the derivative with respect to $\mathbf{w}$ to zero) gives the condition

$$C\mathbf{w} = \lambda\mathbf{w} \tag{17.4}$$

A vector that C only stretches, without turning, is an *eigenvector* of C, and the stretch factor λ (lambda) is its *eigenvalue*. Multiplying Equation (17.4) on the left by $\mathbf{w}^\top$ gives $\mathbf{w}^\top C\mathbf{w} = \lambda$: the variance along an eigenvector is its eigenvalue. So the direction of greatest variance is the eigenvector with the largest eigenvalue. A symmetric $d \times d$ matrix has d eigenvectors that are all at right angles to each other, with real, non-negative eigenvalues for a covariance matrix. Sorted by eigenvalue, they are the principal components, and the eigenvalues are the variances along them [2], [3]. Strang's textbook is a gentle place to learn more about eigenvectors and the SVD [4].

EXAMPLE. Four centered points: $(-2,-1)$, $(-1,-1)$, $(1,1)$, $(2,1)$.

Covariance: $C_{11} = (4+1+1+4)/3 = 10/3 = 3.333$; $C_{22} = (1+1+1+1)/3 = 1.333$; $C_{12} = (2+1+1+2)/3 = 2$.

Eigenvalues solve $(3.333-\lambda)(1.333-\lambda) - 2^2 = 0$, that is $\lambda^2 - 4.667\lambda + 0.444 = 0$, so $\lambda = \left(4.667 \pm \sqrt{21.78 - 1.78}\right)/2 = (4.667 \pm 4.472)/2$: $\lambda_1 = 4.570$ and $\lambda_2 = 0.097$.

First eigenvector: from $(3.333 - 4.570)w_1 + 2w_2 = 0$ we get $w_2 = 0.618w_1$; normalized, $\mathbf{w}_1 = (0.850, 0.526)$. Check: $C\mathbf{w}_1 = (3.333 \times 0.850 + 2 \times 0.526,\ 2 \times 0.850 + 1.333 \times 0.526) = (3.885, 2.401) \approx 4.570 \times (0.850, 0.526)$.

Share of variance on PC1: $4.570/(4.570 + 0.097) = 97.9\%$. Scores along PC1: $-2.226, -1.376, 1.376, 2.226$, whose variance $(4.955 + 1.893 + 1.893 + 4.955)/3 = 4.565$ is λ_1 up to rounding.

17.3.4 How much to keep: explained variance

The total variance of the data is the sum of the variances of the columns, the trace of C, which also equals the sum of all eigenvalues. The share carried by component j is its *explained variance ratio*:

$$r_j = \frac{\lambda_j}{\lambda_1 + \lambda_2 + \cdots + \lambda_d} \tag{17.5}$$

A *scree plot* draws the r_j in order; its name comes from the loose rocks at the foot of a cliff, which is what the small late components look like. We keep the first k components, where k is chosen so that the cumulative share $r_1 + \cdots + r_k$ reaches a target such as 80 or 90 percent, or where the scree plot flattens.

17.3.5 Projecting and reconstructing

Collect the first k components as the rows of a $k \times d$ matrix W. The *scores* of all rows are

$$Z = X_c W^\top \tag{17.6}$$

an $n \times k$ table: each row now described by k numbers instead of d. Going back, the best approximation of the original rows that these scores allow is

$$\hat{X} = ZW + \mathbf{1}\bar{\mathbf{x}} \tag{17.7}$$

With $k = d$ the reconstruction is exact. With fewer components, what is lost is exactly the variance along the dropped directions:

$$\frac{1}{n-1} \| X - \hat{X} \|^2 = \lambda_{k+1} + \lambda_{k+2} + \cdots + \lambda_d \tag{17.8}$$

(Exercise 17.5 derives it.) This is why PCA is optimal in a precise sense: among all ways of describing the data with k numbers per row by a linear projection, it loses the least squared error. Pearson found this “line of closest fit” in 1901 [5].

17.3.6 The same thing by SVD

Every matrix can be written as a product of three simpler ones, its *singular value decomposition* (SVD):

$$X_c = U \Sigma V^\top \tag{17.9}$$

where the columns of U $(n \times d)$ and of V $(d \times d)$ are unit vectors at right angles, and Σ is diagonal with non-negative *singular values* $\sigma_1 \geq \sigma_2 \geq \cdots$. Substituting into Equation (17.2) gives $C = V \frac{\Sigma^2}{n-1} V^\top$, so the columns of V are the principal components and $\lambda_j = \sigma_j^2/(n-1)$. Numerical libraries, scikit-learn’s `PCA` among them, prefer the SVD because it never forms $X_c^\top X_c$, which can lose precision when columns are nearly dependent [6]. Either route gives the same directions, up to a sign: if $\mathbf{w}$ is an eigenvector, so is $-\mathbf{w}$, and different routines may return either.

17.4 Building It Step by Step

17.4.1 PCA from scratch

The folder `Chapter017` needs one library more than the earlier chapters, matplotlib, for the explorer's optional plot; its `requirements.txt` is:

```
numpy==2.4.6
pandas==3.0.6
scikit-learn==1.9.1
matplotlib==3.11.2
pytest==9.1.1
```

Listing 17.1 implements Sections 17.3.1 to 17.3.6 in a small class with the same `fit`, `transform` and `inverse_transform` methods that scikit-learn uses.

Listing 17.1 `pca.py`: PCA from scratch with an eigendecomposition of the covariance matrix, checked against the SVD, on the wine data.

```
# pca.py - principal component analysis from scratch (eigenvectors and SVD)
import numpy as np
from sklearn.datasets import load_wine

class PCA:
    def __init__(self, k):
        self.k = k

    def fit(self, X):
        self.mean = X.mean(axis=0)
        Xc = X - self.mean                              # center every column
        cov = Xc.T @ Xc / (len(X) - 1)                  # d x d covariance
        vals, vecs = np.linalg.eigh(cov)                # ascending order
        order = np.argsort(vals)[::-1]
        self.eigenvalues = vals[order]
        self.components = vecs[:, order].T[: self.k]    # k x d, one per row
        self.ratio = self.eigenvalues / self.eigenvalues.sum()
        return self

    def transform(self, X):
        return (X - self.mean) @ self.components.T      # n x k scores

    def inverse_transform(self, Z):
        return Z @ self.components + self.mean

def standardize(X):
    return (X - X.mean(axis=0)) / X.std(axis=0)

if __name__ == "__main__":
    wine = load_wine()
    X = standardize(wine.data)
    p = PCA(k=2).fit(X)
    print(f"{X.shape[0]} wines, {X.shape[1]} measurements")
    print("eigenvalues:", np.round(p.eigenvalues, 2))
    cum = np.cumsum(p.ratio)
    for i in range(5):
        print(f"PC{i + 1}: {p.ratio[i]:6.1%} of the variance, "
              f"cumulative {cum[i]:6.1%}")
    # the same directions from the singular value decomposition
    U, S, Vt = np.linalg.svd(X - X.mean(axis=0), full_matrices=False)
    same = np.allclose(np.abs(Vt[:2]), np.abs(p.components))
    print("SVD gives the same two directions (up to sign):", same)
    Z = p.transform(X)
```

Listing 17.1 (Continued) *pca.py: PCA from scratch with an eigendecomposition of the covariance matrix, checked against the SVD, on the wine data.*

```
    for c, name in enumerate(wine.target_names):
        m = Z[wine.target == c].mean(axis=0)
        print(f"  {name}: mean score PC1 {m[0]:+.2f}, PC2 {m[1]:+.2f}")
```

`fit` centers the data (Equation (17.1)), forms the covariance matrix (Equation (17.2)), and calls `np.linalg.eigh`, NumPy's routine for symmetric matrices, which returns eigenvalues in *ascending* order; `argsort(...)[::-1]` reverses them so that the largest comes first. The components are stored as rows, and `ratio` is Equation (17.5). `transform` is Equation (17.6) and `inverse_transform` is Equation (17.7). The main block standardizes the thirteen wine measurements, prints the eigenvalues and the explained variance of the first five components, checks the directions against the SVD of Equation (17.9), and prints the average position of each cultivar on the first two components.

```
178 wines, 13 measurements
eigenvalues: [4.73 2.51 1.45 0.92 0.86 0.65 0.55 0.35 0.29 0.25 0.23 0.17 0.1 ]
PC1:  36.2% of the variance, cumulative  36.2%
PC2:  19.2% of the variance, cumulative  55.4%
PC3:  11.1% of the variance, cumulative  66.5%
PC4:   7.1% of the variance, cumulative  73.6%
PC5:   6.6% of the variance, cumulative  80.2%
SVD gives the same two directions (up to sign): True
  class_0: mean score PC1 -2.28, PC2 -0.97
  class_1: mean score PC1 +0.04, PC2 +1.64
  class_2: mean score PC1 +2.75, PC2 -1.24
```

The eigenvalues fall quickly from 4.73 to 2.51 to 1.45 and then level off below 1. Since each standardized column has variance 1, an eigenvalue below 1 means the component carries less variance than a single original column; a common rule of thumb (Kaiser's) keeps only components with eigenvalues above 1, which here would be three. Two components keep 55.4 percent of the variance and five keep 80.2 percent. The SVD agrees. And the three cultivars sit at clearly different places: cultivar 0 at −2.28 on PC1, cultivar 2 at +2.75, cultivar 1 near 0 on PC1 but high on PC2. **Figure 17.2** is the scree plot.

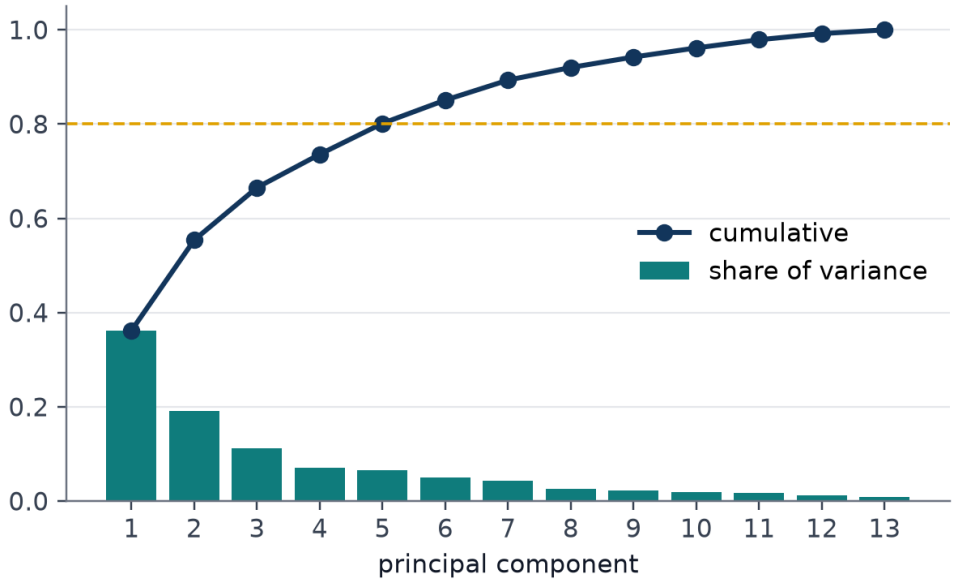

Figure 17.2 Scree plot of the standardized wine data: the share of variance of each of the 13 components (bars) and the cumulative share (line). The dashed line marks 80 percent, reached with five components.

Figure 17.3 is the picture PCA was invented for: all 178 wines on the first two components, colored by cultivar. The three cultivars form three clouds with only a little overlap. We could now train a classifier on two numbers instead of thirteen, or spot a mislabeled bottle as a point sitting in the wrong cloud.

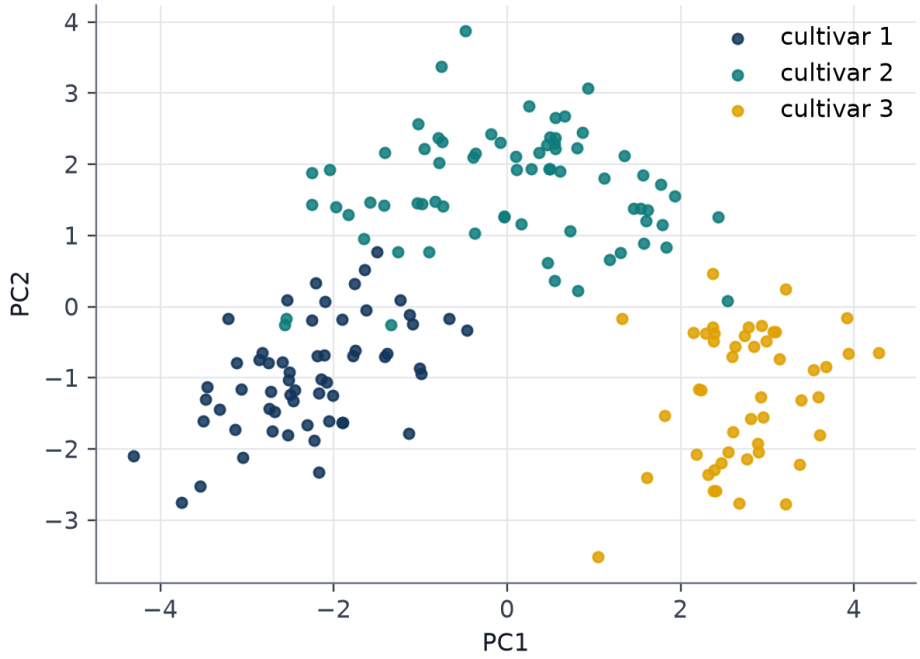

Figure 17.3 The 178 wines on their first two principal components, colored by grape cultivar. PCA never saw the cultivar labels.

17.4.2 Reading the components

What do PC1 and PC2 mean? The loadings, the entries of each component vector, say how much each standardized measurement contributes. **Figure 17.4** draws them. PC1 is dominated by flavanoids, total phenols and the OD280/OD315 ratio (a measure of protein content), all with the same sign: PC1 is essentially a "phenolic richness" axis, and cultivar 0 sits at the rich end (remember that the sign of a component is arbitrary; here "rich" happens to be negative). PC2 is dominated by color intensity, alcohol and proline: an axis of "intensity", on which cultivar 1 stands apart from the other two.

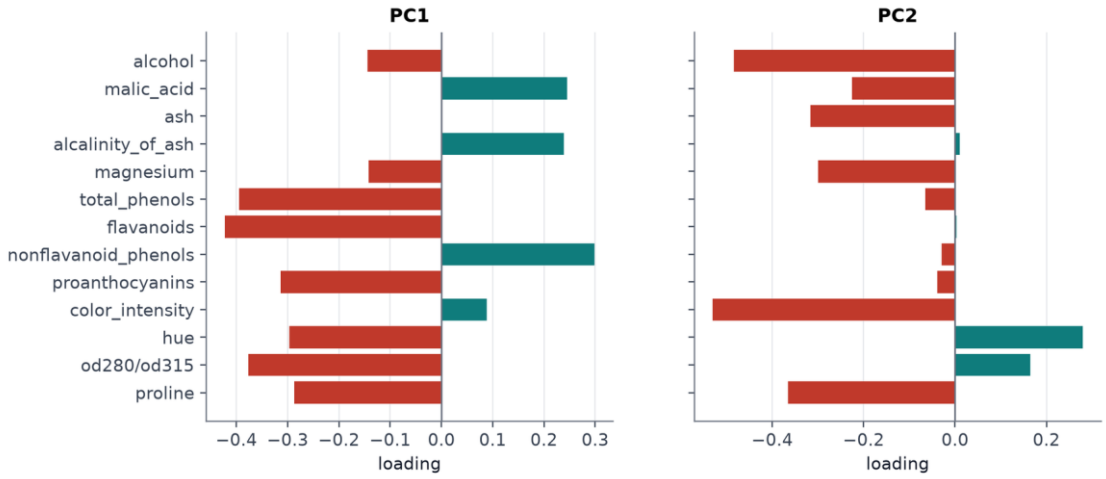

Figure 17.4 Loadings of the thirteen standardized wine measurements on the first two principal components. Bars of the same color pull a wine's score in the same direction.

17.4.3 The explorer app

Listing 17.2 wraps the class in a command-line app that works on any of four bundled data sets. For each requested component it prints the explained variance, the cumulative share, and the three measurements with the largest loadings (in absolute value); then it says how many components are needed for 80, 90 and 95 percent of the variance; and, if asked, it saves a scatter plot of the first two components. Columns that never change (some pixel positions in the digits data are always blank) are dropped first, since standardizing them would divide by zero.

Listing 17.2 `explorer.py`: the PCA data explorer for the wine, iris, breast cancer and digits data sets.

```
# explorer.py - explore any bundled data set with PCA: variance, loadings, a map
import argparse
import numpy as np
from sklearn import datasets
from pca import PCA, standardize

LOADERS = {"wine": datasets.load_wine, "iris": datasets.load_iris,
           "breast_cancer": datasets.load_breast_cancer,
           "digits": datasets.load_digits}

def main():
    ap = argparse.ArgumentParser(description="PCA data explorer")
    ap.add_argument("--dataset", choices=list(LOADERS), default="wine")
    ap.add_argument("--components", type=int, default=2)
    ap.add_argument("--plot", help="save a scatter plot of PC1 and PC2 here")
    a = ap.parse_args()
    data = LOADERS[a.dataset]()
    X = data.data.astype(float)
    std = X.std(axis=0)
    X = standardize(X[:, std > 0])                    # drop constant columns
    names = np.asarray(data.feature_names)[std > 0]
    p = PCA(a.components).fit(X)
    cum = np.cumsum(p.ratio)
    print(f"{a.dataset}: {X.shape[0]} rows, {X.shape[1]} features")
    for i in range(a.components):
        top = np.argsort(np.abs(p.components[i]))[::-1][:3]
        load = ", ".join(f"{names[j]} {p.components[i, j]:+.2f}" for j in top)
        print(f"PC{i + 1} {p.ratio[i]:6.1%} (cum. {cum[i]:6.1%})  {load}")
    for goal in (0.8, 0.9, 0.95):
        print(f"components for {goal:.0%} of the variance: "
              f"{np.searchsorted(cum, goal) + 1}")
    if a.plot:
        import matplotlib
        matplotlib.use("Agg")
        import matplotlib.pyplot as plt
        Z = PCA(2).fit(X).transform(X)
        fig, ax = plt.subplots(figsize=(6, 4.5))
        sc = ax.scatter(Z[:, 0], Z[:, 1], c=data.target, s=12, cmap="viridis")
        ax.set_xlabel("PC1"); ax.set_ylabel("PC2")
        fig.colorbar(sc, label="class")
        fig.savefig(a.plot, dpi=150, bbox_inches="tight")
        print("saved", a.plot)
```

Listing 17.2 (Continued) *explorer.py: the PCA data explorer for the wine, iris, breast cancer and digits data sets.*

```
if __name__ == "__main__":
    main()
```

17.5 Running It

The wines, three components:

```
python explorer.py --dataset wine --components 3
```

```
wine: 178 rows, 13 features
PC1  36.2% (cum.  36.2%)  flavanoids -0.42, total_phenols -0.39,
od280/od315_of_diluted_wines -0.38
PC2  19.2% (cum.  55.4%)  color_intensity -0.53, alcohol -0.48, proline -0.36
PC3  11.1% (cum.  66.5%)  ash +0.63, alcalinity_of_ash +0.61, alcohol -0.21
components for 80% of the variance: 5
components for 90% of the variance: 8
components for 95% of the variance: 10
```

The first two components are the phenolic and intensity axes of **Figure 17.4**; the third is about ash and its alkalinity, a mineral axis. Eight components are needed for 90 percent of the variance: the wines are not secretly two-dimensional, but two dimensions show their main structure.

The breast cancer data set has 569 tumor biopsies described by 30 measurements of cell nuclei [7]:

```
python explorer.py --dataset breast_cancer --components 2 --plot outputs/cancer_pca.png
```

```
breast_cancer: 569 rows, 30 features
PC1  44.3% (cum.  44.3%)  mean concave points -0.26, mean concavity -0.26, worst concave
points -0.25
PC2  19.0% (cum.  63.2%)  mean fractal dimension +0.37, fractal dimension error +0.28,
worst fractal dimension +0.28
components for 80% of the variance: 5
components for 90% of the variance: 7
components for 95% of the variance: 10
saved outputs/cancer_pca.png
```

Here one component carries 44 percent of the variance, and its loadings (concave points, concavity) are all about the irregularity of the cell nuclei, which is exactly what pathologists look for. The 30 columns are highly redundant: ten components keep 95 percent. The saved plot shows benign and malignant tumors separating along PC1; Chapter 20 builds and evaluates classifiers on this data set.

And the handwritten digits, 1,797 images of 8 × 8 pixels:

```
python explorer.py --dataset digits --components 3
```

```
digits: 1797 rows, 61 features
PC1  12.0% (cum.  12.0%)  pixel_0_2 -0.29, pixel_7_2 -0.28, pixel_1_1 -0.25
PC2   9.6% (cum.  21.6%)  pixel_0_5 +0.27, pixel_1_6 +0.27, pixel_6_6 -0.26
PC3   8.4% (cum.  30.0%)  pixel_5_3 -0.32, pixel_4_3 -0.28, pixel_5_4 -0.27
components for 80% of the variance: 21
components for 90% of the variance: 31
components for 95% of the variance: 40
```

Three of the 64 pixel columns are always blank and are dropped. After standardization, the variance is spread thinly: the first component carries only 12 percent, and 31 components are needed for 90 percent. Pixels are not like wine measurements, as the next section shows. Each run of the explorer takes one to two seconds.

17.6 Improving It

17.6.1 PCA for images: compression

For images, standardizing is usually the wrong choice: a pixel at the edge that is almost always blank would be blown up to the same importance as a pixel in the middle of every digit. **Listing 17.3** therefore runs PCA on the raw pixel values (0 to 16) and measures how well each digit can be rebuilt from k components, then uses the compressed version for k-NN.

Listing 17.3 `improve.py`: compressing the digits with PCA, and k-NN on 64 pixels against 20 components.

```
# improve.py - PCA as a tool: compress digits, then speed up k-NN
import time
import numpy as np
from sklearn.datasets import load_digits
from sklearn.decomposition import PCA as SkPCA
from sklearn.model_selection import train_test_split
from sklearn.neighbors import KNeighborsClassifier
from pca import PCA

X, y = load_digits(return_X_y=True)
p = PCA(64).fit(X)
print("digits: 1797 images of 8x8 = 64 pixels")
for k in [2, 5, 10, 20, 30, 64]:
    rec = PCA(k).fit(X)
    err = np.mean((X - rec.inverse_transform(rec.transform(X))) ** 2)
    print(f"k = {k:2d}: variance kept {p.ratio[:k].sum():6.1%}, "
          f"mean squared pixel error {err:6.2f}")

X_tr, X_te, y_tr, y_te = train_test_split(X, y, test_size=0.3,
                                          stratify=y, random_state=0)
for label, k in [("all 64 pixels", None), ("20 components", 20)]:
    A_tr, A_te = X_tr, X_te
    if k:
        sk = SkPCA(n_components=k).fit(X_tr)          # fitted on training only
        A_tr, A_te = sk.transform(X_tr), sk.transform(X_te)
    knn = KNeighborsClassifier(n_neighbors=3, algorithm="brute").fit(A_tr, y_tr)
    t0 = time.perf_counter()
    for _ in range(20):
        acc = knn.score(A_te, y_te)
    ms = (time.perf_counter() - t0) / 20 * 1000
    print(f"3-NN on {label:13s}: accuracy {acc:.3f}, {ms:5.1f} ms per 540 images")
```

```
digits: 1797 images of 8x8 = 64 pixels
k =  2: variance kept  28.5%, mean squared pixel error  13.42
k =  5: variance kept  54.5%, mean squared pixel error   8.54
k = 10: variance kept  73.8%, mean squared pixel error   4.91
k = 20: variance kept  89.4%, mean squared pixel error   1.98
k = 30: variance kept  95.9%, mean squared pixel error   0.77
k = 64: variance kept 100.0%, mean squared pixel error   0.00
3-NN on all 64 pixels: accuracy 0.985,  19.8 ms per 540 images
3-NN on 20 components: accuracy 0.981,  14.5 ms per 540 images
```

On raw pixels the variance is much more concentrated: 20 components keep 89.4 percent (against 31 components for 90 percent after standardizing), and the average squared error per pixel falls from 13.42 with two components to 1.98 with twenty, on a scale where pixels range from 0 to 16. **Figure 17.5** shows what that means: with 2 components every digit is a blur; with 10 the shapes are recognizable; with 20 they are nearly perfect; with all 64 they are exact, as Equation (17.8) requires.

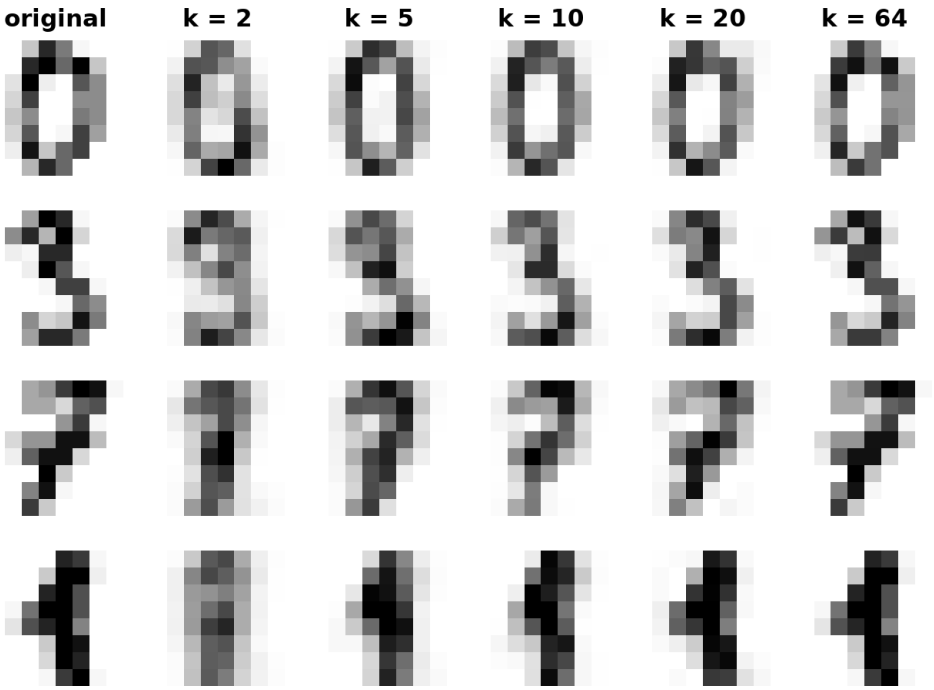

Figure 17.5 Four handwritten digits and their reconstructions from $k = 2,5,10,20$ and 64 principal components of the raw pixel values.

The second part feeds k-NN ($k = 3$) either all 64 pixels or 20 PCA scores. Accuracy barely moves (0.985 against 0.981), and prediction is faster because each distance involves 20 numbers instead of 64. The timings in milliseconds depend on your machine and vary between runs; the ratio is what matters. Note that the PCA is fitted on the training images only and then applied to the test images, for the same reason that scalers are: fitting on everything would let test data shape the features.

17.6.2 Beyond linear PCA

PCA finds flat directions. When the structure in the data is curved (points on a spiral, or faces seen from many angles), linear directions summarize it poorly. Nonlinear methods such as t-SNE and UMAP produce two-dimensional maps that preserve neighborhoods instead of variance, and are popular for exploring data such as the digits [8]. They are for looking, not for measuring: distances between clusters in a t-SNE map mean little. PCA remains the first thing to try, because it is fast, exact, reversible and explainable through its loadings.

The tests of **Listing 17.4** check four properties that any correct PCA must have: orthonormal components, ratios that descend and sum to one, exact reconstruction with all components, and agreement with scikit-learn up to sign.

Listing 17.4 `test_pca.py`: tests for orthonormality, explained variance, reconstruction and agreement with scikit-learn.

```python
# test_pca.py - run with:  python -m pytest -q
import numpy as np
from sklearn.decomposition import PCA as SkPCA
from pca import PCA

rng = np.random.default_rng(17)
X = rng.normal(size=(100, 4)) @ rng.normal(size=(4, 4))

def test_components_are_orthonormal():
    W = PCA(4).fit(X).components
    assert np.allclose(W @ W.T, np.eye(4))

def test_ratios_sum_to_one_and_descend():
    r = PCA(4).fit(X).ratio
    assert np.isclose(r.sum(), 1.0) and np.all(np.diff(r) <= 0)

def test_all_components_reconstruct_exactly():
    p = PCA(4).fit(X)
    assert np.allclose(p.inverse_transform(p.transform(X)), X)

def test_matches_scikit_learn_up_to_sign():
    ours = PCA(2).fit(X).components
    theirs = SkPCA(2).fit(X).components_
    assert np.allclose(np.abs(ours), np.abs(theirs))
```

```

17.6.3 A checklist for exploring a new table

When a new table arrives, whether wine measurements, laundry orders or sensor readings, the explorer of this chapter fits into a short routine that is worth making a habit.

1. **Look at the columns one by one.** Units, ranges, missing values, columns that never change. The explorer drops constant columns, but it cannot tell you that a column is in the wrong unit.
2. **Decide on scaling.** Different units: standardize. Same unit and comparable meaning (pixels, counts of the same thing): usually leave raw. Heavily skewed columns (spend, counts): take logarithms first, as in Chapter 16.
3. **Run PCA and read the scree plot.** A steep drop means a few strong patterns; a flat scree means the columns are mostly independent and PCA will not compress much.
4. **Name the first two or three components from their loadings.** If you cannot name a component, look at the rows with the most extreme scores on it; they often explain it better than the loadings.
5. **Plot the scores and color them by anything you know.** A label, an outlet, a month, a customer segment. Structure that lines up with a known variable is a finding; structure that lines up with nothing known is a question worth asking.
6. **Check the outliers.** Points far from every cloud in the score plot are either data errors or the most interesting rows in the table. Both deserve a look before any model is trained.

None of these steps trains a model, and yet together they usually decide which model is worth training.

17.7 Common Mistakes, and How to Avoid Them

Forgetting to center. PCA without centering finds the direction toward the mean of the data rather than the direction of spread. Our class and scikit-learn both center automatically; hand-written code often forgets.

Standardizing blindly, or never. Measurements in different units need standardizing (Exercise 17.2 shows proline swallowing everything otherwise); pixels in the same unit usually should not be standardized. Decide per data set.

Reading signs as meaningful. $\mathbf{w}$ and $-\mathbf{w}$ are the same component. Compare loadings within a component, not signs across programs.

Fitting PCA on the test data. Fit on training data only, then transform the test data, preferably inside a pipeline.

Treating components as the original features. A component is a mixture. "PC1 predicts well" means "this mixture predicts well"; to explain a model to people, go back to the loadings.

Assuming high variance means importance for prediction. PCA knows nothing about the target. A direction with little variance can be the one that separates the classes; PCA may throw it away.

17.8 Chapter Summary

- PCA centers the data (Equation (17.1)), summarizes it in the covariance matrix (Equation (17.2)), and finds the directions of greatest variance (Equation (17.3)), which are the eigenvectors of that matrix (Equation (17.4)).
- The eigenvalues are the variances along the components; their shares (Equation (17.5)) tell how many components to keep.
- Scores (Equation (17.6)) describe each row with k numbers; reconstruction (Equation (17.7)) loses exactly the dropped eigenvalues (Equation (17.8)).
- The SVD (Equation (17.9)) gives the same components more stably; signs are arbitrary.
- On the wines, two components kept 55 percent of the variance and separated the three cultivars; loadings named them "phenolic richness" and "intensity".
- On digits, 20 components of raw pixels kept 89 percent of the variance, rebuilt the digits almost perfectly, and let k-NN work on a third of the numbers with the same accuracy.

17.9 Exercises

1. For the four points (1,0), (0,1), $(-1,0)$, $(0,-1)$, compute the covariance matrix and its eigenvalues. What is special about the principal components here?
2. Run PCA on the wine data without standardizing. What share of variance does PC1 carry, and which measurement dominates it? Explain.
3. A colleague's program reports the first loading of flavanoids as $+0.42$ while ours reports -0.42. Is one of them wrong?
4. Using the digits output of Section 17.5 and the output of **Listing 17.3**, compare how many components each approach needs for about 90 percent of the variance, and explain the difference.

5. Show Equation (17.8) for $k = d - 1$: the reconstruction error of dropping only the last component equals $(n - 1)\lambda_d$.
6. A student fits PCA on all 1,797 digits, keeps 20 components, and then splits the scores into training and test sets for k-NN. What is wrong, and does it matter much here?

17.10 Solutions to the Exercises

Exercise 17.1. The points are centered already. $C_{11} = (1 + 0 + 1 + 0)/3 = 2/3$, $C_{22} = 2/3$, $C_{12} = (0 + 0 + 0 + 0)/3 = 0$. So $C = \frac{2}{3}I$, with the double eigenvalue $2/3$. Every direction is an eigenvector with the same variance: the cloud is perfectly round, and there is no preferred direction. PCA returns *some* pair of perpendicular directions, but which pair is arbitrary, and each carries 50 percent. When eigenvalues are nearly equal, their components are unstable and should not be interpreted.

Exercise 17.2. **Listing 17.5** runs PCA on the raw and on the standardized measurements.

Listing 17.5 `solutions/ex_nostd.py`: PCA on the wine data with and without standardization.

```
# ex_nostd.py - Exercise 17.2: PCA on the wine data without standardizing
import sys
from pathlib import Path
import numpy as np
from sklearn.datasets import load_wine
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from pca import PCA, standardize

wine = load_wine()
for label, X in [("raw units", wine.data),
                 ("standardized", standardize(wine.data))]:
    p = PCA(2).fit(X)
    j = np.argmax(np.abs(p.components[0]))
    print(f"{label:12s}: PC1 keeps {p.ratio[0]:6.1%}, largest loading "
          f"{wine.feature_names[j]} {p.components[0, j]:+.3f}")
print("standard deviation of proline:", round(wine.data[:, 12].std(), 1),
      " of hue:", round(wine.data[:, 10].std(), 2))
```

```
raw units   : PC1 keeps  99.8%, largest loading proline +1.000
standardized: PC1 keeps  36.2%, largest loading flavanoids -0.423
standard deviation of proline: 314.0  of hue: 0.23
```

On raw units PC1 carries 99.8 percent of the variance and is simply the proline column (loading $+1.000$). Proline is measured in milligrams per liter with a standard deviation of 314, while hue has a standard deviation of 0.23; its variance is about 1.9×10^6 times larger. PCA, which maximizes variance, just finds the column with the biggest numbers. Standardizing gives every column variance 1, and then PC1 (36.2 percent) reflects the correlations between measurements, which is what we want to explore.

Exercise 17.3. Neither is wrong. If $\mathbf{w}$ satisfies Equation (17.4), so does $-\mathbf{w}$, with the same eigenvalue and the same variance. The routines simply returned opposite signs; all loadings of that component will be flipped together, and all scores will be mirrored. Only the relative signs within one component carry meaning.

Exercise 17.4. Standardized pixels (explorer): 31 components for 90 percent. Raw pixels (`improve.py`): 20 components keep 89.4 percent. Standardizing gives every pixel variance 1, including edge pixels that are almost always blank and vary only through a few stray strokes; their noise then counts as much as the informative central pixels, spreading the variance over

more components. On raw pixels, the central pixels, which vary most, dominate, and a few components capture the main strokes.

Exercise 17.5. With $k = d - 1$, W holds all components but the last, $\mathbf{w}_d$. Since all d components form a complete set of perpendicular unit vectors, each centered row splits as $\mathbf{x}_c = \sum_{j=1}^{d} z_j \, \mathbf{w}_j$, and the reconstruction keeps all terms but $z_d \mathbf{w}_d$. The error of one row is therefore $\| \, z_d \mathbf{w}_d \, \|^2 = z_d^2$, and summing over rows gives $\sum_i z_{i,d}^2 = (n-1)\,\mathrm{Var}(z_d) = (n-1)\lambda_d$ by Equation (17.3) and Equation (17.4). The same argument with several dropped components gives the sum of their eigenvalues.

Exercise 17.6. The PCA directions and the mean were computed with the test images included, so information from the test set shaped the features: a (mild) form of leakage, and the reported test accuracy is slightly optimistic. With 1,797 images and a method that does not use the labels, the effect is usually small, but the habit is dangerous: with supervised preprocessing or small data sets it can inflate results badly. Fit PCA inside a pipeline on the training data, as **Listing 17.3** does.

Chapter 18

Handwritten Digit Recognizer: Support Vector Machines

Reading handwriting was one of the first tasks that made machine learning famous: postal codes on envelopes, amounts on cheques, numbers on forms. This chapter builds a recognizer for handwritten digits with the *support vector machine* (SVM), the method that dominated such tasks in the late 1990s and 2000s and that remains one of the strongest classifiers for small and medium data sets. By the end of the chapter you will be able to explain what a *margin* is and why a classifier with a wide margin generalizes well; write the hard-margin and soft-margin SVM problems and read the role of the parameter C; recognize the hinge loss and train a linear SVM from scratch with the Pegasos algorithm; extend two-class SVMs to ten digits; explain the *kernel trick* and the RBF kernel with its width γ; tune C and γ by cross-validation; see why the recognizer fails on digits drawn in a different style or shifted by one pixel, and fix the shifting problem by data augmentation; and run an app that reads a digit you draw in a text file.

18.1 Why a Digit Recognizer?

At Profitina Laundry every order has a paper tag with a number written by hand: the rack, the order number, the weight. At the end of a busy Saturday someone types those numbers into the system, and every typing mistake means a bag of clothes that cannot be found on Monday. A camera over the counter could read the tags, if a program could recognize handwritten digits. The same problem appears in every office that still receives handwritten forms, and it was the first large commercial success of machine learning: by the late 1990s, neural networks and SVMs read a large share of the cheques written in the United States [1].

We work with the digits data set that ships with scikit-learn: 1,797 handwritten digits from 43 people, collected for the UCI repository by Alpaydin and Kaynak [2]. Each original 32 × 32 black-and-white image was divided into 4 × 4 blocks, and each block became one pixel whose value (0 to 16) counts the black dots in it. The result is a small 8 × 8 gray image, 64 numbers per digit. **Figure 18.1** shows thirty of them with their labels.

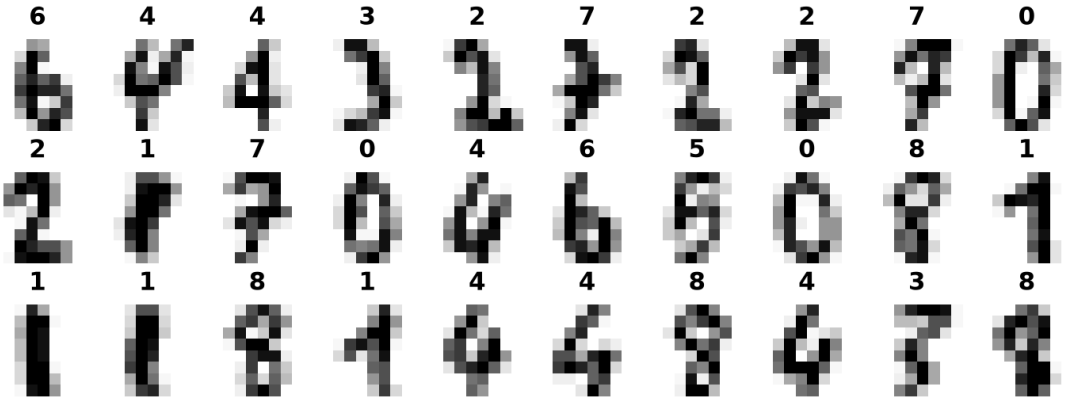

Figure 18.1 Thirty training images of the digits data set, 8 × 8 pixels each, with their labels.

The app we build recognizes a digit that you draw yourself, eight lines of eight characters in a text file:

```
python digit_app.py samples/seven.txt
```

18.2 The Idea in Plain Words

Imagine a football field where the players of two teams stand scattered, one team mostly on the left and the other mostly on the right, and the referee must paint a single straight line to separate them. Many lines would do. A line that barely scrapes past the nearest players of each team is fragile: a player who takes one step is on the wrong side. The safest line runs down the middle of the widest empty corridor between the teams. The width of that corridor is the *margin*, and an SVM chooses the line with the widest margin.

Look at **Figure 18.2**. The solid line is the SVM's boundary; the dashed lines mark the edges of the corridor. Only a few points touch the edges; these are the *support vectors*, circled in red. They alone decide where the line goes: move any other point a little, and the line does not change. That is where the method gets its name, and it is also why SVMs are robust. The decision depends on the hard cases near the border, not on the easy ones far away.

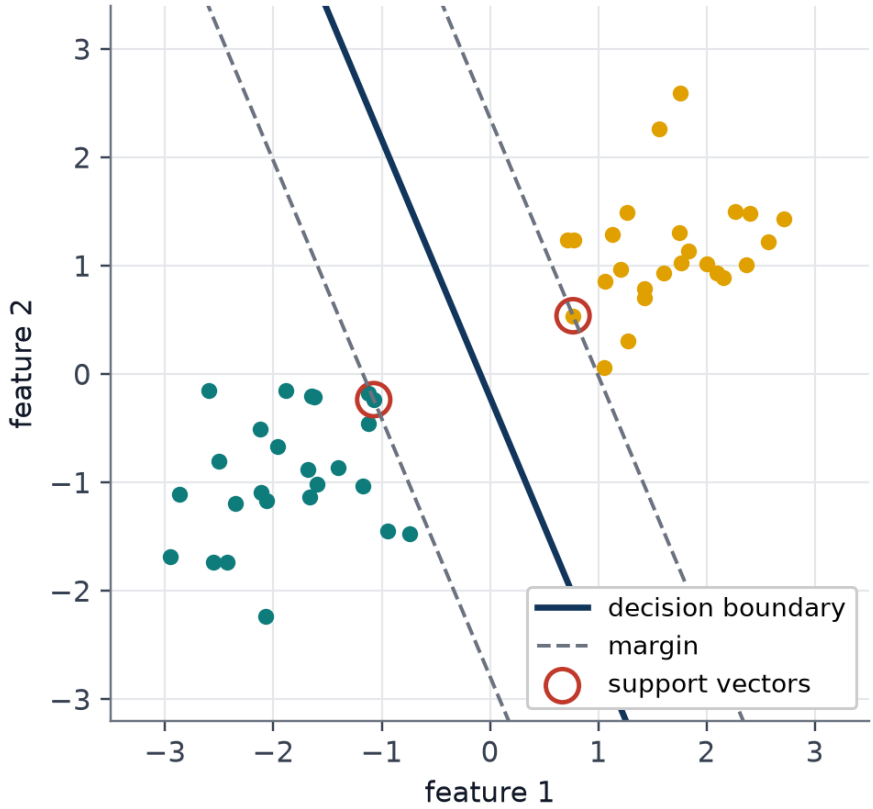

Figure 18.2 A linear SVM on two groups of points: the decision boundary (solid), the edges of the margin (dashed) and the support vectors (circled) that alone determine it.

Real data are messier. A few players may stand deep in the other team's half, and no straight line separates everyone. The *soft-margin* SVM allows some points inside the corridor or even on the wrong side, but charges a penalty for each one; a setting called C decides how expensive such violations are. A large C says "avoid violations at almost any cost", which gives a narrow corridor that bends to every awkward point; a small C says "a wide corridor matters more than a few violations".

Handwritten digits are not separable by straight lines in their 64-pixel space, at least not easily. The *kernel trick* lets an SVM draw curved boundaries while keeping all the mathematics of straight lines: it measures similarity between images in a way that corresponds to a straight line in a much larger, hidden space. With the popular RBF kernel, a new image is compared with the support vectors, and nearby support vectors count more, a little like the neighbors of Chapter 13, but with learned weights.

> **KEY INSIGHT:** An SVM draws the boundary with the widest safety margin between classes, and only the points on the edge of that margin (the support vectors) decide where it goes. Kernels let the same idea draw curved boundaries.

18.3 The Mathematics, Gently

18.3.1 A line, and the distance to it

For two classes, write the labels as $y = +1$ and $y = -1$. A *hyperplane* (a line in two dimensions, a plane in three, and its analogue in 64) is the set of points $\mathbf{x}$ where

$$\mathbf{w} \cdot \mathbf{x} + b = 0 \tag{18.1}$$

with a weight vector $\mathbf{w}$ and a bias b, as in the linear models of Chapters 11 and 12. A point is classified by the sign of $f(\mathbf{x}) = \mathbf{w} \cdot \mathbf{x} + b$. The distance from a point $\mathbf{x}_i$ to the hyperplane is

$$\text{dist}(\mathbf{x}_i) = \frac{|\mathbf{w} \cdot \mathbf{x}_i + b|}{\| \mathbf{w} \|} \tag{18.2}$$

where $\| \mathbf{w} \|$ is the length of $\mathbf{w}$. The product $y_i f(\mathbf{x}_i)$ is positive exactly when point i is on its correct side; we call it the point's *functional margin*.

18.3.2 The widest margin

Multiplying $\mathbf{w}$ and b by the same number does not move the hyperplane, so we may fix the scale by asking that the closest points of each class have functional margin exactly 1. The corridor then runs between $f(\mathbf{x}) = -1$ and $f(\mathbf{x}) = +1$, and by Equation (18.2) its width is $2/\| \mathbf{w} \|$. Maximizing the width is the same as minimizing $\| \mathbf{w} \|^2$, so the *hard-margin SVM* is

$$\min_{\mathbf{w},b} \frac{1}{2} \| \mathbf{w} \|^2 \quad \text{subject to} \quad y_i(\mathbf{w} \cdot \mathbf{x}_i + b) \geq 1 \text{ for all } i \tag{18.3}$$

The points whose constraint holds with equality lie on the edges of the corridor: the support vectors.

18.3.3 Soft margins and the hinge loss

When the classes overlap, Equation (18.3) has no solution. The *soft-margin SVM* gives each point a slack $\xi_i \geq 0$ (xi) that measures how far it violates the margin, and pays C for each unit of slack [3]:

$$\min_{\mathbf{w},b,\boldsymbol{\xi}} \frac{1}{2} \| \mathbf{w} \|^2 + C \sum_{i=1}^{n} \xi_i \quad \text{subject to} \quad y_i(\mathbf{w} \cdot \mathbf{x}_i + b) \geq 1 - \xi_i, \ \xi_i \geq 0 \tag{18.4}$$

At the optimum each slack is as small as allowed: $\xi_i = \max(0, 1 - y_i f(\mathbf{x}_i))$. Substituting it gives an equivalent problem without constraints, written with $\lambda = 1/(nC)$ and after dividing by nC:

$$\min_{\mathbf{w},b} \frac{\lambda}{2} \| \mathbf{w} \|^2 + \frac{1}{n} \sum_{i=1}^{n} \max(0,\ 1 - y_i(\mathbf{w} \cdot \mathbf{x}_i + b)) \tag{18.5}$$

The term $\max(0,1 - yf)$ is the *hinge loss*, drawn in **Figure 18.3**. It is zero for points safely outside the margin ($yf \geq 1$), grows linearly for points inside it, and keeps growing for points on the wrong side. Compare the logistic loss of Chapter 12: both are smooth-ish stand-ins for "was it a mistake?", but the hinge loss is *exactly* zero for easy points, which is why only the support vectors matter. Equation (18.5) is also the same shape as regularized logistic regression: a penalty on the weights plus an average loss.

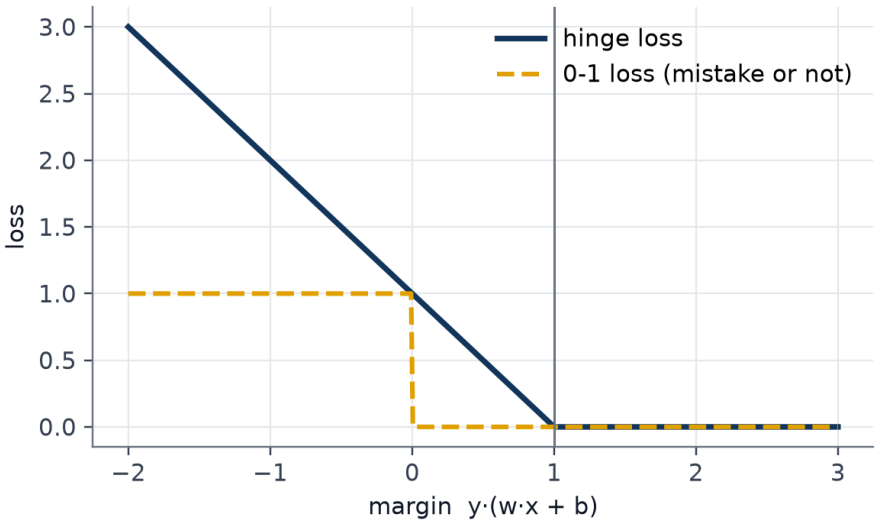

Figure 18.3 The hinge loss $\max(0,1 - yf)$ against the functional margin yf, with the 0-1 loss that simply counts mistakes. Points beyond margin 1 cost nothing.

EXAMPLE. Take $\mathbf{w} = (1,1)$ and $b = -3$, so $\| \mathbf{w} \| = \sqrt{2} = 1.414$ and the corridor is $2/1.414 = 1.414$ wide.

Point $A = (1,1)$ with $y = -1$: $f = 1 + 1 - 3 = -1$, functional margin $yf = 1$. It lies exactly on the edge of the corridor: a support vector, hinge loss 0, distance $1/1.414 = 0.707$ from the boundary.

Point $B = (3,2)$ with $y = +1$: $f = 2$, $yf = 2$. Safely outside: hinge loss 0, distance $2/1.414 = 1.414$.

Point $C = (2,0.5)$ with $y = +1$: $f = -0.5$, $yf = -0.5$. On the wrong side: hinge loss $1 - (-0.5) = 1.5$. A soft-margin SVM with this $\mathbf{w}$ would pay 1.5 C for it.

18.3.4 Training by stochastic sub-gradients: Pegasos

Equation (18.5) can be minimized by the same idea as Chapters 11 and 12: step against the slope. The hinge has a corner at $yf = 1$, where it has no single slope, so we use a *sub-gradient*, any slope between those on either side. Pegasos [4] picks one training point at a time, in random order, and at step t uses the step size $\eta_t = 1/(\lambda t)$:

$$\mathbf{w} \leftarrow (1 - \eta_t \lambda)\, \mathbf{w} + \begin{cases} \eta_t\, y_i \mathbf{x}_i & \text{if } y_i(\mathbf{w} \cdot \mathbf{x}_i + b) < 1 \\ \mathbf{0} & \text{otherwise} \end{cases} \tag{18.6}$$

The first factor is the penalty pulling every weight toward zero; the second term pushes the boundary away from a point that is inside the margin or misclassified. Points outside the margin cause no push at all. The shrinking step size makes early steps bold and late steps careful. Pegasos also works well when the late weight vectors are averaged, which smooths out the zigzag of single-point steps; our implementation averages over the second half of training.

18.3.5 From two classes to ten

An SVM separates two classes. For ten digits, the *one-vs-rest* scheme trains ten SVMs, "0 against all others", "1 against all others", and so on, and predicts the digit whose SVM gives the largest score $f_c(\mathbf{x})$. The *one-vs-one* scheme trains one SVM for every pair of digits, $\binom{10}{2} = 45$ of them, and lets them vote; each digit takes part in 9 duels. scikit-learn's `SVC` uses one-vs-one internally [5].

18.3.6 Kernels

Every SVM solution can be written using only dot products between training points. The trained classifier takes the form

$$f(\mathbf{x}) = \sum_{i \in \mathrm{SV}} \alpha_i \, y_i \, K(\mathbf{x}_i, \mathbf{x}) + b \tag{18.7}$$

where the sum runs over the support vectors, the $\alpha_i \geq 0$ are weights found by training (at most C each), and $K(\mathbf{x}_i, \mathbf{x}) = \mathbf{x}_i \cdot \mathbf{x}$ for a linear SVM. The *kernel trick* replaces this dot product by another similarity function K that corresponds to a dot product in some larger space of features, without ever computing those features. The most popular choice is the *radial basis function* (RBF) kernel:

$$K(\mathbf{x}, \mathbf{z}) = \exp(-\gamma \parallel \mathbf{x} - \mathbf{z} \parallel^2) \tag{18.8}$$

It equals 1 when $\mathbf{x} = \mathbf{z}$ and falls toward 0 as they move apart; γ (gamma) sets how fast. With the RBF kernel, Equation (18.7) says: compare the new image with every support vector, weight each comparison by how similar they are, and add up. A small γ makes every support vector influence a wide region, giving smooth boundaries; a large γ makes each one influence only its immediate neighborhood, giving boundaries that wrap tightly around individual training images, which is overfitting. Boser, Guyon and Vapnik introduced kernels into maximum-margin classifiers in 1992 [6], and Cortes and Vapnik added the soft margin in 1995 [3].

18.4 Building It Step by Step

18.4.1 A linear SVM from scratch

The folder `Chapter018` has the same `requirements.txt` as Chapter 11. **Listing 18.1** holds the from-scratch linear SVM, the one-vs-rest wrapper, the data split shared by every script, and a helper that shifts images by whole pixels (used in Section 18.6).

Listing 18.1 `svm.py`: a linear SVM trained by Pegasos, one-vs-rest for ten digits, the shared data split, and the pixel-shift helper.

```python
# svm.py - a linear support vector machine from scratch (Pegasos), one-vs-rest
import numpy as np
from sklearn.datasets import load_digits
from sklearn.model_selection import train_test_split

def pegasos(X, y, lam=1e-3, epochs=20, seed=0):
    # y in {-1, +1}; minimizes lam/2 |w|^2 + mean hinge loss
    rng = np.random.default_rng(seed)
    n, d = X.shape
    w, b, t = np.zeros(d), 0.0, 0
    w_sum, b_sum, count = np.zeros(d), 0.0, 0
    for epoch in range(epochs):
        for i in rng.permutation(n):
            t += 1
            eta = 1.0 / (lam * (t + 100))              # shrinking step size
            margin = y[i] * (X[i] @ w + b)
            w *= 1 - eta * lam                         # the penalty's pull to 0
            if margin < 1:                             # inside the margin: push
                w += eta * y[i] * X[i]
                b += eta * y[i]
            if epoch >= epochs // 2:                   # average the late steps
                w_sum += w
                b_sum += b
                count += 1
    return w_sum / count, b_sum / count

class OneVsRest:
    def fit(self, X, y, **kw):
        self.classes = np.unique(y)
        self.models = [pegasos(X, np.where(y == c, 1, -1), **kw)
                       for c in self.classes]
        return self

    def decision(self, X):
        return np.column_stack([X @ w + b for w, b in self.models])

    def predict(self, X):
        return self.classes[self.decision(X).argmax(axis=1)]
```

Listing 18.1 (Continued) *svm.py: a linear SVM trained by Pegasos, one-vs-rest for ten digits, the shared data split, and the pixel-shift helper.*

```
def load_split():
    X, y = load_digits(return_X_y=True)
    X = X / 16.0                                        # pixels to 0..1
    return train_test_split(X, y, test_size=0.3, stratify=y, random_state=0)

def shift(X, dy, dx):
    imgs = X.reshape(-1, 8, 8)
    out = np.roll(imgs, (dy, dx), axis=(1, 2))
    if dy > 0:                                          # clear what rolled in
        out[:, :dy] = 0
    if dy < 0:
        out[:, dy:] = 0
    if dx > 0:
        out[:, :, :dx] = 0
    if dx < 0:
        out[:, :, dx:] = 0
    return out.reshape(len(X), 64)

if __name__ == "__main__":
    X_tr, X_te, y_tr, y_te = load_split()
    print(f"{len(X_tr)} training and {len(X_te)} test images of 8x8 pixels")
    for lam in [1e-1, 1e-2, 1e-3, 1e-4]:
        model = OneVsRest().fit(X_tr, y_tr, lam=lam)
        acc = np.mean(model.predict(X_te) == y_te)
        print(f"lambda {lam:g}: test accuracy {acc:.3f}")
```

`pegasos` is Equation (18.6). The step size is $1/(\lambda(t+100))$ rather than $1/(\lambda t)$: the extra 100 tames the first few steps, which with a small λ would otherwise be enormous. The bias b is not penalized; it moves by the same step as the weights. After half the epochs the function starts adding up the weight vectors and returns their average. `OneVsRest` trains one Pegasos model per digit with labels $+1$ for that digit and -1 for the rest, and predicts the digit with the highest score. `load_split` scales the pixels from 0–16 to 0–1 and keeps 30 percent of the images, stratified by digit, as the test set.

```
1257 training and 540 test images of 8x8 pixels
lambda 0.1: test accuracy 0.926
lambda 0.01: test accuracy 0.956
lambda 0.001: test accuracy 0.961
lambda 0.0001: test accuracy 0.957
```

Training ten models for 20 epochs over 1,257 images takes about four seconds of pure Python loops. The best penalty here is $\lambda = 0.001$ with 96.1 percent test accuracy; a heavier penalty ($\lambda = 0.1$) forces weights so small that the boundaries cannot fit the data (92.6 percent). A linear classifier on raw pixels already reads 19 digits out of 20.

18.4.2 Kernels and tuning with scikit-learn

scikit-learn's `SVC` wraps LIBSVM, a mature library that solves the soft-margin problem exactly rather than by stochastic steps [7], [5]. **Listing 18.2** first compares three kernels with their default settings, then searches a grid of C and γ values for the RBF kernel with 5-fold cross-validation on the training images, and finally tests the best model once.

Listing 18.2 `sklearn_svm.py`: linear, polynomial and RBF kernels, and a cross-validated search for C and γ.

```python
# sklearn_svm.py - kernel SVM: choose C and gamma by cross-validation
import numpy as np
from sklearn.metrics import confusion_matrix
from sklearn.model_selection import GridSearchCV, StratifiedKFold
from sklearn.svm import SVC
from svm import load_split

X_tr, X_te, y_tr, y_te = load_split()                # the same split as svm.py
for kernel in ["linear", "poly", "rbf"]:
    acc = SVC(kernel=kernel).fit(X_tr, y_tr).score(X_te, y_te)
    print(f"{kernel:6s} kernel, default settings: test accuracy {acc:.3f}")

grid = {"C": [0.1, 1, 10, 100], "gamma": [0.01, 0.1, 1, 10]}
cv = StratifiedKFold(n_splits=5, shuffle=True, random_state=0)
search = GridSearchCV(SVC(kernel="rbf"), grid, cv=cv).fit(X_tr, y_tr)
print("best:", search.best_params_, f"cv accuracy {search.best_score_:.3f}")
best = search.best_estimator_
pred = best.predict(X_te)
print(f"test accuracy {np.mean(pred == y_te):.3f}, "
      f"support vectors {best.n_support_.sum()} of {len(X_tr)}")
print(confusion_matrix(y_te, pred))
```

```
linear kernel, default settings: test accuracy 0.985
poly   kernel, default settings: test accuracy 0.993
rbf    kernel, default settings: test accuracy 0.987
best: {'C': 1, 'gamma': 0.1} cv accuracy 0.985
test accuracy 0.985, support vectors 599 of 1257
[[54  0  0  0  0  0  0  0  0  0]
 [ 0 55  0  0  0  0  0  0  0  0]
 [ 0  0 53  0  0  0  0  0  0  0]
 [ 0  0  0 53  0  1  0  1  0  0]
 [ 0  0  0  0 52  0  0  0  2  0]
 [ 0  0  0  0  0 55  0  0  0  0]
 [ 0  0  0  0  0  0 54  0  0  0]
 [ 0  0  0  0  0  0  0 54  0  0]
 [ 0  2  0  0  0  0  0  0 49  1]
 [ 0  0  0  0  0  1  0  0  0 53]]
```

Three observations. First, scikit-learn's exact linear SVM reaches 98.5 percent, more than our 96.1: the exact solver and the one-vs-one scheme both help, and 20 epochs of Pegasos are an approximation. Second, all three kernels are within one percentage point of each other on this test set of 540 images (0.985 to 0.993); one image is worth 0.19 points, so these differences are four or five images and should not be over-read. Third, the grid search chooses $C = 1$ and $\gamma = 0.1$ with a cross-validated accuracy of 98.5 percent, and the test accuracy agrees. The model keeps 599 of the 1,257 training images as support vectors: in 64 dimensions many images lie near some boundary between two of the ten digits. The confusion matrix shows eight mistakes, mostly 8s and 4s taken for other digits. **Figure 18.4** shows the whole grid: accuracy collapses when γ is large (10), whatever C is, because each support vector then only recognizes images almost identical to itself.

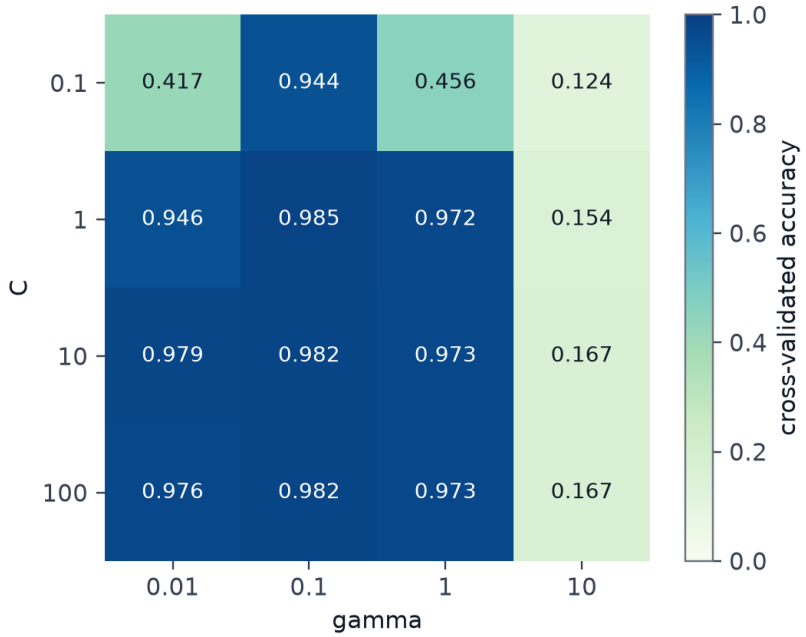

Figure 18.4 Five-fold cross-validated accuracy of the RBF SVM for each combination of C and γ on the training images.

Figure 18.5 shows the eight test images the tuned model gets wrong, with the true label and the prediction. Several are hard even for a person: the "8 → 1" images are thin, upright strokes, and the "3 → 7" has lost its lower curve.

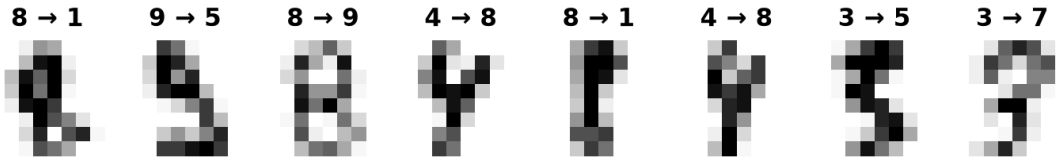

Figure 18.5 The eight misclassified test images, labeled "true → predicted".

A note for readers of older tutorials: until recently one wrote `SVC(probability=True)` to get probabilities from an SVM. In scikit-learn 1.9 this option is deprecated, and the recommended route is to wrap the SVM in `CalibratedClassifierCV` [8]. Our app does not need probabilities; it reports the `decision_function` scores instead.

18.4.3 The app

Listing 18.3 reads a digit drawn in a text file, eight lines of eight characters, where `.` is blank, `:` light ink, `+` medium ink and `#` full ink. It trains the tuned RBF SVM, shows the digit back as a small picture, and prints the prediction with the three best scores from `decision_function`. With `--index` it recognizes a test image instead, and shows its true label.

Listing 18.3 `digit_app.py`: the digit recognizer app for drawings in text files and for test images.

```python
# digit_app.py - recognize an 8x8 digit drawn in a text file, or a test image
import argparse
from pathlib import Path
import numpy as np
from sklearn.svm import SVC
from svm import load_split

SHADES = {".": 0.0, ":": 0.33, "+": 0.67, "#": 1.0}

def read_ascii(path):
    rows = Path(path).read_text().split()
    if len(rows) != 8 or any(len(r) != 8 for r in rows):
        raise SystemExit("the drawing must be 8 lines of 8 characters")
    return np.array([[SHADES.get(ch, 1.0) for ch in r] for r in rows]).ravel()

def show(x):
    marks = " .:+#"
    for r in x.reshape(8, 8):
        print("   " + "".join(marks[min(4, int(v * 4 + 0.5))] * 2 for v in r))

def main():
    ap = argparse.ArgumentParser(description="Handwritten digit recognizer (SVM)")
    ap.add_argument("drawing", nargs="?", help="text file, 8 lines x 8 chars")
    ap.add_argument("--index", type=int, help="use test image number INDEX")
    a = ap.parse_args()
    X_tr, X_te, y_tr, y_te = load_split()
    model = SVC(kernel="rbf", C=1, gamma=0.1).fit(X_tr, y_tr)   # from the grid
    if a.index is not None:
        x, truth = X_te[a.index], y_te[a.index]
    else:
        x, truth = read_ascii(a.drawing), None
    show(x)
    scores = model.decision_function([x])[0]           # one score per digit
    top = np.argsort(scores)[::-1][:3]
    print("prediction:", model.predict([x])[0],
          "" if truth is None else f"(true label {truth})")
    print("top scores:", ", ".join(f"{d}: {scores[d]:.2f}" for d in top))

if __name__ == "__main__":
    main()
```

The scores need a word of explanation. With one-vs-one, each digit takes part in 9 duels; `decision_function` returns, for each digit, its number of duels won plus a small confidence adjustment (always less than one-third in either direction). A score near 9.3 therefore means "won all nine duels", and the runner-up near 8.2 means "won eight, lost only to the winner".

18.5 Running It

The sample drawings are made in the style of the data set: thick strokes, gray edges, filling the square. A seven:

```
python digit_app.py samples/seven.txt
```

```
     ..###########++
     ..++++++++####
             ####..
           ..####
       ..########..
         ####..
       ..####
       #####++
prediction: 7
top scores: 7: 9.30, 2: 8.21, 3: 7.19
```

A one and a three:

```
python digit_app.py samples/one.txt
```

```
         ..####
       ++######
     ..##++####
         ..####
         ..####
         ..####
         ..####
         ..####
prediction: 1
top scores: 1: 9.30, 3: 8.28, 8: 7.28
```

```
python digit_app.py samples/three.txt
```

```
     ..########..
     ##++    ####
             ####
         ######..
             ++##..
               ####
     ++..    ++###++
     ..########..
prediction: 3
top scores: 3: 9.27, 9: 8.28, 2: 7.16
```

All three are recognized, each winning all nine of its duels. A test image, to see what the data really look like:

```
python digit_app.py --index 7
```

```
     ..####..
     ..#####++
     ::#####++
       ..##::
       ::##..
       ##++
     ..########..
     ..######::
prediction: 2 (true label 2)
top scores: 2: 9.30, 8: 8.29, 1: 7.25
```

Now draw the same digits the way most people would in a text editor, with thin, one-pixel strokes (the files `thin_one.txt` and `thin_three.txt`):

```
python digit_app.py samples/thin_one.txt
```

```
          ##
        ####
      ##  ##
          ##
          ##
          ##
          ##
      ##########
prediction: 2
top scores: 2: 9.28, 1: 8.27, 3: 7.27
```

```
python digit_app.py samples/thin_three.txt
```

```
    ##########
             ##
             ##
      ########
             ##
             ##
             ##
    ##########
prediction: 9
top scores: 9: 9.27, 5: 8.26, 3: 7.20
```

Both are wrong. The one is read as a 2 and the three as a 9. The model is not broken; it has never seen a thin stroke. Every training digit was produced by counting dots in 4×4 blocks, which blurs and thickens every stroke. A thin line lights up pixels that in the training data belong to other shapes. This is *distribution shift*: the data met in use differ from the data used for training, and it is the most common reason why a model that scored 98.5 percent in testing disappoints in the field. The remedy is not a cleverer classifier but data that look like the real use: tags photographed at the laundry counter, preprocessed exactly the way the training images were. Each run takes about two seconds, most of it importing scikit-learn and training the SVM at start-up.

18.6 Improving It

A related weakness is easy to measure. A digit written a little to the left of the usual position is still the same digit, but its 64 pixel values are completely different. **Listing 18.4** tests the tuned SVM on the test images shifted by one pixel up, down, left and right, then retrains it on the training images plus four shifted copies of each, a simple form of *data augmentation*.

Listing 18.4 `improve.py`: training on shifted copies (data augmentation) and testing on shifted images.

```python
# improve.py - make the recognizer robust: train on shifted copies of each digit
import numpy as np
from sklearn.svm import SVC
from svm import load_split, shift

X_tr, X_te, y_tr, y_te = load_split()
moves = [(0, 1), (0, -1), (1, 0), (-1, 0)]
X_aug = np.vstack([X_tr] + [shift(X_tr, dy, dx) for dy, dx in moves])
y_aug = np.concatenate([y_tr] * 5)
X_moved = np.vstack([shift(X_te, dy, dx) for dy, dx in moves])
y_moved = np.concatenate([y_te] * 4)

for label, X, y in [("original training set", X_tr, y_tr),
                    ("plus shifted copies", X_aug, y_aug)]:
    m = SVC(kernel="rbf", C=1, gamma=0.1).fit(X, y)
    print(f"{label:22s} ({len(y):4d} images): test {m.score(X_te, y_te):.3f}, "
          f"shifted test {m.score(X_moved, y_moved):.3f}")
```

```
original training set  (1257 images): test 0.985, shifted test 0.532
plus shifted copies    (6285 images): test 0.989, shifted test 0.981
```

The effect is dramatic. Trained on the original images, the SVM reads unshifted test digits at 98.5 percent but shifted ones at only 53.2 percent: one pixel of displacement halves its accuracy. Trained with the shifted copies (6,285 images instead of 1,257), it reads shifted digits at 98.1 percent and unshifted ones slightly better than before, 98.9 percent. The SVM itself did not change; we taught it, by example, that position does not matter. Training on five times as many images takes correspondingly longer, which is the usual price of augmentation.

Augmentation is a general idea with many forms for images: small rotations, scaling, thickening or thinning of strokes (which would help with the thin drawings), added noise. Chapter 49 builds a data augmentation lab around it. The deeper fix, used by modern digit readers, is a model whose structure ignores small shifts by design: the convolutional networks of Chapter 35, trained on the 70,000 digits of MNIST [1], reach over 99 percent on much harder images.

The tests in **Listing 18.5** check that Pegasos separates two clear clouds, that the shift helper moves pixels and clears the edge, and that the app reads a drawing as 64 pixel values.

Listing 18.5 `test_svm.py`: tests for Pegasos, the pixel shift, and the drawing reader.

```python
# test_svm.py - run with:  python -m pytest -q
from pathlib import Path
import numpy as np
from digit_app import read_ascii
from svm import pegasos, shift

def test_pegasos_separates_two_clouds():
    rng = np.random.default_rng(0)
    X = np.vstack([rng.normal(-2, 0.5, (30, 2)), rng.normal(2, 0.5, (30, 2))])
    y = np.array([-1] * 30 + [1] * 30)
    w, b = pegasos(X, y, lam=0.01, epochs=10)
    assert np.all(np.sign(X @ w + b) == y)

def test_shift_moves_a_pixel_and_clears_the_edge():
    img = np.zeros((1, 64))
    img[0, 7] = 1.0                                  # top-right corner
    assert shift(img, 0, 1).sum() == 0               # rolled off the edge
    assert shift(img, 1, 0)[0, 15] == 1.0            # one row down

def test_ascii_drawing_has_64_pixels():
    x = read_ascii(Path(__file__).parent / "samples" / "one.txt")
    assert x.shape == (64,) and x.max() == 1.0
```

```
...                                                                      [100%]
3 passed in 1.51s
```

18.7 Common Mistakes, and How to Avoid Them

Forgetting to scale features. SVMs, like k-NN, depend on distances and dot products. Features on wildly different scales distort both; here pixels share a scale, and dividing by 16 keeps the useful range of γ predictable.

Tuning C and gamma on the test set. Both settings have a strong effect (**Figure 18.4**); choose them by cross-validation on training data, then test once.

Using a huge gamma. With γ too large, the RBF SVM memorizes: 100 percent training accuracy and chance-level test accuracy (Exercise 18.5).

Reading decision scores as probabilities. `decision_function` returns margins or vote counts, not probabilities. If probabilities are needed, calibrate with `CalibratedClassifierCV`; `probability=True` is deprecated in scikit-learn 1.9.

Expecting the lab accuracy in the field. A change in how the data are produced (thin strokes, a new camera, a shifted crop) can destroy accuracy. Test on data collected the way the app will be used.

Training kernel SVMs on very large data. Training time grows roughly between the square and the cube of the number of examples. For hundreds of thousands of images use a linear SVM, a stochastic solver like Pegasos, or a neural network.

18.8 Chapter Summary

- A linear classifier separates classes with the hyperplane of Equation (18.1); the distance of a point to it is Equation (18.2).

- The SVM chooses the hyperplane with the widest margin (Equation (18.3)); the soft-margin version (Equation (18.4)) pays C per unit of violation, which is the same as minimizing the hinge loss plus an L2 penalty (Equation (18.5)).
- Only support vectors, the points on or inside the margin, determine the boundary.
- Pegasos trains a linear SVM by stochastic sub-gradient steps (Equation (18.6)); on the digits it reached 96.1 percent from scratch.
- Kernels (Equation (18.7)), especially the RBF kernel (Equation (18.8)), give curved boundaries; with C and γ tuned by cross-validation, scikit-learn's SVC reached 98.5 percent.
- The recognizer failed on thin strokes it had never seen and lost half its accuracy on digits shifted by one pixel; training on shifted copies restored it to 98.1 percent. Data that look like real use matter as much as the model.

18.9 Exercises

1. For $\mathbf{w} = (2, -1)$ and $b = 1$, classify the points (0,0), (1,4) and (−1,0), compute their distances to the hyperplane, and the width of the margin corridor.
2. Compute the hinge loss for functional margins $yf = 2,1,0.5,0$ and -1, and compare with the logistic loss $\ln(1 + e^{-yf})$ of Chapter 12 at the same margins.
3. Two images differ by a squared distance $\| \mathbf{x} - \mathbf{z} \|^2 = 4$ (after scaling to 0–1). Compute the RBF kernel for $\gamma = 0.01,0.1,1$ and 10, and explain what these numbers say about overfitting.
4. Why does the app's top score come out near 9.3 for a confident prediction? What would a top score of 7.4 with a runner-up of 7.2 tell you?
5. Train the RBF SVM with $C = 1$ and $\gamma = 0.001,0.01,0.1,1,10,100$. Report training accuracy, test accuracy and the number of support vectors, and explain the pattern.
6. The thin drawings of Section 18.5 were misread. Suggest two changes, one to the data and one to the preprocessing of the drawing, that would make the app read them correctly.

18.10 Solutions to the Exercises

Exercise 18.1. $\| \mathbf{w} \| = \sqrt{4 + 1} = \sqrt{5} = 2.236$. (0,0): $f = 1$, class $+1$, distance $1/2.236 = 0.447$. (1,4): $f = 2 - 4 + 1 = -1$, class -1, distance 0.447. (−1,0): $f = -2 + 1 = -1$, class -1, distance 0.447. All three lie exactly on the edges $f = \pm 1$ of the corridor, whose width is $2/2.236 = 0.894$.

Exercise 18.2. Hinge $\max(0,1 - yf)$: 0,0,0.5,1,2. Logistic $\ln(1 + e^{-yf})$: $\ln(1.135) = 0.127$, $\ln(1.368) = 0.313$, $\ln(1.607) = 0.474$, $\ln 2 = 0.693$, $\ln(3.718) = 1.313$. Both grow for wrong answers, but the hinge is exactly zero beyond margin 1, whereas the logistic loss keeps pulling on every point, however safe. That is why the SVM solution depends only on support vectors, while logistic regression depends on all points.

Exercise 18.3. $K = e^{-4\gamma}$: $\gamma = 0.01$ gives $e^{-0.04} = 0.961$; $\gamma = 0.1$ gives $e^{-0.4} = 0.670$; $\gamma = 1$ gives $e^{-4} = 0.018$; $\gamma = 10$ gives $e^{-40} \approx 4 \times 10^{-18}$. Two digits at squared distance 4 are moderately different. With a tiny γ they count as almost identical (everything looks alike: underfitting); with $\gamma = 10$ they count as completely unrelated, so each support vector only speaks for images almost identical to itself (memorizing: overfitting).

Exercise 18.4. With one-vs-one, a digit's score is its number of won duels (out of 9) plus a confidence adjustment smaller than one-third. About 9.3 means all nine duels won, clearly. A top

score of 7.4 with a runner-up at 7.2 means the two best digits each won about seven duels (and one beat the other only narrowly): an uncertain case that an app should flag for a person to check.

Exercise 18.5. Listing 18.6 trains six SVMs.

Listing 18.6 `solutions/ex_gamma.py`: training accuracy, test accuracy and support vectors for six values of γ.

```
# ex_gamma.py - Exercise 18.5: how the RBF width gamma trades fit for overfit
import sys
from pathlib import Path
from sklearn.svm import SVC
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from svm import load_split

X_tr, X_te, y_tr, y_te = load_split()
for gamma in [0.001, 0.01, 0.1, 1, 10, 100]:
    m = SVC(kernel="rbf", C=1, gamma=gamma).fit(X_tr, y_tr)
    print(f"gamma {gamma:7g}: train {m.score(X_tr, y_tr):.3f}  "
          f"test {m.score(X_te, y_te):.3f}  support vectors {m.n_support_.sum()}")
```

```
gamma   0.001: train 0.680  test 0.670  support vectors 1257
gamma    0.01: train 0.957  test 0.952  support vectors 1004
gamma     0.1: train 0.995  test 0.985  support vectors 599
gamma       1: train 1.000  test 0.983  support vectors 1010
gamma      10: train 1.000  test 0.128  support vectors 1257
gamma     100: train 1.000  test 0.102  support vectors 1257
```

With $\gamma = 0.001$ the kernel is so wide that all images look alike: 68 percent on training and test alike, and every training image is a support vector (underfitting). Accuracy rises to its best at $\gamma = 0.1$ with the fewest support vectors (599). At $\gamma = 1$ training accuracy is perfect and test accuracy still high. At $\gamma = 10$ and 100 training accuracy stays perfect but test accuracy collapses to 12.8 and 10.2 percent, near the 10 percent of random guessing: each support vector recognizes only itself, and a new image resembles none of them. The number of support vectors is a useful warning light: near n at both extremes, smallest where the model generalizes best.

Exercise 18.6. Data: add training examples drawn the way the app will be used (thin strokes in text files, or photographs of real tags), or augment the existing images by thinning their strokes. Preprocessing: make the drawing resemble the training images before classifying it, for example by thickening (dilating) the strokes by one pixel and blurring them slightly, or better, by drawing on a 32×32 grid and reducing it with the same 4×4 dot counting that produced the data set. The principle is the same either way: training data and real inputs must pass through the same pipeline.

Chapter 19

Churn Predictor: Random Forests and Gradient Boosting

A single decision tree, as Chapter 14 showed, is readable but nervous: a small change in the data can change its first question and with it the whole tree. This chapter turns that weakness into strength by growing many trees and combining them. *Random forests* grow hundreds of trees on shuffled versions of the data and average their votes; *gradient boosting* grows small trees one after another, each correcting the mistakes of those before it. Together they are the strongest general-purpose methods for tables of data, the kind of data every business keeps. We use them to predict *churn*: which Profitina Laundry customers are likely to stop coming in the next two months. By the end of the chapter you will be able to turn a transaction log into training examples with a proper time cut; explain bootstrap sampling and why averaging reduces variance; build a random forest and a gradient-boosting model from single trees; compare them with a single tree and a logistic-regression baseline using the AUC and a business measure, "how many real churners are among the 50 customers we would call"; measure which features matter with permutation importance; and avoid the leak that makes churn models look better in the lab than in the shop.

19.1 Why a Churn Predictor?

In Chapter 16 we found a customer, C0047, who had placed 21 orders and then not come for 101 days. By the time a segmentation noticed, the customer had long gone. A laundry does not lose customers with a slammed door; they simply stop coming, and the loss is only visible in hindsight. Keeping a customer is much cheaper than finding a new one: a phone call, a small voucher, a question about whether something went wrong. But the staff cannot call 250 customers every month. They need a short list of the customers most likely to stop *before* they stop.

That is a prediction problem with a yes-or-no answer, like the spam filter of Chapter 12 and the loan advisor of Chapter 14, but with a twist: the answer lies in the future. "Churn" must be defined as something we can observe. We use a simple, practical definition: *a customer has churned at a given date if they place no order in the 60 days after it*. For regular laundry customers, who come every week or two, two months of silence is a strong sign.

The method is the family of *tree ensembles*. Breiman showed in 1996 that averaging trees grown on resampled data (*bagging*) reduces their errors [1], and in 2001 added random feature selection to make the trees more different from each other: the *random forest* [2]. In the same year Friedman described *gradient boosting* [3], which later became XGBoost, LightGBM and scikit-learn's `HistGradientBoostingClassifier`, the workhorses of data-science competitions and of industry [4], [5]. On typical tabular data, tree ensembles still match or beat deep neural networks [6].

The app prints the ten customers most at risk:

```
python churn_app.py
```

19.2 The Idea in Plain Words

Suppose you want to guess the price of a used motorcycle at a market in Surabaya. You could ask one mechanic. His guess might be good, but it depends on his particular experience: if he happened to see three overpriced bikes last week, he guesses high. Now ask a hundred mechanics, each of whom has seen a different random selection of bikes, and average their guesses. Each guess still has its quirks, but the quirks point in different directions and largely cancel. The average is steadier than any single guess. That is a random forest: many trees, each trained on a random resample of the data (and, at every split, allowed to look at only a random few of the features, so that they do not all think alike), with their predictions averaged.

Gradient boosting is a different idea. Imagine a team of apprentices estimating the price in turn. The first gives a rough guess, the average price of all bikes. The second looks only at how wrong that guess was for each bike and learns to predict the *error*: "for bikes with low mileage, add a million". The third learns what error remains after the first two, and so on. Each apprentice is weak (a tiny tree with two levels of questions), but each one fixes a part of what the others got wrong, and together they become precise. To avoid over-correcting, every correction is scaled down by a *learning rate*, so progress is steady rather than jumpy.

Both ensembles lose the simple readability of a single tree: nobody can read 500 trees. We get back some understanding by asking which features the ensemble relies on, which Section 19.4 measures.

> **KEY INSIGHT:** A random forest averages many different, deep trees to cancel their individual errors (it reduces variance). Gradient boosting adds many small trees in sequence, each fitting the remaining error (it reduces bias). Both turn a nervous single tree into a strong model.

19.3 The Mathematics, Gently

19.3.1 Turning a log into examples: snapshots

We have 2,953 bills with dates, from October 2025 to September 2026. To learn "who will stop coming", we need examples of the form (what we knew about a customer at some date, what happened next). We take a *snapshot* on the first day of each month: for every customer who had ordered before that *cutoff*, we compute features from the bills *before* the cutoff and a label from the 60 days *after* it, as **Figure 19.1** shows.

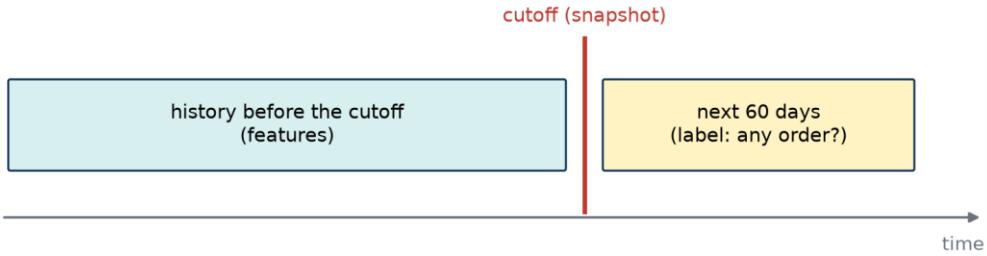

Figure 19.1 A snapshot: features come only from the history before the cutoff; the label asks whether the customer ordered in the following 60 days.

The eight features are: *recency* (days since the last order), *orders_90* and *spend_90* (orders and spending in the last 90 days), *orders_all* (all orders so far), *avg_gap* (average days between orders), *tenure* (days since the first order), *express_share* (share of express orders) and *trend* (orders in the last 30 days minus half those in the 60 days before). Snapshots from January to

April 2026 form the training set; those from May to July form the test set. The test set is *later* than the training set, exactly as it will be when the model is used.

19.3.2 Bootstrap samples

A *bootstrap sample* of n training rows is drawn by picking n rows at random *with replacement*: some rows are picked twice or more, and some are not picked at all. The probability that a given row is never picked is

$$\left(1-\frac{1}{n}\right)^{n} \approx e^{-1} = 0.368 \tag{19.1}$$

for large n. So each bootstrap sample contains about 63 percent of the distinct rows, some repeated, and misses about 37 percent. Every tree of a random forest is grown on its own bootstrap sample, so every tree sees a slightly different data set. (The missed rows, called *out-of-bag*, can be used to estimate the forest's accuracy without a separate test set.)

19.3.3 Why averaging helps

A random forest with B trees predicts the average of the trees' probabilities:

$$\hat{p}(\mathbf{x}) = \frac{1}{B}\sum_{b=1}^{B} \hat{p}_b(\mathbf{x}) \tag{19.2}$$

Suppose each tree's prediction has variance σ^2 (how much it swings from one training sample to another), and any two trees' predictions have correlation ρ (rho). Then the variance of the average is

$$\mathrm{Var}(\hat{p}) = \rho\sigma^2 + \frac{1-\rho}{B}\sigma^2 \tag{19.3}$$

[7]. The second term shrinks as trees are added; the first does not. Averaging many trees therefore removes most of the variance *except the part the trees share*, and the way to reduce that shared part is to make the trees less alike. That is why a random forest, at every split, lets a tree choose only among a random subset of the features (usually $\sqrt{d}$ of the d features): the trees are forced to try different questions, their errors become less correlated, and the average improves.

19.3.4 Gradient boosting

Boosting builds an *additive model*, a sum of small trees $h_1, h_2, \ldots, h_M$:

$$F_M(\mathbf{x}) = F_0 + \eta\sum_{m=1}^{M} h_m(\mathbf{x}) \tag{19.4}$$

where η is the learning rate. For a yes-or-no target, F is a score on the log-odds scale of Chapter 12, and the probability is $\sigma(F)$, the sigmoid. The starting value is the log-odds of the base rate $\bar{y}$ (the share of churners in the training data):

$$F_0 = \ln\frac{\bar{y}}{1-\bar{y}} \tag{19.5}$$

Each new tree is fitted, by ordinary least squares, to the current *residuals*:

$$r_i = y_i - \sigma(F_{m-1}(\mathbf{x}_i)) \tag{19.6}$$

"truth minus prediction", which is exactly the negative gradient of the log-loss with respect to the score, as we derived in Chapter 12 (Equation (19.6) is the gradient step of Chapter 11, taken in the space of functions instead of weights). A tree that predicts the residuals well moves every score in the right direction. The learning rate, typically 0.05 to 0.1, and a small tree depth keep each step modest; too many rounds, though, and boosting begins to fit the noise.

EXAMPLE. Four customers with labels $y = (1,1,0,0)$. The base rate is 0.5, so $F_0 = \ln 1 = 0$ and every predicted probability is $\sigma(0) = 0.5$.

Residuals: $1 - 0.5 = 0.5,\ 0.5,\ -0.5,\ -0.5$. Suppose one feature separates the first two customers from the last two. A one-split tree predicts the mean residual on each side: $+0.5$ and -0.5.

With $\eta = 0.1$: $F_1 = 0 + 0.1 \times 0.5 = 0.05$ for the first two and -0.05 for the last two. New probabilities: $\sigma(0.05) = 0.5125$ and $\sigma(-0.05) = 0.4875$. A small step in the right direction; the next tree will fit the new, slightly smaller residuals.

19.3.5 Judging a ranking: AUC

A churn model is used to *rank* customers, so we judge the ranking. The *area under the ROC curve* (AUC) has a simple meaning:

$$\text{AUC} = P(\hat{p}(\text{random churner}) > \hat{p}(\text{random non-churner})) \tag{19.7}$$

the probability that a randomly chosen customer who did churn gets a higher score than a randomly chosen customer who did not. Random scores give 0.5, a perfect ranking gives 1. Chapter 20 draws ROC curves and computes the AUC from scratch. Alongside it we use a measure the laundry understands directly: if the staff call the 50 customers with the highest scores, how many of them really stopped coming?

19.4 Building It Step by Step

19.4.1 Snapshots

The folder `Chapter019` uses the same `requirements.txt` as Chapter 11 and the same `data/bills.csv` as Chapter 16. **Listing 19.1** builds the snapshots.

Listing 19.1 `features.py`: monthly snapshots with eight features from the past and a 60-day churn label from the future.

```
# features.py - monthly snapshots: what we knew, and what happened next
from pathlib import Path
import numpy as np
import pandas as pd

HORIZON = 60                                        # days to watch after a snapshot
FEATURES = ["recency", "orders_90", "orders_all", "spend_90", "avg_gap",
            "tenure", "express_share", "trend"]

def load_bills(path=None):
    path = path or Path(__file__).parent / "data" / "bills.csv"
    return pd.read_csv(path, parse_dates=["arrived"])

def snapshot(bills, cutoff):
    past = bills[bills["arrived"] < cutoff]
    future = bills[(bills["arrived"] >= cutoff)
                   & (bills["arrived"] < cutoff + pd.Timedelta(days=HORIZON))]
    rows = []
    for cid, g in past.groupby("Customer_id"):
        days = (cutoff - g["arrived"]).dt.days.to_numpy()
        gaps = np.diff(np.sort(g["arrived"].to_numpy())) / np.timedelta64(1, "D")
        recent = days < 90
        rows.append({
            "customer": cid, "cutoff": cutoff,
            "recency": days.min(),
            "orders_90": recent.sum(),
            "orders_all": len(g),
            "spend_90": g.loc[recent, "payment"].sum() / 1000,
            "avg_gap": gaps.mean() if len(gaps) else days.max(),
            "tenure": days.max(),
            "express_share": (g["Service_id"] == "S0002").mean(),
            "trend": (days < 30).sum() - (days[(days >= 30) & (days < 90)]
                                          .size / 2),   # last month vs usual
            "churned": int(cid not in set(future["Customer_id"])),
        })
    return pd.DataFrame(rows)

def build(bills, cutoffs):
    return pd.concat([snapshot(bills, pd.Timestamp(c)) for c in cutoffs],
                     ignore_index=True)
```

Listing 19.1 (Continued) *features.py: monthly snapshots with eight features from the past and a 60-day churn label from the future.*

```
TRAIN_CUTOFFS = ["2026-01-01", "2026-02-01", "2026-03-01", "2026-04-01"]
TEST_CUTOFFS = ["2026-05-01", "2026-06-01", "2026-07-01"]

if __name__ == "__main__":
    bills = load_bills()
    train, test = build(bills, TRAIN_CUTOFFS), build(bills, TEST_CUTOFFS)
    print(f"training rows {len(train)} (churn rate {train.churned.mean():.1%}), "
          f"test rows {len(test)} (churn rate {test.churned.mean():.1%})")
    print(train[FEATURES + ["churned"]].head().round(2).to_string())
```

`snapshot` splits the bills at the cutoff into the past and the next `HORIZON` days. For every customer in the past it computes the eight features, and marks `churned` as 1 if the customer does not appear in the future window. `build` stacks several snapshots. Note that one customer appears in many snapshots, once per month, with different features each time; the model learns from customer-months.

```
training rows 634 (churn rate 21.8%), test rows 656 (churn rate 30.9%)
   recency  orders_90  orders_all  spend_90  avg_gap  tenure  express_share  trend  churned
0       17          2           2     101.0    40.18      57           0.00    0.5        0
1        3          6           6     272.0    12.20      64           0.50    3.0        0
2        9          7           7     333.0     9.54      66           0.00    1.0        0
3       23          1           1      64.0    23.00      23           0.00    1.0        0
4        2          8           8     413.0    12.16      87           0.12    0.5        1
```

The training set has 634 customer-months with a churn rate of 21.8 percent; the test set, 656 with 30.9 percent. The rate is not stable over time: more customers went quiet over the middle of 2026 than early in the year. A model trained on the past must cope with that change, which is typical of real data.

19.4.2 Forests and boosting around single trees

Listing 19.2 builds both ensembles around scikit-learn's single trees, so that the ensemble logic, which is the new idea, stays visible.

Listing 19.2 `ensemble.py`: a random forest and gradient boosting built from single scikit-learn trees.

```
# ensemble.py - random forest and gradient boosting, written around single trees
import numpy as np
from sklearn.metrics import roc_auc_score
from sklearn.tree import DecisionTreeClassifier, DecisionTreeRegressor
from features import FEATURES, TEST_CUTOFFS, TRAIN_CUTOFFS, build, load_bills

class Forest:
    def __init__(self, n_trees=100, seed=0):
        self.n_trees, self.seed = n_trees, seed

    def fit(self, X, y):
        rng = np.random.default_rng(self.seed)
        self.trees = []
        for _ in range(self.n_trees):
            rows = rng.integers(0, len(y), len(y))      # bootstrap sample
            tree = DecisionTreeClassifier(max_features="sqrt", min_samples_leaf=10,
                                          random_state=int(rng.integers(1e9)))
            self.trees.append(tree.fit(X[rows], y[rows]))
        return self

    def predict_proba(self, X):                         # average of the votes
        return np.mean([t.predict_proba(X)[:, 1] for t in self.trees], axis=0)

class Boosting:
    def __init__(self, n_rounds=100, rate=0.1, depth=2):
        self.n_rounds, self.rate, self.depth = n_rounds, rate, depth

    def fit(self, X, y):
        p0 = y.mean()
        self.f0 = np.log(p0 / (1 - p0))                 # start at the base rate
        F = np.full(len(y), self.f0)
        self.trees = []
        for _ in range(self.n_rounds):
            residual = y - 1 / (1 + np.exp(-F))         # truth minus prediction
            tree = DecisionTreeRegressor(max_depth=self.depth, random_state=0)
            tree.fit(X, residual)
            F += self.rate * tree.predict(X)
            self.trees.append(tree)
        return self

    def predict_proba(self, X):
        F = self.f0 + self.rate * sum(t.predict(X) for t in self.trees)
        return 1 / (1 + np.exp(-F))
```

Listing 19.2 (Continued) *ensemble.py: a random forest and gradient boosting built from single scikit-learn trees.*

```
if __name__ == "__main__":
    bills = load_bills()
    train, test = build(bills, TRAIN_CUTOFFS), build(bills, TEST_CUTOFFS)
    X, y = train[FEATURES].to_numpy(float), train["churned"].to_numpy()
    Xt, yt = test[FEATURES].to_numpy(float), test["churned"].to_numpy()
    for seed in range(3):
        tree = DecisionTreeClassifier(min_samples_leaf=10, random_state=seed)
        auc = roc_auc_score(yt, tree.fit(X, y).predict_proba(Xt)[:, 1])
        print(f"single tree, seed {seed}: test AUC {auc:.3f}")
    for n in [1, 10, 100, 300]:
        auc = roc_auc_score(yt, Forest(n).fit(X, y).predict_proba(Xt))
        print(f"forest of {n:3d} trees : test AUC {auc:.3f}")
    for n in [10, 50, 100, 300]:
        auc = roc_auc_score(yt, Boosting(n).fit(X, y).predict_proba(Xt))
        print(f"boosting, {n:3d} rounds: test AUC {auc:.3f}")
```

`Forest.fit` draws a bootstrap sample of row numbers for each tree (Equation (19.1)), and grows a `DecisionTreeClassifier` with `max_features="sqrt"`, so that each split considers only a random $\sqrt{8} \approx 3$ of the eight features, and `min_samples_leaf=10` so that leaves are not tiny. `predict_proba` is Equation (19.2). `Boosting.fit` starts from Equation (19.5), computes the residuals of Equation (19.6), fits a depth-2 `DecisionTreeRegressor` to them, and adds a tenth of its prediction to the scores (Equation (19.4)). The main block compares single trees with three different random seeds against forests and boosting of growing size.

```
single tree, seed 0: test AUC 0.669
single tree, seed 1: test AUC 0.680
single tree, seed 2: test AUC 0.669
forest of   1 trees : test AUC 0.677
forest of  10 trees : test AUC 0.747
forest of 100 trees : test AUC 0.747
forest of 300 trees : test AUC 0.747
boosting,  10 rounds: test AUC 0.737
boosting,  50 rounds: test AUC 0.740
boosting, 100 rounds: test AUC 0.739
boosting, 300 rounds: test AUC 0.725
```

A single tree scores an AUC of 0.669 to 0.680, depending on the seed. A forest of one tree is no better (0.677), but ten trees jump to 0.747, and more trees keep that level: the variance term of Equation (19.3) has been averaged away, and what remains is the shared part. Boosting reaches 0.740 after 50 rounds and then slowly *falls* (0.725 after 300): unlike a forest, boosting can overfit, and the number of rounds must be chosen like any other setting. **Figure 19.2** draws both curves.

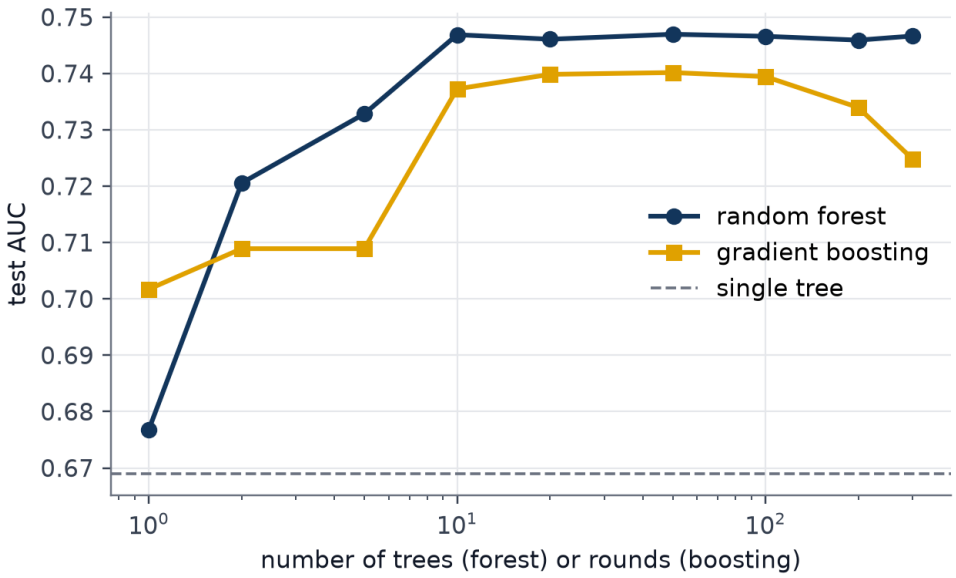

Figure 19.2 Test AUC of the from-scratch random forest and gradient boosting as the number of trees or rounds grows, against a single tree. The forest levels off; boosting peaks and then overfits.

Figure 19.3 summarizes the two ideas side by side.

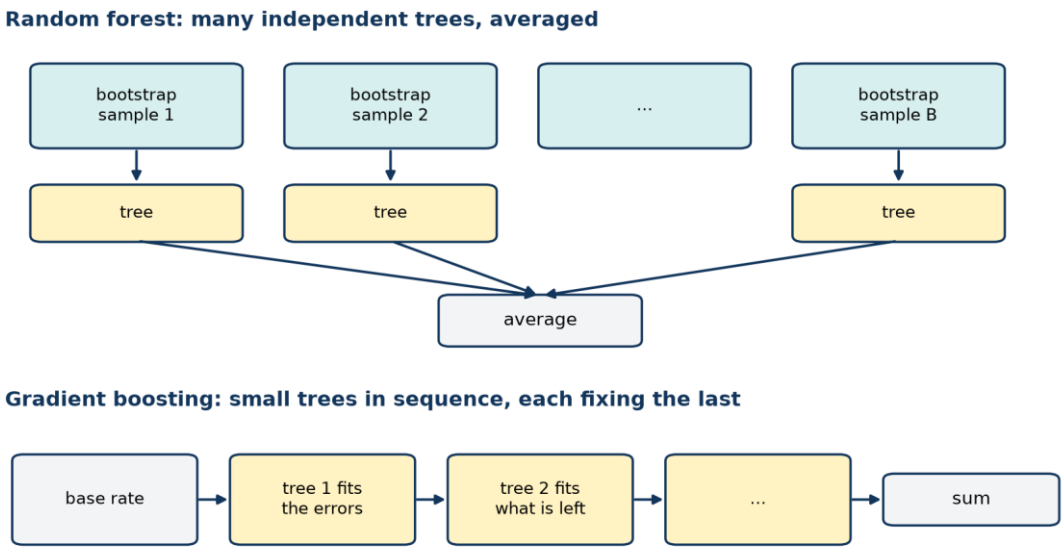

Figure 19.3 The two ensemble ideas: a random forest averages independent trees grown on bootstrap samples; gradient boosting adds small trees in sequence, each fitted to the errors left by the ones before.

19.4.3 scikit-learn's ensembles, and an honest baseline

Listing 19.3 compares scikit-learn's `RandomForestClassifier` and `HistGradientBoostingClassifier` (a fast, histogram-based boosting similar to LightGBM [5], [8]) with a single tree and with logistic regression, and then asks the forest which features matter.

Listing 19.3 `compare.py`: four models compared by test AUC and by the number of real churners among the 50 highest-risk customers; permutation importance for the forest.

```python
# compare.py - scikit-learn's ensembles against a single tree and a linear baseline
import numpy as np
from sklearn.ensemble import (HistGradientBoostingClassifier,
                              RandomForestClassifier)
from sklearn.inspection import permutation_importance
from sklearn.linear_model import LogisticRegression
from sklearn.metrics import roc_auc_score
from sklearn.pipeline import make_pipeline
from sklearn.preprocessing import StandardScaler
from sklearn.tree import DecisionTreeClassifier
from features import FEATURES, TEST_CUTOFFS, TRAIN_CUTOFFS, build, load_bills

bills = load_bills()
train, test = build(bills, TRAIN_CUTOFFS), build(bills, TEST_CUTOFFS)
X, y = train[FEATURES], train["churned"]
Xt, yt = test[FEATURES], test["churned"]
models = {
    "logistic regression": make_pipeline(StandardScaler(), LogisticRegression()),
    "decision tree": DecisionTreeClassifier(max_depth=4, random_state=0),
    "random forest": RandomForestClassifier(n_estimators=500, min_samples_leaf=10,
                                            random_state=0),
    "hist. gradient boosting": HistGradientBoostingClassifier(
        learning_rate=0.05, max_depth=3, max_iter=150, random_state=0),
}
print(f"test: {len(yt)} customer-months, {yt.sum()} churned")
for name, m in models.items():
    p = m.fit(X, y).predict_proba(Xt)[:, 1]
    top = np.argsort(p)[::-1][:50]                  # the 50 most at risk
    print(f"{name:24s} AUC {roc_auc_score(yt, p):.3f}   "
          f"churned among top 50: {yt.iloc[top].sum()}")

rf = models["random forest"]
imp = permutation_importance(rf, Xt, yt, scoring="roc_auc", n_repeats=10,
                             random_state=0)
print("permutation importance (drop in test AUC when a column is shuffled):")
for j in np.argsort(imp.importances_mean)[::-1]:
    print(f"  {FEATURES[j]:14s} {imp.importances_mean[j]:+.3f}")
```

```
test: 656 customer-months, 203 churned
logistic regression      AUC 0.757   churned among top 50: 35
decision tree            AUC 0.690   churned among top 50: 36
random forest            AUC 0.751   churned among top 50: 37
hist. gradient boosting  AUC 0.735   churned among top 50: 33
permutation importance (drop in test AUC when a column is shuffled):
  recency        +0.056
  avg_gap        +0.020
  orders_90      +0.015
  spend_90       +0.010
  tenure         +0.008
  orders_all     +0.007
  express_share  +0.004
  trend          -0.004
```

The single tree reaches an AUC of 0.690; the random forest, 0.751; boosting, 0.735. And the humble logistic regression scores 0.757, the best of the four. That is not a failure of the ensembles but an honest finding about this data: churn here is driven mostly by a few features in a simple, steadily increasing way (the longer since the last visit and the fewer the recent orders, the higher the risk), and a linear model on well-chosen features captures that. Ensembles shine when the effects are nonlinear and interact, as the loan policy of Chapter 14 did; they do not beat a linear model that already fits. In other words, the strength of a method always depends on the shape of the relationship in the data; no method wins on every data set, and the only way to know is to measure. *Always keep a simple baseline*: without it, we would have celebrated the forest's 0.751 without knowing that a model of eight weights does as well.

The business measure tells the same story in words the laundry understands. Of the 656 test customer-months, 203 were churns, 31 percent. Among the 50 customer-months each model ranks highest, 33 to 37 were real churners, about 70 percent: a phone list more than twice as accurate as calling at random.

Permutation importance answers "what does the model rely on?" [8]. Shuffle one column of the test data, breaking its link with the label, and measure how much the AUC drops. Recency matters most by far (0.056), then the average gap between orders, recent orders and recent spending. Shuffling `trend` even *raises* the AUC slightly, meaning the forest gains nothing from it. **Figure 19.4** draws the result with its spread over ten shuffles.

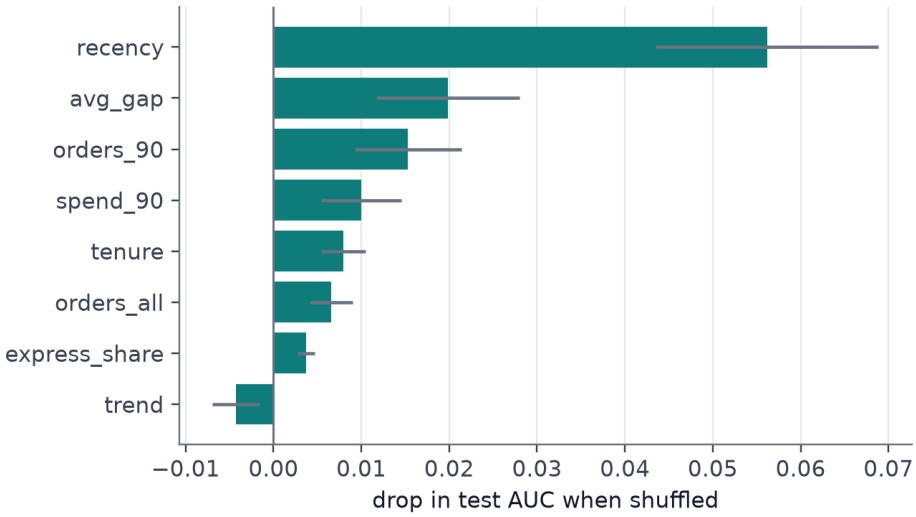

Figure 19.4 Permutation importance of the eight features for the random forest: the drop in test AUC when each column is shuffled, averaged over ten shuffles, with its standard deviation.

19.4.4 The app

Listing 19.4 trains a random forest on all seven months of labeled snapshots, takes a fresh snapshot on October 1, 2026 (whose future is unknown), and lists the customers seen in the last 90 days, sorted by risk. It also shows the expected number of churners, the sum of the probabilities.

Listing 19.4 `churn_app.py`: the churn-risk app for Profitina Laundry.

```
# churn_app.py - who is likely to stop coming in the next 60 days?
import argparse
import pandas as pd
from sklearn.ensemble import RandomForestClassifier
from features import (FEATURES, TEST_CUTOFFS, TRAIN_CUTOFFS, build, load_bills,
                      snapshot)

TODAY = pd.Timestamp("2026-10-01")

def main():
    ap = argparse.ArgumentParser(description="Laundry churn risk")
    ap.add_argument("--customer", help="customer id, e.g. C0047")
    ap.add_argument("--top", type=int, default=10)
    a = ap.parse_args()
    bills = load_bills()
    history = build(bills, TRAIN_CUTOFFS + TEST_CUTOFFS)    # every labeled month
    model = RandomForestClassifier(n_estimators=500, min_samples_leaf=10,
                                   random_state=0)
    model.fit(history[FEATURES], history["churned"])
    now = snapshot(bills, TODAY).drop(columns="churned")    # future unknown
    now["risk"] = model.predict_proba(now[FEATURES])[:, 1]
    now = now.set_index("customer")
    cols = ["risk", "recency", "orders_90", "avg_gap", "orders_all"]
    if a.customer:
        print(now.loc[[a.customer], cols].round(2).to_string())
        return
    active = now[now["recency"] <= 90]              # still reachable customers
    print(f"{len(active)} customers seen in the last 90 days; "
          f"expected to stop: {active['risk'].sum():.0f}")
    top = active.sort_values("risk", ascending=False).head(a.top)
    print(top[cols].round(2).to_string())

if __name__ == "__main__":
    main()
```

19.5 Running It

```
python churn_app.py
```

```
191 customers seen in the last 90 days; expected to stop: 58
          risk  recency  orders_90  avg_gap  orders_all
customer
C0144     0.63       68          1   183.23           2
C0115     0.63       48          2   100.13           4
C0126     0.62       80          1    74.35           4
C0159     0.62       50          1   177.41           2
C0208     0.61       75          1    92.29           2
C0174     0.60       51          2    40.52           5
C0160     0.59       70          1    51.99           4
C0203     0.57       70          1   104.11           2
C0217     0.57       73          1    25.45           4
C0157     0.57       10          3    56.10           5
```

Of the 191 customers seen in the last three months, the model expects about 58 to stop coming in the next 60 days. The list is headed by customers with one or two recent orders who have not come for 50 to 80 days, several of whom used to come only every 100 to 180 days anyway. The model rates them at about 60 percent: it is honest about its uncertainty, and the list is a guide for phone calls, not a verdict. The whole run takes three to seven seconds on the build machine, depending on its load; training the 500 trees takes most of it.

Now the customer from Chapter 16:

```
python churn_app.py --customer C0047
```

```
          risk  recency  orders_90  avg_gap  orders_all
customer
C0047     0.47      101          0    13.17          21
```

A risk of only 0.47 for someone who used to come every 13 days and has now been away for 101 days looks wrong, and it is instructive. In the training snapshots, customers with 21 orders almost never went 100 days without a visit; the model has hardly any examples like C0047, and a forest cannot extrapolate beyond what its leaves have seen. It falls back on the other features (many orders, long tenure) that usually mean loyalty. The app sidesteps the case by listing only customers seen in the last 90 days: C0047 is no longer a churn *risk* but a churned customer, and belongs on the win-back list of Chapter 16. A good system combines a model with such simple, explicit rules.

19.6 Improving It

19.6.1 Watch the split

The most important improvement is not a better algorithm but an honest test. Our training and test snapshots are separated in time. A tempting shortcut is to put all snapshots in one pile and split it at random. Exercise 19.5 does exactly that: the random split reports an AUC of 0.772, against 0.751 for the split in time. The random split is too optimistic, because the same customers appear in training and test in neighboring months with nearly identical features, and because the model gets to see the future months' churn rate during training. When a model will be used on the future, test it on a later period than it was trained on.

19.6.2 Better features

Permutation importance shows that recency and the rhythm of visits carry most of the signal. Features that describe the rhythm more directly may help: the recency *divided by* the customer's usual gap ("how overdue is this customer?"), the change in spending, the number of complaints, whether the last order was picked up late. In our data, the ratio did not raise the AUC noticeably, which is itself useful knowledge; with real data, conversations with the staff ("customers who complain about a lost sock never come back") are the richest source of features.

19.6.3 Tuning, and knowing when to stop

Forests need little tuning: more trees never hurt accuracy, only time, and `min_samples_leaf` or `max_features` are the settings worth trying. Boosting needs more care: the number of rounds, the learning rate and the tree depth interact, and `HistGradientBoostingClassifier` offers *early stopping*, which holds out part of the training data and stops adding trees when the held-out score stops improving. Chapter 20 shows how to compare such settings fairly with cross-validation. Here, with 634 training rows and a mostly linear signal, the returns are small: a list that is right 70 percent of the time is already a large improvement over calling at random, and the next gains will come from better data, not better tuning.

The tests in **Listing 19.5** check that both ensembles learn a simple rule, that boosting with zero rounds predicts the base rate of Equation (19.5), and that a snapshot labels a customer from the next 60 days only.

Listing 19.5 `test_ensemble.py`: tests for the forest, boosting and the snapshot labels.

```python
# test_ensemble.py - run with:  python -m pytest -q
import numpy as np
import pandas as pd
from ensemble import Boosting, Forest
from features import snapshot

def toy():
    rng = np.random.default_rng(0)
    X = rng.normal(size=(300, 3))
    y = (X[:, 0] + 0.5 * X[:, 1] > 0).astype(int)
    return X, y

def test_forest_and_boosting_learn_a_simple_rule():
    X, y = toy()
    for model in (Forest(30), Boosting(50)):
        p = model.fit(X, y).predict_proba(X)
        assert np.mean((p >= 0.5) == y) > 0.9
        assert p.min() >= 0 and p.max() <= 1

def test_boosting_with_no_rounds_predicts_the_base_rate():
    X, y = toy()
    p = Boosting(n_rounds=0).fit(X, y).predict_proba(X)
    assert np.allclose(p, y.mean())

def test_snapshot_label_looks_only_at_the_next_60_days():
    bills = pd.DataFrame({
        "arrived": pd.to_datetime(["2026-01-05", "2026-02-10", "2026-01-07"]),
        "payment": [10000.0, 12000.0, 8000.0],
        "Customer_id": ["A", "A", "B"], "Service_id": ["S0001"] * 3})
    s = snapshot(bills, pd.Timestamp("2026-02-01")).set_index("customer")
    assert s.loc["A", "churned"] == 0 and s.loc["B", "churned"] == 1
    assert s.loc["A", "recency"] == 27
```

```
...                                                                  [100%]
3 passed in 1.25s
```

19.7 Common Mistakes, and How to Avoid Them

Leaking the future into the features. Every feature must be computable at the cutoff date from data available then. A feature like "total orders this year" computed over the whole year includes the very future we are predicting.

Splitting time-ordered data at random. Neighboring snapshots of the same customer are nearly identical, and a random split lets the model see the answer's twin. Split by time (Exercise 19.5).

Skipping the baseline. Compare every ensemble with logistic regression and with a one-feature rule (here, recency alone). A complex model that does not beat them is not worth its cost.

Boosting too long. Unlike forests, boosting overfits with too many rounds. Use early stopping or choose the number of rounds by validation.

Trusting impurity-based importances. The built-in `feature_importances_` of trees favor features with many distinct values. Permutation importance on held-out data is more trustworthy.

Treating scores as certainties. A risk of 0.6 means that about six in ten such customers stop. Use the ranking to prioritize calls, and keep the explicit rules (such as "no visit for 90 days") that a model may miss.

19.8 Chapter Summary

- Churn is defined as something observable, here "no order in the next 60 days", and the log is turned into monthly snapshots with features from before and labels from after each cutoff.
- A random forest averages trees grown on bootstrap samples (Equation (19.1)) with random feature subsets (Equation (19.2)); averaging removes the variance the trees do not share (Equation (19.3)).
- Gradient boosting adds small trees fitted to the residuals (Equation (19.4), Equation (19.5), Equation (19.6)); it reduces bias but can overfit with too many rounds.
- The AUC (Equation (19.7)) judges a ranking; the number of real churners among the top 50 turns it into business terms.
- On the laundry data the ensembles lifted the AUC from a single tree's 0.67–0.69 to about 0.75, but logistic regression did just as well: a simple baseline is essential.
- Permutation importance showed that recency and the rhythm of visits carry the signal; a random split of snapshots overstated the AUC compared with an honest split in time.

19.9 Exercises

1. Compute the probability that a given row is left out of a bootstrap sample for $n = 5$ and for $n = 450$, and compare with e^{-1}.
2. Using Equation (19.3) with $\sigma^2 = 1$, compute the variance of an average of $B = 1{,}10{,}100$ trees for $\rho = 0.3$, and for $\rho = 0.8$. What does this say about why random forests pick random features at each split?
3. Continue the boosting example of Section 19.3.4 for one more round: compute the new residuals, the tree's predictions, and the new probabilities.
4. Explain, from the numbers printed by the app, why customer C0047 gets a risk of only 0.47, and suggest a rule or a feature that would flag such a customer.
5. Split all seven months of snapshots at random into training and test sets of the same sizes as the time split, and compare the AUC with the split in time. How many customers appear on both sides of the random split?
6. A call costs Rp 2,000 of staff time. A customer who stays is worth Rp 100,000 over the next six months, and a call persuades 20 percent of would-be churners to stay. Above what predicted churn probability is a call worth making?

19.10 Solutions to the Exercises

Exercise 19.1. $n = 5$: $(4/5)^5 = 0.328$. $n = 450$: $(449/450)^{450} = e^{450\ln(449/450)} = e^{-1.0011} = 0.3675$. $e^{-1} = 0.3679$. Already for a few hundred rows the limit is reached: about 37 percent of rows are out of each bootstrap sample.

Exercise 19.2. $\rho = 0.3$: $B = 1$ gives $0.3 + 0.7 = 1$; $B = 10$ gives $0.3 + 0.07 = 0.37$; $B = 100$ gives $0.3 + 0.007 = 0.307$. $\rho = 0.8$: 1, $0.8 + 0.02 = 0.82$, 0.802. With highly correlated trees, averaging hardly helps: the floor $\rho\sigma^2$ dominates. Choosing random features at every split makes the trees

disagree more, lowering ρ and therefore the floor, even though each individual tree gets slightly worse.

Exercise 19.3. After round 1 the probabilities are 0.5125,0.5125,0.4875,0.4875. Residuals: $1 - 0.5125 = 0.4875$ (twice) and $0 - 0.4875 = -0.4875$ (twice). The same split gives tree predictions $+0.4875$ and -0.4875. With $\eta = 0.1$: $F_2 = 0.05 + 0.04875 = 0.09875$ and -0.09875. Probabilities: $\sigma(0.09875) = 0.5247$ and 0.4753. Each round moves the probabilities a little further toward the labels, with steps that shrink as the residuals shrink.

Exercise 19.4. C0047 has 21 orders, a usual gap of 13 days, and a recency of 101 days with no orders in the last 90. In the training snapshots, customers with so many orders and such a short usual gap almost never had a recency near 100, so the forest has no leaf built from such cases; its trees route the customer by the familiar features (many orders, long tenure) toward low-risk leaves. A rule "recency above three times the usual gap: flag", or the feature recency divided by usual gap (7.7 here), would catch it; so would simply treating anyone unseen for 90 days as churned, which the app does.

Exercise 19.5. **Listing 19.6** trains the same forest on both splits.

Listing 19.6 `solutions/ex_split.py`: the AUC of a random split of snapshots against a split in time.

```
# ex_split.py - Exercise 19.5: a random split of snapshots versus a split in time
import sys
from pathlib import Path
from sklearn.ensemble import RandomForestClassifier
from sklearn.metrics import roc_auc_score
from sklearn.model_selection import train_test_split
sys.path.insert(0, str(Path(__file__).resolve().parent.parent))
from features import FEATURES, TEST_CUTOFFS, TRAIN_CUTOFFS, build, load_bills

bills = load_bills()
train, test = build(bills, TRAIN_CUTOFFS), build(bills, TEST_CUTOFFS)
data = build(bills, TRAIN_CUTOFFS + TEST_CUTOFFS)
rand_tr, rand_te = train_test_split(data, test_size=len(test), random_state=0)

def auc(tr, te):
    m = RandomForestClassifier(n_estimators=300, min_samples_leaf=10,
                               random_state=0).fit(tr[FEATURES], tr["churned"])
    return roc_auc_score(te["churned"], m.predict_proba(te[FEATURES])[:, 1])

print(f"split in time (past -> future): AUC {auc(train, test):.3f}")
print(f"random split of all snapshots : AUC {auc(rand_tr, rand_te):.3f}")
shared = set(rand_tr["customer"]) & set(rand_te["customer"])
print(f"customers on both sides of the random split: {len(shared)}")
```

```
split in time (past -> future): AUC 0.751
random split of all snapshots : AUC 0.772
customers on both sides of the random split: 207
```

The random split reports 0.772, the time split 0.751. The difference comes from 207 customers who appear on both sides of the random split, often in neighboring months with nearly the same features, and from the random split mixing the lower early churn rate and the higher later one on both sides. The time split is the honest estimate of how the model will do next month. The gap of 0.02 looks small, but it is larger than the difference between the forest and logistic regression, so a random split could easily lead to choosing the wrong model.

Exercise 19.6. A call is worth making when its expected gain exceeds its cost: $p \times 0.2 \times 100{,}000 > 2{,}000$, that is $p > 0.1$. Any customer with a predicted churn probability above 10 percent is worth a call; with the app's list, that is almost everyone at the top, and the real limit is the staff's time. If the staff can make 20 calls a day, call the 20 highest scores.

Chapter 20

Model Evaluation Dashboard: Metrics, ROC and Cross-Validation

Every chapter of this part ended with numbers: an RMSE, an accuracy, a recall, an AUC. This last chapter of Part 2 steps back and asks how such numbers should be computed, compared and trusted, and builds a dashboard that shows them honestly. We evaluate six classifiers from the earlier chapters on one medical data set, where the difference between a missed case and a false alarm is not a matter of convenience. By the end of the chapter you will be able to derive every common classification metric from the four cells of a confusion matrix, and say which question each one answers; compute an ROC curve and its area from scratch, two different ways; explain why a single train/test split is not enough and how stratified k-fold cross-validation fixes it; report a result as a mean with its spread across folds; compare two models fairly with paired fold-by-fold differences; choose a decision threshold from the costs of the two kinds of error; and generate a self-contained HTML dashboard, served on your own machine, that puts all of this on one page.

20.1 Why an Evaluation Dashboard?

A model is only as useful as our knowledge of how good it is. In Chapter 12 a spam filter scored 93 percent accuracy on 54 test messages, and we had to warn that one message was worth almost two percentage points. In Chapter 19 a random split of snapshots made a churn model look better than an honest split in time. In Chapter 18 a digit recognizer that scored 98.5 percent in the lab read half of the slightly shifted digits wrongly. Each time the model was fine; the *measurement* was the problem.

The stakes are clearest in medicine. The data set of this chapter, bundled with scikit-learn, holds 569 breast tumor biopsies from the University of Wisconsin, each described by 30 measurements of the cell nuclei in a digitized image, and labeled benign or malignant after diagnosis [1]. We met it briefly in Chapter 17, where PCA showed the two kinds separating. A classifier that says “benign” about a malignant tumor sends a patient home; one that says “malignant” about a benign tumor sends a worried patient for another test. Both are errors, but they are not equal, and a single number called “accuracy” cannot tell them apart. (This chapter uses the data to teach evaluation; nothing here is a diagnostic tool.)

The dashboard we build compares six models (logistic regression, k-NN, a decision tree, a random forest, an SVM and naive Bayes) with one protocol, and shows the result on one page:

```
python evaluate.py
python dashboard.py --serve
```

20.2 The Idea in Plain Words

Judging a classifier is like judging a security guard at a mall entrance who must decide, for each visitor, whether to search their bag. Four things can happen. The guard stops someone who is carrying something forbidden: a catch. The guard waves through someone who is carrying

something: a miss. The guard stops an innocent shopper: a false alarm. The guard waves through an innocent shopper: a correct clearance. Counting these four outcomes over a day is the *confusion matrix*, and every metric in this chapter is a way of combining the four counts to answer a particular question. "Of the people stopped, how many were carrying something?" "Of the people carrying something, how many were stopped?" A strict guard catches more and annoys more; a relaxed guard annoys fewer and misses more. The *threshold* is how strict the guard is, and the *ROC curve* shows every possible strictness at once.

The second idea is about luck. If we judge the guard on one hour of one day, we may have picked an easy hour. Better to judge on many different hours and look at both the average and how much it varies. *Cross-validation* does this for models: it splits the data into k parts, holds each part out in turn, trains on the rest, and scores on the part held out. Every example is used for testing exactly once, and we get k scores instead of one, so we can see the spread.

The third idea is fairness in comparison. If guard A had a better average than guard B, but they were judged on different days, the difference might be the days. Judge them on the *same* hours, and compare hour by hour: that is a *paired* comparison, and it is much more sensitive.

> **KEY INSIGHT:** A metric answers a question; choose the question first. Measure on data the model did not train on, repeat the measurement over several splits, report the spread along with the mean, and compare models on the same splits.

20.3 The Mathematics, Gently

20.3.1 The confusion matrix and its metrics

Call "malignant" the *positive* class (the one we are looking for) and "benign" the *negative* class. **Figure 20.1** lays out the four cells: true positives (TP), false negatives (FN), false positives (FP) and true negatives (TN).

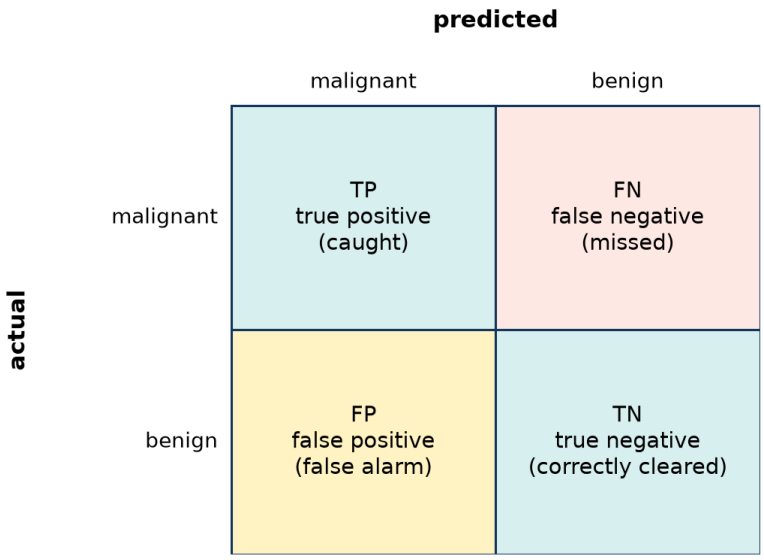

Figure 20.1 The confusion matrix for a two-class problem: rows are the actual classes, columns the predicted ones.

From these four counts, with $n = TP + FP + FN + TN$:

$$\text{accuracy} = \frac{TP + TN}{n} \tag{20.1}$$

the share of all cases that were classified correctly;

$$\text{precision} = \frac{TP}{TP + FP}, \qquad \text{recall} = \frac{TP}{TP + FN} \tag{20.2}$$

(of those called malignant, how many were; of those that were malignant, how many we caught; recall is also called *sensitivity* or the *true positive rate*);

$$\text{specificity} = \frac{TN}{TN + FP}, \qquad \text{FPR} = \frac{FP}{FP + TN} = 1 - \text{specificity} \tag{20.3}$$

(of the benign cases, how many were cleared correctly, and its complement, the *false positive rate*). Precision and recall are combined into one number by their *harmonic mean*, the F1 score:

$$F_1 = \frac{2 \cdot \text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}} \tag{20.4}$$

The harmonic mean punishes imbalance: a model with precision 1.0 and recall 0.1 has an arithmetic mean of 0.55 but an F_1 of only 0.18. Chapter 12 introduced precision and recall for the spam filter; the rest of the family is completed here [2].

EXAMPLE. The dashboard's confusion matrix for logistic regression at threshold 0.5 (Section 20.5): TP 199, FN 13, FP 2, TN 355, so $n = 569$.

Accuracy: $(199 + 355)/569 = 554/569 = 0.974$. Precision: $199/201 = 0.990$. Recall: $199/212 = 0.939$. Specificity: $355/357 = 0.994$. FPR: $2/357 = 0.006$.

$F_1 = 2 \times 0.990 \times 0.939/(0.990 + 0.939) = 1.859/1.929 = 0.964$.

In words: of 212 malignant tumors, 13 were missed; of 357 benign ones, 2 raised a false alarm.

Which of these numbers to watch depends on the question. For the spam filter of Chapter 12, where a lost customer message is expensive, precision matters most. For cancer screening, where a missed tumor is the worst outcome, recall matters most. For the churn list of Chapter 19, where the staff can call only fifty people, the precision of the top of the list matters most. Accuracy is the right headline only when both kinds of error cost about the same and the classes are roughly balanced, which is rarer than it seems.

20.3.2 The ROC curve and its area

A classifier that outputs a score (a probability, or a distance from an SVM's boundary) becomes a yes-or-no rule only when we choose a threshold: "malignant if score $\geq t$". Every threshold gives one confusion matrix and hence one pair (FPR, recall). The *receiver operating characteristic* (ROC) curve plots recall, the true positive rate (TPR), against FPR for every possible threshold [3]:

$$\text{TPR}(t) = \frac{\#\{\text{positives with score} \geq t\}}{\#\,\text{positives}}, \qquad \text{FPR}(t) = \frac{\#\{\text{negatives with score} \geq t\}}{\#\,\text{negatives}} \tag{20.5}$$

At a very high threshold nothing is flagged: the point (0, 0). At a very low one everything is: the point (1, 1). A perfect model reaches (0, 1), all positives caught with no false alarms. A model that

guesses at random lies on the diagonal. To draw the curve we sort the cases by score, highest first, and walk down the list: each positive steps the curve up by $1/P$ and each negative steps it right by $1/N$, where P and N are the numbers of positives and negatives.

The *area under the curve* (AUC) summarizes the whole curve in one number. Computed geometrically, by trapezoids between consecutive points (x_{j-1}, y_{j-1}) and (x_j, y_j):

$$\mathrm{AUC} = \sum_{j} (x_j - x_{j-1}) \, \frac{y_j + y_{j-1}}{2} \tag{20.6}$$

Remarkably, the same number has a probabilistic meaning, shown by Hanley and McNeil [4]: it is the probability that a randomly chosen positive gets a higher score than a randomly chosen negative, counting ties as half:

$$\mathrm{AUC} = \frac{1}{PN} \sum_{i \in \mathrm{pos}} \sum_{l \in \mathrm{neg}} \left([s_i > s_l] + \frac{1}{2} [s_i = s_l] \right) \tag{20.7}$$

We compute both in Section 20.4 and they agree to every digit. The AUC does not depend on any threshold, which makes it the right number for comparing *rankings*; but when a model will be used at one particular threshold, the confusion matrix at that threshold matters more.

20.3.3 Cross-validation

In k-fold cross-validation the n examples are divided into k folds of nearly equal size. In round f, fold f is the validation set and the other $k - 1$ folds are the training set (**Figure 20.2**). Each round gives a score s_f; we report their mean and standard deviation

$$\bar{s} = \frac{1}{k} \sum_{f=1}^{k} s_f \,, \qquad \mathrm{sd} = \sqrt{\frac{1}{k} \sum_{f=1}^{k} (s_f - \bar{s})^2} \tag{20.8}$$

The mean estimates how well the method does on new data; the standard deviation shows how much a single split could mislead. *Stratified* folds keep the share of each class the same in every fold (here about 37 percent malignant), so that no fold is accidentally easy or hard. With $k = 10$ each model is trained ten times on 90 percent of the data, a standard choice supported by Kohavi's classic study [5].

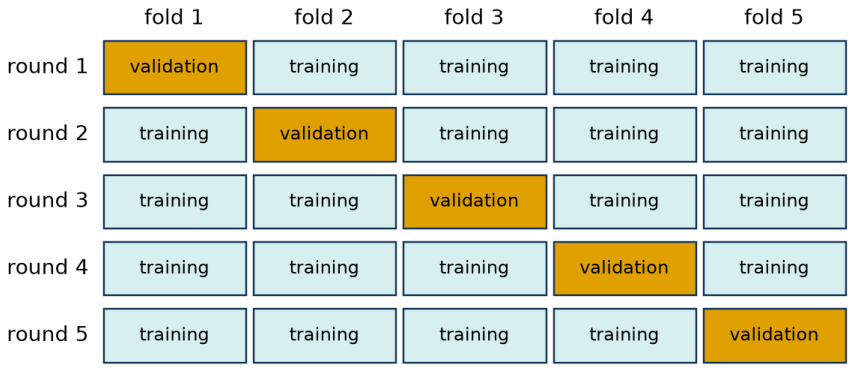

Figure 20.2 Five-fold cross-validation: in each round a different fold is held out for validation and the model is trained on the other four. Every example is validated exactly once.

20.3.4 Comparing two models fairly

Two models evaluated on the *same* folds give paired scores a_f and b_f. Their differences $d_f = a_f - b_f$ remove the variation that comes from the folds themselves (some folds are simply harder for everyone). The average difference and its standard error

$$\bar{d} = \frac{1}{k}\sum_{f=1}^{k} d_f\,, \qquad \mathrm{SE}(\bar{d}) = \frac{\mathrm{sd}(d)}{\sqrt{k}} \tag{20.9}$$

(with $\mathrm{sd}(d)$ computed with $k-1$ in the denominator) give a rough sense of whether one model is really better: if $\bar{d}$ is not clearly larger than about two standard errors, the data cannot tell the models apart. Folds share training data, so this is only an approximation; Dietterich discusses more careful tests [6]. Counting the folds in which each model wins is a simple, robust complement.

20.4 Building It Step by Step

20.4.1 Metrics from scratch

The folder `Chapter020` needs NumPy, scikit-learn, matplotlib (for the dashboard's charts) and pytest:

```
numpy==2.4.6
scikit-learn==1.9.1
matplotlib==3.11.2
pytest==9.1.1
```

Listing 20.1 implements Section 20.3 and checks it against scikit-learn on one fold of the data.

Listing 20.1 `metrics.py`: the confusion matrix, derived scores, ROC curve, AUC two ways and stratified folds, from scratch.

```python
# metrics.py - evaluation metrics from scratch: confusion, F1, ROC, AUC, k folds
import numpy as np

def confusion(y, yhat):
    tp = int(np.sum((y == 1) & (yhat == 1)))
    fp = int(np.sum((y == 0) & (yhat == 1)))
    fn = int(np.sum((y == 1) & (yhat == 0)))
    tn = int(np.sum((y == 0) & (yhat == 0)))
    return tp, fp, fn, tn

def scores(y, yhat):
    tp, fp, fn, tn = confusion(y, yhat)
    precision = tp / (tp + fp) if tp + fp else 0.0
    recall = tp / (tp + fn) if tp + fn else 0.0
    f1 = (2 * precision * recall / (precision + recall)
          if precision + recall else 0.0)
    return {"accuracy": (tp + tn) / len(y), "precision": precision,
            "recall": recall, "specificity": tn / (tn + fp) if tn + fp else 0.0,
            "f1": f1}

def roc_curve(y, score):
    order = np.argsort(-score, kind="stable")          # highest score first
    y, score = y[order], score[order]
    tps = np.cumsum(y)                                 # flagged and positive
    fps = np.cumsum(1 - y)                             # flagged and negative
    last = np.r_[np.flatnonzero(np.diff(score)), len(y) - 1]   # tie groups
    tpr = np.r_[0, tps[last] / y.sum()]
    fpr = np.r_[0, fps[last] / (len(y) - y.sum())]
    return fpr, tpr, np.r_[np.inf, score[last]]

def auc_trapezoid(fpr, tpr):
    return float(np.sum(np.diff(fpr) * (tpr[1:] + tpr[:-1]) / 2))

def auc_rank(y, score):
    # probability that a random positive outranks a random negative
    pos, neg = score[y == 1], score[y == 0]
    wins = (pos[:, None] > neg[None, :]).sum() + 0.5 * (
        pos[:, None] == neg[None, :]).sum()
    return wins / (len(pos) * len(neg))
```

Listing 20.1 (Continued) *metrics.py: the confusion matrix, derived scores, ROC curve, AUC two ways and stratified folds, from scratch.*

```
def stratified_folds(y, k=5, seed=0):
    rng = np.random.default_rng(seed)
    fold = np.empty(len(y), dtype=int)
    for c in np.unique(y):
        idx = rng.permutation(np.flatnonzero(y == c))
        fold[idx] = np.arange(len(idx)) % k            # deal like playing cards
    return [(np.flatnonzero(fold != f), np.flatnonzero(fold == f))
            for f in range(k)]

if __name__ == "__main__":
    from sklearn import metrics as skm
    from sklearn.datasets import load_breast_cancer
    from sklearn.linear_model import LogisticRegression
    from sklearn.pipeline import make_pipeline
    from sklearn.preprocessing import StandardScaler

    data = load_breast_cancer()
    X, y = data.data, 1 - data.target                  # 1 = malignant
    tr, te = stratified_folds(y, k=4, seed=20)[0]
    model = make_pipeline(StandardScaler(), LogisticRegression(C=0.1))
    p = model.fit(X[tr], y[tr]).predict_proba(X[te])[:, 1]
    yhat = (p >= 0.5).astype(int)
    print("confusion (TP, FP, FN, TN):", confusion(y[te], yhat))
    for name, v in scores(y[te], yhat).items():
        print(f"  {name:11s} {v:.3f}")
    fpr, tpr, _ = roc_curve(y[te], p)
    print(f"AUC by trapezoids {auc_trapezoid(fpr, tpr):.4f}, "
          f"by ranks {auc_rank(y[te], p):.4f}, "
          f"scikit-learn {skm.roc_auc_score(y[te], p):.4f}")
    print(f"scikit-learn F1 {skm.f1_score(y[te], yhat):.3f}")
```

`confusion` counts the four cells; `scores` applies Equation (20.1) to Equation (20.4), returning 0 when a denominator is empty. `roc_curve` sorts by score, highest first, and accumulates true and false positives; the variable `last` marks the end of each group of tied scores, so that tied cases enter the curve together (otherwise the curve would depend on the arbitrary order of ties). It returns the points of Equation (20.5). `auc_trapezoid` is Equation (20.6); `auc_rank` is Equation (20.7), comparing every positive with every negative through broadcasting. `stratified_folds` shuffles each class separately and deals its members round the k folds like playing cards, so each fold gets its share of each class.

The main block labels malignant tumors 1 (scikit-learn codes them 0, so we flip the target), holds out one of four stratified folds, fits a regularized logistic regression, and evaluates at threshold 0.5:

```
confusion (TP, FP, FN, TN): (49, 0, 4, 90)
  accuracy    0.972
  precision   1.000
  recall      0.925
  specificity 1.000
  f1          0.961
AUC by trapezoids 0.9990, by ranks 0.9990, scikit-learn 0.9990
scikit-learn F1 0.961
```

On this fold of 143 tumors the model misses 4 of 53 malignant ones and raises no false alarm. The three AUC computations, trapezoids, ranks and scikit-learn's `roc_auc_score`, agree to four decimals, and so does the F_1 [2].

20.4.2 Six models, one protocol

Listing 20.2 evaluates six models with the same stratified 10-fold cross-validation, using scikit-learn's `cross_validate` for five metrics at once and `cross_val_predict` for *out-of-fold* scores: for each tumor, the score given by the model trained on the nine folds that did not contain it [7]. Models that depend on distances (k-NN, SVM) or on a penalty (logistic regression) are wrapped in a pipeline with `StandardScaler`, so that scaling is learned inside each training fold.

Listing 20.2 `evaluate.py`: six classifiers evaluated with stratified 10-fold cross-validation, with out-of-fold scores saved for the dashboard.

```
# evaluate.py - six models, one honest protocol: stratified 10-fold cross-validation

    print(f"{len(y)} tumors, {y.sum()} malignant; 10 folds of about "
          f"{len(y) // 10}")
    print(f"{'model':20s} {'accuracy':>14s} {'recall':>14s} {'AUC':>14s}")
    for name in MODELS:
        r = res[name]
        cells = [f"{np.mean(r[m]):.3f} +/- {np.std(r[m]):.3f}"
                 for m in ("accuracy", "recall", "roc_auc")]
        print(f"{name:20s} " + " ".join(f"{c:>14s}" for c in cells))
    out = Path(__file__).parent / "outputs" / "results.json"
    out.write_text(json.dumps(res))
    print("saved", out.name)
```

```
569 tumors, 212 malignant; 10 folds of about 56
model                       accuracy         recall            AUC
logistic regression  0.974 +/- 0.018 0.939 +/- 0.050 0.996 +/- 0.007
k-NN (k = 7)         0.961 +/- 0.027 0.911 +/- 0.079 0.986 +/- 0.013
decision tree        0.942 +/- 0.035 0.902 +/- 0.067 0.936 +/- 0.049
random forest        0.963 +/- 0.024 0.944 +/- 0.041 0.991 +/- 0.012
SVM (RBF)            0.975 +/- 0.014 0.958 +/- 0.043 0.997 +/- 0.005
naive Bayes          0.938 +/- 0.034 0.892 +/- 0.075 0.987 +/- 0.011
saved results.json
```

The whole run takes about 30 seconds, most of it the random forest trained ten times plus ten more times for the out-of-fold scores. The table deserves careful reading.

- The SVM (0.975) and logistic regression (0.974) have the best accuracy, but their difference, 0.001, is tiny next to the fold-to-fold spread of 0.014 to 0.018. Section 20.6 compares them properly.
- The single decision tree is the weakest by AUC (0.936) and the most variable (standard deviation 0.049), exactly the nervousness Chapter 19 described; the random forest built from such trees reaches 0.991.
- Recall, the share of malignant tumors caught, is lower than accuracy for every model (0.892 to 0.958): at threshold 0.5 the models err more often on the side of "benign". Accuracy hides this; recall shows it.

20.4.3 The dashboard

Listing 20.3 turns the saved results into one self-contained HTML page. It draws the ROC curves of all six models from their out-of-fold scores and a box plot of the ten fold accuracies of each, embeds both images in the page as base64 text (so the page is a single file you can e-mail), and adds three tables: the cross-validated metrics, the confusion matrix of one chosen model at one chosen threshold, and a sweep of recall, precision and F_1 over six thresholds. With `--serve` it starts Python's built-in web server on port 5020, so the page can be opened at `http://localhost:5020/dashboard.html`.

Listing 20.3 `dashboard.py`: the model evaluation dashboard as a single HTML page, optionally served on port 5020.

```python
# dashboard.py - one HTML page that answers "which model, and how sure are we?"
import argparse
import base64
import io
import json
from pathlib import Path
import numpy as np
import matplotlib
matplotlib.use("Agg")

    main()
```

One line of this program carries a current detail. For years, horizontal box plots were requested with `boxplot(..., vert=False)`; in matplotlib 3.11 the `vert` argument is deprecated in favor of `orientation="horizontal"`, and it will be removed in 3.13 [8]. The first version of this program used `vert=False` and printed a deprecation warning; the listing uses the new form. Warnings like this are worth reading: they are the library telling you which line will break next year. Running your programs against the newest library versions from time to time is a cheap way to find such lines before your users do.

20.5 Running It

```
python dashboard.py
```

```
wrote dashboard.html: 6 models; logistic regression at threshold 0.5: TP 199, FN 13, FP 2,
TN 355
```

Figure 20.3 shows the page as served on port 5020 and captured in a browser.

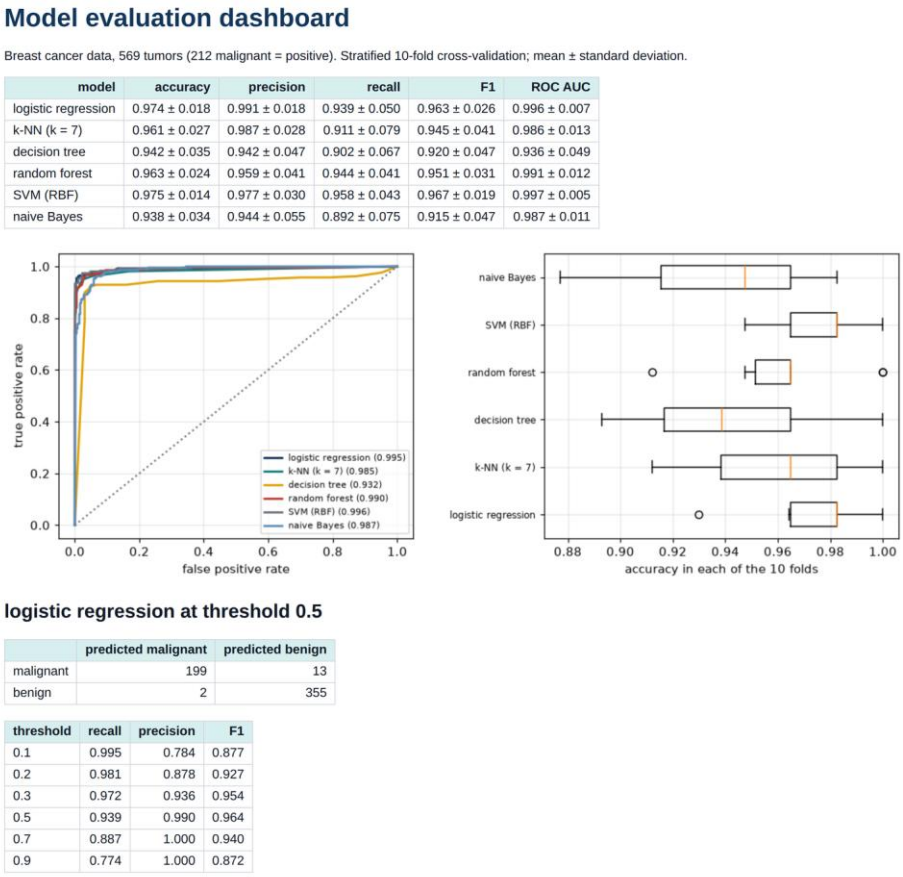

Figure 20.3 The evaluation dashboard in a browser: cross-validated metrics of six models, their ROC curves and fold-by-fold accuracies, and the confusion matrix and threshold sweep of logistic regression.

The ROC curves hug the top-left corner for every model except the decision tree. The legend's AUC values (0.995 for logistic regression) differ slightly from the table's (0.996): the legend pools the out-of-fold scores of all ten folds into one curve, while the table averages the ten per-fold AUCs. Both are legitimate; they answer slightly different questions, and a report should say which one it gives. **Figure 20.4** redraws the curves in the house style with a zoom on the top-left corner, where the models differ.

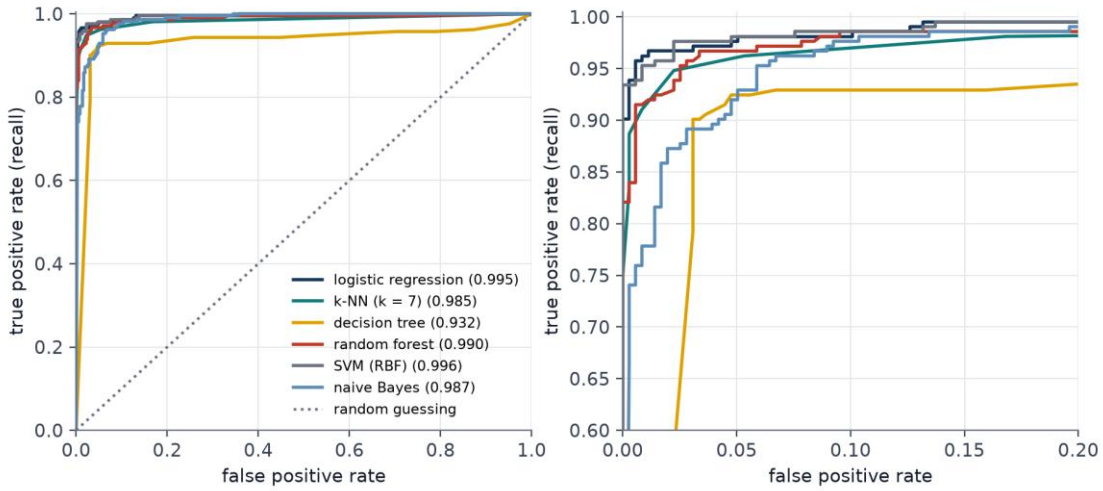

Figure 20.4 ROC curves of the six models from out-of-fold scores (left) and the top-left corner enlarged (right), with the pooled AUC in the legend.

The threshold sweep in the dashboard is where evaluation meets decision. At 0.5, logistic regression misses 13 malignant tumors. Lowering the threshold to 0.2:

```
python dashboard.py --threshold 0.2
```

```
wrote dashboard.html: 6 models; logistic regression at threshold 0.2: TP 208, FN 4, FP 29,
TN 328
```

misses only 4, at the price of 29 false alarms instead of 2. For screening, where a false alarm means a further examination and a miss means a cancer left untreated, that trade is usually worth making; for a test with painful or costly follow-up, perhaps not. The dashboard does not make the choice; it shows the consequences of each choice so that the people responsible can make it. The page builds in about a second; serving it takes no noticeable time. The server keeps running until you press Ctrl+C.

20.6 Improving It

20.6.1 Compare models in pairs

Is the SVM better than logistic regression? Their mean accuracies differ by 0.0018, and each has a fold spread near 0.015. Exercise 20.3 compares them fold by fold, as in Equation (20.9): the SVM wins 4 folds, loses 2 and ties 4, and the mean difference in accuracy (+0.0018) is small against its standard error (about 0.0055). The data cannot separate the two models. Faced with a tie, prefer the simpler and more explainable model: logistic regression's thirty weights can be read, checked by a doctor, and explained to a patient.

20.6.2 Do not choose and report on the same numbers

We picked "the best" among six models by their cross-validated scores. If we now report that best score as the expected performance, we are optimistic: with six candidates, the winner is partly the one that got lucky on these folds. The clean remedy is *nested cross-validation*: an outer loop of folds for reporting, and inside each outer training set an inner loop for choosing the model and its settings [9]. A simpler remedy, when data allow, is to keep a final test set aside from the start and look at it once, after every choice has been made. The same applies to choosing a threshold: the sweep in the dashboard uses out-of-fold scores, which is fair for exploring, but the chosen threshold's performance should be confirmed on data not used to choose it.

20.6.3 More than accuracy on the page

Useful additions to the dashboard are a *precision–recall curve*, which is more informative than the ROC curve when positives are rare (as in fraud or rare diseases), a *calibration plot*, which checks whether "70 percent" really means seven in ten, and a breakdown of errors by subgroup, as Chapter 14 showed for loan applicants. Chapter 70 builds evaluation and backtesting for forecasts, Chapter 89 an evaluation harness for language models, and Chapter 98 monitoring for models in production, all extending the ideas of this chapter.

The tests of **Listing 20.4** check the metrics on a hand-made example, both AUC computations against scikit-learn on random scores, and that the stratified folds cover every example once with the right class balance.

Listing 20.4 `test_metrics.py`: tests for the confusion matrix, the two AUC computations and the stratified folds.

```python
# test_metrics.py - run with:  python -m pytest -q
import numpy as np
from sklearn.metrics import roc_auc_score
from metrics import (auc_rank, auc_trapezoid, confusion, roc_curve, scores,
                     stratified_folds)

def test_confusion_and_scores_by_hand():
    y = np.array([1, 1, 0, 1, 0])
    yhat = np.array([1, 0, 0, 1, 1])
    assert confusion(y, yhat) == (2, 1, 1, 1)
    s = scores(y, yhat)
    assert np.isclose(s["precision"], 2 / 3) and np.isclose(s["recall"], 2 / 3)

def test_auc_two_ways_and_against_scikit_learn():
    rng = np.random.default_rng(3)
    y = rng.integers(0, 2, 200)
    score = y + rng.normal(0, 1, 200)
    fpr, tpr, _ = roc_curve(y, score)
    assert np.isclose(auc_trapezoid(fpr, tpr), roc_auc_score(y, score))
    assert np.isclose(auc_rank(y, score), roc_auc_score(y, score))

def test_folds_are_stratified_and_cover_everything():
    y = np.array([1] * 20 + [0] * 30)
    folds = stratified_folds(y, k=5)
    assert sorted(np.concatenate([te for _, te in folds])) == list(range(50))
    assert all(y[te].sum() == 4 for _, te in folds)
```

```
...                                                                  [100%]
3 passed in 2.60s
```

20.7 Common Mistakes, and How to Avoid Them

Reporting accuracy alone. On imbalanced data a useless model can score high accuracy. Report recall and precision (or specificity) for the class that matters, and the confusion matrix.

Scaling or selecting features outside the cross-validation. A scaler, a PCA or a feature selector fitted on all the data leaks information from the validation folds. Put every learned step in a pipeline so that it is refitted inside each training fold.

Trusting a single split. One split's score can be several points off. Use cross-validation and report the spread.

Comparing models on different splits. Differences between splits can be larger than differences between models. Use the same folds and compare fold by fold.

Choosing the best and reporting its score. Selection makes the winning score optimistic; use nested cross-validation or a final held-out test set.

Treating the threshold as fixed at 0.5. The threshold is a decision about costs, not a property of the model. Show the trade-off and choose with the people who bear the costs.

Mixing up pooled and averaged AUC. Say which one you report; they differ slightly.

20.8 Chapter Summary

- The confusion matrix (**Figure 20.1**) is the source of every classification metric: accuracy (Equation (20.1)), precision and recall (Equation (20.2)), specificity and false positive rate (Equation (20.3)), and F_1 (Equation (20.4)).
- The ROC curve (Equation (20.5)) shows every threshold at once; its area can be computed by trapezoids (Equation (20.6)) or as the probability that a positive outranks a negative (Equation (20.7)), with identical results.
- Stratified k-fold cross-validation (**Figure 20.2**) gives k scores whose mean and spread (Equation (20.8)) describe a model far better than one split.
- Paired, fold-by-fold differences (Equation (20.9)) are the fair way to compare models; on the breast cancer data, the SVM and logistic regression could not be told apart.
- The threshold is a decision: lowering it from 0.5 to 0.2 cut missed malignant tumors from 13 to 4 at the cost of 27 more false alarms.
- A self-contained HTML dashboard, served locally on port 5020, puts the metrics, curves, spreads and trade-offs on one page for the people who must decide.

This closes Part 2. We have met the classic learners (linear and logistic regression, k-NN, decision trees, naive Bayes, k-means, PCA, SVMs, forests and boosting) and the discipline of measuring them. Part 3 turns to language, where the bag of words of Chapters 12 and 15 is only the beginning.

20.9 Exercises

1. A model at some threshold has TP 208, FN 4, FP 29, TN 328. Compute accuracy, precision, recall, specificity and F_1.
2. Five cases have labels $y = (1,1,0,1,0)$ and scores $(0.9,0.8,0.7,0.6,0.2)$. Draw the ROC curve by hand, compute the AUC by trapezoids and by counting pairs, and check that they agree.
3. Compare the SVM and logistic regression fold by fold, using the saved cross-validation results, for accuracy and for AUC. Can the data tell them apart?
4. For breast cancer screening, which threshold from the dashboard's sweep would you recommend, and why? What information would you want before deciding?
5. A colleague scales the whole data set with `StandardScaler`, then runs 10-fold cross-validation of k-NN on the scaled data. Explain what is wrong, and how to fix it in one line.
6. With 212 malignant and 357 benign tumors and 10 stratified folds, how many malignant tumors does each validation fold contain? Why does stratification matter more for small data sets and rare classes?

20.10 Solutions to the Exercises

Exercise 20.1. $n = 569$. Accuracy $(208 + 328)/569 = 536/569 = 0.942$. Precision $208/237 = 0.878$. Recall $208/212 = 0.981$. Specificity $328/357 = 0.919$. $F_1 = 2 \times 0.878 \times 0.981/(0.878 + 0.981) = 1.723/1.859 = 0.927$. These match the dashboard's row for threshold 0.2 (recall 0.981, precision 0.878, F_1 0.927). Accuracy fell from 0.974 to 0.942 while recall rose from 0.939 to 0.981: a lower accuracy can be the better choice.

Exercise 20.2. Sorted by score: 1, 1, 0, 1, 0, with $P = 3$ and $N = 2$. Walking down: $(0,0) \to (0,1/3) \to (0,2/3) \to (1/2,2/3) \to (1/2,1) \to (1,1)$. Trapezoids: the first two steps are vertical (width 0); from $x = 0$ to 0.5 at height $2/3$: $0.5 \times 2/3 = 0.333$; the vertical step at $x = 0.5$ adds

nothing; from 0.5 to 1 at height 1: 0.5. Total 0.833. Pairs: the positive at 0.9 beats both negatives (2), the one at 0.8 beats both (2), the one at 0.6 beats only the negative at 0.2 (1): $5/(3 \times 2) = 0.833$. They agree.

Exercise 20.3. **Listing 20.5** reads the saved results and pairs the folds.

Listing 20.5 `solutions/ex_paired.py`: fold-by-fold differences between the SVM and logistic regression.

```
# ex_paired.py - Exercise 20.3: is the SVM really better than logistic regression?
import json
from pathlib import Path
import numpy as np

res = json.loads((Path(__file__).resolve().parent.parent / "outputs"
                  / "results.json").read_text())
for metric in ("accuracy", "roc_auc"):
    a = np.array(res["SVM (RBF)"][metric])
    b = np.array(res["logistic regression"][metric])
    d = a - b                                          # same folds: pair them
    print(f"{metric}: SVM - logistic per fold {np.round(d, 3)}")
    print(f"  mean difference {d.mean():+.4f}, std {d.std(ddof=1):.4f}, "
          f"SVM better in {np.sum(d > 0)} folds, worse in {np.sum(d < 0)}")
```

```
accuracy: SVM - logistic per fold [ 0.018  0.018 -0.035  0.    -0.018  0.018  0.018  0.
0.     0.   ]
  mean difference +0.0018, std 0.0174, SVM better in 4 folds, worse in 2
roc_auc: SVM - logistic per fold [ 0.006  0.003  0.    -0.001 -0.001  0.003  0.001  0.
0.    -0.001]
  mean difference +0.0009, std 0.0025, SVM better in 4 folds, worse in 3
```

For accuracy the SVM wins 4 folds and loses 2 (four ties); the mean difference is $+0.0018$ with a standard deviation of 0.0174, so the standard error is $0.0174/\sqrt{10} = 0.0055$, three times the difference. For AUC the picture is the same: $+0.0009$ against a standard error of $0.0025/\sqrt{10} = 0.0008$, won in 4 folds and lost in 3. The data cannot tell the models apart; choose on other grounds, such as simplicity and explainability.

Exercise 20.4. From the sweep: 0.5 misses 13 cancers with 2 false alarms; 0.3 misses 6 with about 14 false alarms (precision 0.936 on 212 × 0.972 = 206 caught gives $206/0.936 - 206 \approx 14$); 0.2 misses 4 with 29; 0.1 misses 1 with 58. For screening, 0.2 or 0.3 is a reasonable starting point: misses are far more costly than extra examinations. Before deciding one would want the actual costs and harms of follow-up tests, the prevalence in the population where the model will be used (the data set's 37 percent malignant is far higher than in general screening), confirmation on data from that population, and the judgment of the clinicians responsible. A model evaluated on 569 cases from one hospital decades ago is a teaching example, not a clinical tool.

Exercise 20.5. The scaler's means and standard deviations were computed on all 569 tumors, including each validation fold, so information from the validation data shaped the features: leakage, and slightly optimistic scores. For k-NN, whose distances depend directly on the scaling, the effect can be noticeable. Fix: put the scaler in a pipeline, `make_pipeline(StandardScaler(), KNeighborsClassifier(7))`, and pass the pipeline to `cross_validate`, as `evaluate.py` does; the scaler is then refitted inside every training fold.

Exercise 20.6. $212/10 = 21.2$: two folds get 22 malignant tumors and eight get 21 (and 35 or 36 benign ones). Without stratification, a random fold of 57 tumors would contain on average 21 malignant ones but could easily contain 15 or 28, changing what "recall on this fold" means from

fold to fold. With rare classes (say 10 positives in 500 cases) an unstratified fold might contain no positive at all, making recall undefined; stratification guarantees each fold its share.

Chapter 21
Tokenizer and Word Counter

This chapter opens Part 3 of the book, *Language*, ten applications that read, sort, summarize and generate text written by people. Every one of them starts with the same humble step: cutting a stream of characters into pieces a program can count. By the end of this chapter you will be able to write a tokenizer that understands Indonesian and English text, including rupiah amounts, decimal commas, reduplicated words such as *anak-anak* and English contractions such as *don't*; split a paragraph into sentences without being fooled by abbreviations such as *Jl.* and *No.*; count tokens, types, the type–token ratio and the words that occur only once; see Zipf's law and Heaps' law appear in a corpus of our own; and split Indonesian clitics such as *-nya* and *-lah* off a word safely. All the code is plain Python with no library beyond the standard one, and the corpus of 96 short news items in Indonesian and English was written for this book, so everything runs offline.

21.1 Why Count Words?

Imagine that you run a small laundry in Rungkut, Surabaya, and your customers send you messages all day: "Mas, cucian saya sudah selesai belum?", "Can I get express service tomorrow?", "Harganya berapa per kilo?". After a month you have two thousand messages. Which questions come up most? Are people asking about prices, about pickup times, about stains? Nobody wants to read two thousand messages to find out. A program can, but only if it can first answer a question that sounds almost too simple to ask: *what is a word?*

That question is harder than it looks. Is *cucian* the same word as *Cucian* at the start of a sentence? Is *Rp80.000* one thing or three (*Rp*, *80*, *000*)? Is *anak-anak* one word or two? Is *harganya* the word *harga* with *-nya* attached, and if it is, what about *hanya*, which also ends in *nya* but has nothing to do with *ha*? Is *don't* one word? Where does a sentence end when the text says "Kami di Jl. Kenari No. 21. Buka setiap hari."?

Every language application in the rest of this part, from the spell checker of Chapter 22 to the plagiarism checker of Chapter 30, relies on answers to these questions. Search engines, the keyword extractor of Chapter 23, the topic classifier of Chapter 25, and the large language models of Part 9 all begin by turning text into a sequence of units. In large language models those units are *subword* pieces learned from data [1], [2], but the problems that motivate them are exactly the ones we meet in this chapter. A good tokenizer is invisible; a bad one quietly ruins everything built on top of it.

So our first application is modest and essential: a **tokenizer**, which cuts text into tokens and sentences, and a **word counter**, which turns the tokens into statistics that describe a body of text. Along the way we meet two laws that every body of human text obeys, Zipf's law and Heaps' law, and we watch them appear in our own small corpus.

21.2 The Idea in Plain Words

Think of a becak driver who counts the passengers he carries in a day. He does not count legs or hats; he has decided in advance what "one passenger" means. A mother carrying a baby might count as one or as two, and he must decide which. Once the rule is fixed, counting is easy.

A tokenizer is that rule for text. It walks along the characters from left to right and decides where each unit begins and ends. Each unit is called a **token**. In the sentence

Harga cabai naik jadi Rp80.000/kg!

a sensible tokenizer produces the tokens *Harga*, *cabai*, *naik*, *jadi*, *Rp80.000*, */*, *kg* and *!*. The amount *Rp80.000* stays in one piece because it means one thing, a price; the slash and the exclamation mark are tokens of their own because they are punctuation.

Two words are needed to talk about counting.

> **DEFINITION.** A *token* is one occurrence of a unit in a text. A *type* is a distinct unit, however many times it occurs. The sentence "the cat saw the dog" has five tokens and four types, because *the* occurs twice.

A **corpus** is simply a collection of texts that we study together. Ours, in `data/news.tsv`, holds 96 very short news items: 48 in Indonesian and 48 in English, twelve each about business, sports, technology and health. The English items tell the same stories as the Indonesian ones, which lets us compare the two languages fairly.

The plan of the application is short:

1. read each news item from the file;
2. split it into sentences and the sentences into tokens;
3. keep the word tokens, lowercase them, and optionally drop very common function words such as *yang*, *di*, *the* and *of*, which are called **stop words**;
4. count how many times each type occurs and print the statistics.

The hard part is step 2, so most of this chapter is about it. The programs use nothing beyond Python's standard library; they run on Python 3.11 or newer and were written with the current release, Python 3.14, in mind [3].

21.3 The Mathematics, Gently

We need only a little mathematics, and every symbol is introduced before it is used.

21.3.1 Tokens, types, and their ratio

Let N be the number of tokens in a text, and V the number of types, that is, the size of its vocabulary. Because every type occurs at least once, $V \le N$. The **type–token ratio** measures how varied the vocabulary is:

$$\mathrm{TTR} = \frac{V}{N} \tag{21.1}$$

A text that repeats the same word over and over has a TTR close to 0; a text in which no word repeats has a TTR of exactly 1. For example, "the cat saw the dog" has $N = 5$ and $V = 4$, so by Equation (21.1) its TTR is $4/5 = 0.8$.

For each type w, let $c(w)$ be its **count**, the number of tokens equal to w. Its **relative frequency**, or share, is

$$p(w) = \frac{c(w)}{N} \tag{21.2}$$

The shares of all the types add up to 1, because the counts add up to N. In the example, $p(\text{the}) = 2/5 = 0.4$. A type that occurs exactly once, with $c(w) = 1$, is called a **hapax legomenon** (Greek for "said once"), or simply a *hapax*.

21.3.2 Zipf's law

Sort the types from the most frequent to the least frequent and number them: the most frequent has **rank** $r = 1$, the next $r = 2$, and so on. Write $f(r)$ for the count of the type at rank r. In the 1930s and 1940s George Kingsley Zipf noticed that, in book after book and language after language, the frequency falls roughly as a power of the rank [4]:

$$f(r) \approx \frac{C}{r^s} \tag{21.3}$$

Here C is a constant close to the count of the most frequent word, and s is an exponent close to 1 in large English corpora. With $s = 1$ the law says something striking: the second word occurs about half as often as the first, the third about a third as often, and the product $r \cdot f(r)$ stays roughly constant. Most of the vocabulary lives in a long tail of rare words, and most of the tokens are a few very common ones. Linguists still debate *why* this happens [5], but that it happens is not in doubt.

How do we measure s in our own corpus? Take the logarithm of both sides of Equation (21.3). The logarithm turns a quotient into a difference and a power into a product:

$$\log f(r) \approx \log C - s \log r \tag{21.4}$$

This is the equation of a straight line. If we plot $y = \log f(r)$ against $x = \log r$, the points should lie near a line whose slope is $-s$ and whose height at $x = 0$ is $\log C$. That is why Zipf plots are always drawn on logarithmic axes.

21.3.3 Fitting a straight line

Given points $(x_1, y_1), \ldots, (x_n, y_n)$, the **least-squares** line $y = a + bx$ is the line that makes the sum of the squared vertical distances $\sum_i (y_i - a - bx_i)^2$ as small as possible. Setting the derivatives of that sum with respect to a and b to zero and solving the two equations gives, with $\bar{x}$ and $\bar{y}$ the averages of the x_i and the y_i,

$$b = \frac{\sum_{i=1}^{n} (x_i - \bar{x})\,(y_i - \bar{y})}{\sum_{i=1}^{n} (x_i - \bar{x})^2}, \qquad a = \bar{y} - b\,\bar{x} \tag{21.5}$$

In words: the slope is how much x and y move together, divided by how much x moves by itself, and the line passes through the point of averages $(\bar{x}, \bar{y})$. We use Equation (21.5) on the log–log points to read off $s = -b$ and $C = e^a$.

21.3.4 Heaps' law

A second question: as we read more text, how fast does the vocabulary grow? Let $V(N)$ be the number of types seen after reading N tokens. Harold Heaps described the growth as [6]

$$V(N) \approx KN^{\beta} \tag{21.6}$$

with $0 < \beta < 1$. Because β is below 1, the vocabulary keeps growing but more and more slowly: every new page brings new words, but fewer than the page before it. Taking logarithms again, $\log V = \log K + \beta \log N$, which is once more a straight line, and Equation (21.5) gives β as its slope. Heaps' law also explains a trap: by Equation (21.1) and Equation (21.6), $\text{TTR} = V/N \approx KN^{\beta-1}$, which shrinks as N grows. Comparing the TTR of a short text with that of a long one is therefore unfair; the long one will always look poorer [7].

21.4 Building the Tokenizer

21.4.1 Regular expressions in one page

The tool for cutting text is the **regular expression**, a small pattern language that Python provides in its `re` module [8]. We need only a handful of pieces:

- `\d` matches one digit, `\s` one whitespace character, `\w` one "word" character (a letter, digit or underscore, in any alphabet).
- `[...]` matches one character from a set; `[^...]` one character *not* in the set. So `[^\W\d_]` means "not a non-word character, not a digit, not an underscore", which is a clumsy but exact way to say *a letter*, including letters such as *é*.
- `+` means "one or more of the previous thing", `*` "zero or more", `?` "optional", and `{2,3}` "two or three".
- `(?:...)` groups without capturing; `(?P<NAME>...)` captures and gives the group a name.
- `a|b` means "a or b"; the alternatives are tried from left to right, and the first that matches wins.

With `re.VERBOSE` we may spread a pattern over several lines and add comments, which makes a complicated pattern readable.

21.4.2 One alternative per kind of token

Our tokenizer is a single pattern with one named alternative per kind of token, listed in **Table 21.1**. The order is the heart of the design. The pattern for money must come before the pattern for numbers, or *Rp80.000* would never be recognized as money because *Rp* would already have been taken as a word; the pattern for e-mail addresses must come before words, or *info@laundry.id* would be cut into five pieces.

Table 21.1 The seven kinds of token, in the order in which the tokenizer tries them.

Kind	Pattern idea	Examples
`URL`	`http://` or `www.` up to the next space	`https://profitina.com`
`EMAIL`	name, `@`, domain	`info@laundry.id`
`MONEY`	`Rp` or `$`, then a number	`Rp80.000`, `$3.50`
`ALNUM`	digits followed by letters	`5G`, `4K`, `2nd`
`NUMBER`	digits with `.` or `,` groups, optional `-digits`	`5.000`, `0,3`, `4-0`
`WORD`	letters, optionally joined by `-` or an apostrophe	`anak-anak`, `don't`
`PUNCT`	any other single non-space character	`.`, `/`, `!`

Notice how one pattern serves both languages. Indonesian writes thousands with a period and decimals with a comma (*Rp80.000*, *0,3 persen*); English does the opposite (*Rp80,000*, *0.3 percent*). The pattern `\d+(?:[.,]\d+)*` accepts both, because it only asks for digits separated by periods or commas. It does not try to know which convention a text uses; that question belongs to a later stage that converts tokens into numbers.

The `WORD` pattern allows a hyphen or an apostrophe *between* letters. That keeps Indonesian reduplication together: *anak-anak* (children), *kupu-kupu* (butterfly) and *desa-desa* (villages) are single words written with a hyphen, as the official spelling guide *Ejaan Bahasa Indonesia yang Disempurnakan*, fifth edition (EYD V), prescribes [9]. It also keeps English contractions and possessives such as *don't* and *bird's* in one piece. Because the hyphen must sit between two letters, a dash used as punctuation is still a token of its own.

Listing 21.1 is the complete module. Besides `tokenize`, it has `words`, which keeps only the word tokens, `split_sentences`, which we discuss in Section 21.4.4, and `split_clitics`, which waits until Section 21.7.

Listing 21.1 `tokenizer.py`: the tokenizer, the sentence splitter, and the Indonesian clitic splitter.

```
"""tokenizer.py - split Indonesian and English text into sentences and tokens."""
import re
from collections import namedtuple

Token = namedtuple("Token", "text kind start")

# One alternative per token kind. Order matters: the first one that fits wins.
TOKEN_RE = re.compile(r"""

                 "mr", "mrs", "ms", "st", "vs", "etc", "e.g", "i.e", "approx"}
BOUNDARY_RE = re.compile(r"[.!?]+[\"'”’)\]]*\s+")
LAST_WORD_RE = re.compile(r"([\w.]+)$")
```

Listing 21.1 (Continued) *tokenizer.py: the tokenizer, the sentence splitter, and the Indonesian clitic splitter.*

```
def split_sentences(text):
    """Split text into sentences at . ! ? followed by space."""
    sentences, start = [], 0
    for m in BOUNDARY_RE.finditer(text):
        last = LAST_WORD_RE.search(text, 0, m.start())
        word = last.group(1).lower() if last else ""
        nxt = text[m.end():m.end() + 1]
        if word in ABBREVIATIONS or (len(word) == 1 and word.isalpha()):
            continue                    # "Jl. Kenari", "J. K. Rowling"
        if nxt.islower():
            continue                    # "dll. dan" - no capital after it
        sentences.append(text[start:m.end()].strip())
        start = m.end()
    if text[start:].strip():
        sentences.append(text[start:].strip())
    return sentences

CLITICS = ("nya", "lah", "kah", "pun", "ku", "mu")

def split_clitics(word, vocabulary):
    """Split an Indonesian clitic off word when the rest is a known word."""
    for clitic in CLITICS:
        stem = word[:-len(clitic)]
        if word.endswith(clitic) and len(stem) > 2 and stem in vocabulary:
            return [stem, "-" + clitic]
    return [word]

if __name__ == "__main__":
    demo = ("Harga cabai di Jl. Kenari Raya naik jadi Rp80.000/kg! "
            "Anak-anak don't care: skor 4-0, sinyal 5G, info@laundry.id.")
    for t in tokenize(demo):
        print(f"{t.start:3d}  {t.kind:<6}  {t.text}")
    for sentence in split_sentences(demo):
        print("SENTENCE:", sentence)
```

Read the important lines one by one.

- `Token = namedtuple("Token", "text kind start")` defines a tiny record type. Each token remembers its text, its kind, and the position of its first character in the original string. Keeping the position costs nothing and later lets us highlight a token in the original text, which the plagiarism checker of Chapter 30 needs.
- `TOKEN_RE.finditer(text)` walks along the text and yields a match object for each token. Characters that no alternative matches, which here means only whitespace, are skipped silently.
- `m.lastgroup` is the name of the alternative that matched, such as `"MONEY"`. This is the trick that makes a single pattern classify as well as cut.
- `words` keeps tokens of kind `WORD` or `ALNUM` and lowercases them, so that *Harga* at the start of a sentence and *harga* in the middle count as the same type.

21.4.3 Running the tokenizer

Run the module on its demonstration sentence:

```
python tokenizer.py
```

```
  0  WORD    Harga
  6  WORD    cabai
 12  WORD    di
 15  WORD    Jl
 17  PUNCT   .
 19  WORD    Kenari
 26  WORD    Raya
 31  WORD    naik
 36  WORD    jadi
 41  MONEY   Rp80.000
 49  PUNCT   /
 50  WORD    kg
 52  PUNCT   !
 54  WORD    Anak-anak
 64  WORD    don't
 70  WORD    care
 74  PUNCT   :
 76  WORD    skor
 81  NUMBER  4-0
 84  PUNCT   ,
 86  WORD    sinyal
 93  ALNUM   5G
 95  PUNCT   ,
 97  EMAIL   info@laundry.id
112  PUNCT   .
SENTENCE: Harga cabai di Jl. Kenari Raya naik jadi Rp80.000/kg!
SENTENCE: Anak-anak don't care: skor 4-0, sinyal 5G, info@laundry.id.
```

Each line shows the start position, the kind, and the text of one token. *Rp80.000* is money, *4-0* is a score kept as one number, *5G* is letters mixed with digits, the e-mail address survives intact, and *Anak-anak* and *don't* are single words. **Figure 21.1** draws the same result as colored boxes.

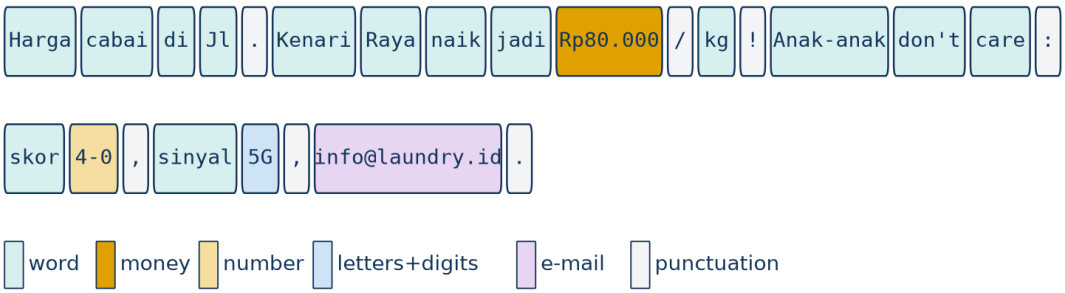

Figure 21.1 The demonstration text cut into tokens. Each box is one token, colored by the kind of the alternative that matched it.

21.4.4 Splitting sentences

A sentence usually ends with a period, a question mark or an exclamation mark followed by a space. “Usually” is the problem. In Indonesian addresses, *Jl.* (jalan, street) and *No.* (nomor, number) end with a period in the middle of a sentence, and so do *dll.* (dan lain-lain, and so on), *dr.* (dokter), *Mr.* and *e.g.* A splitter that cuts at every period produces nonsense such as “Kami di Jl.” as a sentence.

The function `split_sentences` in **Listing 21.1** uses three simple rules:

1. `BOUNDARY_RE` finds candidate boundaries: one or more of `.`, `!` or `?`, optionally followed by a closing quote or bracket, and then whitespace.
2. The word just before the boundary is looked up in `ABBREVIATIONS`; a single letter, such as the initial in “J. K.”, is treated the same way. Either one means “not a boundary”.

3. If the next character is a lowercase letter, it is not a boundary either, because a new sentence starts with a capital.

These rules are a hand-made version of what serious sentence splitters learn from data, for example the Punkt algorithm, which discovers abbreviations by noticing words that are very often followed by a period [10]. In the output of Section 21.4.3 the text was split into two sentences, and *Jl. Kenari* stayed whole.

21.5 Building the Word Counter

21.5.1 Stop words

The most frequent words of any language are small function words: *yang*, *di*, *dan*, *untuk* in Indonesian, *the*, *a*, *to*, *of* in English. They hold a sentence together but say little about its topic. For many tasks we remove them, using a **stop-word list**. **Listing 21.2** has two short lists written for this book. They are deliberately small: every word on them was checked against the corpus, and a word that carries meaning, such as *tidak* (not), must be removed with care because it reverses the meaning of what follows it.

Listing 21.2 `stopwords.py`: small stop-word lists for Indonesian and English.

```
"""stopwords.py - small stop-word lists for Indonesian and English."""

STOP_ID = set("""
ada adalah agar akan antara atau bagi bahwa baru banyak beberapa belum
bisa dalam dan dapat dari dengan di hanya harus ia ini itu jika juga
kami karena ke kepada kita lagi lebih masih mereka para pada saat sampai
sangat satu secara sebagai sebelum sedang sejak setelah setiap sudah
tetapi tidak untuk yang
""".split())

STOP_EN = set("""
a about after all also an and are as at be been before but by can could
did do for from had has have he her his if in into is it its more most
not of on or our she so than that the their them there they this to
up was we were when which who will with would you
""".split())

STOPWORDS = STOP_ID | STOP_EN
```

21.5.2 The counter

Listing 21.3 reads the corpus, splits every item into sentences and words, removes stop words if asked, and prints the statistics of Section 21.3.1. The counting itself is done by `collections.Counter`, a dictionary that maps each type to its count and can list the most common types.

Listing 21.3 `wordcount.py`: token, type and frequency statistics for the corpus.

```
"""wordcount.py - count tokens, types and the most frequent words."""
import argparse
import csv
from collections import Counter

from stopwords import STOPWORDS
from tokenizer import split_sentences, words

def load_texts(path, lang):
    """Read title and text of every document in the TSV file."""
    with open(path, encoding="utf-8", newline="") as f:
        rows = list(csv.DictReader(f, delimiter="\t"))
    return [r["title"] + ". " + r["text"] for r in rows
            if lang == "all" or r["lang"] == lang]

def main():
    ap = argparse.ArgumentParser(description=__doc__)
    ap.add_argument("--file", default="data/news.tsv")
    ap.add_argument("--lang", default="all", choices=["id", "en", "all"])
    ap.add_argument("--top", type=int, default=10)
    ap.add_argument("--no-stopwords", action="store_true")
    args = ap.parse_args()

    texts = load_texts(args.file, args.lang)
    n_sent = sum(len(split_sentences(t)) for t in texts)
    tokens = [w for t in texts for w in words(t)]
    if args.no_stopwords:
        tokens = [w for w in tokens if w not in STOPWORDS]
    counts = Counter(tokens)
    n, v = len(tokens), len(counts)
    hapax = sum(1 for c in counts.values() if c == 1)

    print(f"documents  : {len(texts)}")
    print(f"sentences  : {n_sent}")
    print(f"tokens  N  : {n}")
    print(f"types   V  : {v}")
    print(f"TTR = V/N  : {v / n:.3f}")
    print(f"hapax      : {hapax} ({hapax / v:.0%} of the types)")
    print(f"\nrank  word            count   share")
    for rank, (word, c) in enumerate(counts.most_common(args.top), 1):
        print(f"{rank:4d}  {word:<14}{c:7d}   {c / n:6.2%}")

if __name__ == "__main__":
    main()
```

Listing 21.3 (Continued) *wordcount.py: token, type and frequency statistics for the corpus.*

A few details deserve a word.

- The data file is tab-separated, with a header line `id lang topic title text`. `csv.DictReader` with `delimiter="\t"` turns each line into a dictionary, so `r["lang"]` is the language code. Opening the file with `encoding="utf-8"` is not optional: without it, Windows may read the file with a different default encoding and mangle any character outside plain ASCII.
- The title and the text are joined with "." so that the title becomes a sentence of its own.
- `argparse` gives the program a proper command-line interface, including `--help` for free.

21.5.3 Running the counter

First the whole corpus, both languages together:

```
python wordcount.py
```

```
documents  : 96
sentences  : 384
tokens  N  : 3267
types   V  : 1519
TTR = V/N  : 0.465
hapax      : 905 (60% of the types)

rank  word            count   share
   1  the               107    3.28%
   2  a                  55    1.68%
   3  to                 36    1.10%
   4  di                 31    0.95%
   5  in                 31    0.95%
   6  and                30    0.92%
   7  dan                27    0.83%
   8  of                 25    0.77%
   9  are                19    0.58%
  10  is                 18    0.55%
```

The corpus has $N = 3267$ word tokens and $V = 1519$ types, so its TTR is $1519/3267 = 0.465$ by Equation (21.1). Of the 1519 types, 905, which is 60%, are hapaxes. That is Zipf's long tail in one number: most words are rare. The top of the list is exactly what Zipf predicts too, a handful of function words from both languages. The English article *the*, with 107 tokens, is by itself 3.28% of the whole corpus, as Equation (21.2) computes: $107/3267 = 0.0328$. Indonesian has no articles, so its most frequent word, the preposition *di*, is much less dominant.

Now the Indonesian half without stop words:

```
python wordcount.py --lang id --no-stopwords
```

```
documents  : 48
sentences  : 192
tokens  N  : 1291
types   V  : 717
TTR = V/N  : 0.555
hapax      : 430 (60% of the types)

rank  word            count   share
   1  harga             11    0.85%
   2  dua               10    0.77%
   3  tiga              10    0.77%
   4  tahun              9    0.70%
   5  daerah             9    0.70%
   6  memakai            8    0.62%
   7  kecil              8    0.62%
   8  kota               8    0.62%
   9  emas               8    0.62%
  10  tim                8    0.62%
```

With the function words gone, the list starts to say something about the content: prices (*harga*, *emas*), numbers (*dua*, *tiga*), places (*kota*, *daerah*) and teams (*tim*). Numerals such as *dua* and *tiga* are candidates for a domain stop list, a point Exercise 21.6 returns to. The TTR rose to 0.555, simply because we removed the most repeated tokens.

The English half, showing only the top five:

```
python wordcount.py --lang en --no-stopwords --top 5
```

```
documents  : 48
sentences  : 192
tokens  N  : 1256
types   V  : 761
TTR = V/N  : 0.606
hapax      : 504 (66% of the types)

rank  word            count   share
   1  new                12    0.96%
   2  health             12    0.96%
   3  small               9    0.72%
   4  every               9    0.72%
   5  year                8    0.64%
```

The English half has more types, 761 against 717, for about the same number of content tokens. One reason is that Indonesian builds many words from a root with affixes, and English inflection gives many small variants (*player*, *players*, *played*); the other is simply that the English texts are slightly longer. Chapter 22 and Chapter 23 will care about these differences.

21.6 Zipf and Heaps on Our Corpus

Listing 21.4 fits Zipf's law and Heaps' law to each language, using exactly the formulas of Section 21.3. `fit_line` is Equation (21.5) written out in Python. `zipf_fit` takes the top 100 types, turns ranks and frequencies into logarithms, fits the line of Equation (21.4), and returns C and s. `heaps_curve` reads the tokens one by one, records (N, V) every 250 tokens, and `heaps_fit` fits Equation (21.6) in log–log form.

Listing 21.4 `zipf.py`: least-squares fits of Zipf's law and Heaps' law.

```
"""zipf.py - fit Zipf's law and Heaps' law to the corpus."""
import math
from collections import Counter

from tokenizer import words
from wordcount import load_texts

def fit_line(xs, ys):
    """Least-squares line y = a + b*x; returns (a, b)."""
    n = len(xs)
    mx, my = sum(xs) / n, sum(ys) / n
    sxy = sum((x - mx) * (y - my) for x, y in zip(xs, ys))
    sxx = sum((x - mx) ** 2 for x in xs)
    b = sxy / sxx
    return my - b * mx, b

def zipf_fit(tokens, max_rank=100):
    """Fit log f = log C - s log r on the top max_rank words."""
    freqs = [c for _, c in Counter(tokens).most_common(max_rank)]
    xs = [math.log(r) for r in range(1, len(freqs) + 1)]
    ys = [math.log(f) for f in freqs]
    a, b = fit_line(xs, ys)
    return math.exp(a), -b

def heaps_curve(tokens, step=250):
    """Return (N, V) after every step tokens."""
    seen, points = set(), []
    for i, w in enumerate(tokens, 1):
        seen.add(w)
        if i % step == 0 or i == len(tokens):
            points.append((i, len(seen)))
    return points

def heaps_fit(points):
    """Fit log V = log K + beta log N; returns (K, beta)."""
    a, b = fit_line([math.log(n) for n, _ in points],
                    [math.log(v) for _, v in points])
    return math.exp(a), b
```

Listing 21.4 (Continued) *zipf.py: least-squares fits of Zipf's law and Heaps' law.*

```
if __name__ == "__main__":
    for lang in ("id", "en"):
        tokens = [w for t in load_texts("data/news.tsv", lang) for w in words(t)]
        c, s = zipf_fit(tokens)
        k, beta = heaps_fit(heaps_curve(tokens))
        print(f"[{lang}] N={len(tokens)}  Zipf: C={c:.1f} s={s:.2f}   "
              f"Heaps: K={k:.2f} beta={beta:.2f}")
        top = Counter(tokens).most_common(5)
        print("   r  word        f   r*f")
        for r, (w, f) in enumerate(top, 1):
            print(f"  {r:2d}  {w:<10}{f:3d}  {r * f:4d}")
```

```
python zipf.py
```

```
[id] N=1516  Zipf: C=30.3 s=0.48   Heaps: K=1.79 beta=0.83
   r  word        f   r*f
   1  di         31    31
   2  dan        27    54
   3  untuk      17    51
   4  dari       15    60
   5  yang       15    75
[en] N=1751  Zipf: C=82.4 s=0.74   Heaps: K=1.81 beta=0.82
   r  word        f   r*f
   1  the      107   107
   2  a         55   110
   3  to        36   108
   4  in        31   124
   5  and       30   150
```

Look first at the English column $r \cdot f$. For the top five words it stays between 107 and 150, close to constant, just as Equation (21.3) with s near 1 predicts. The fitted exponent on the top 100 words is $s = 0.74$ for English and $s = 0.48$ for Indonesian. Both are below the value of about 1 reported for large corpora, and there is an honest reason: our corpus has only about 1,500 tokens per language, so beyond rank 30 or so most counts are tied at 1, 2 or 3 and the tail is flat. Indonesian deviates more because it has no article to occupy rank 1 with a very high count. **Figure 21.2** shows both effects: on the left, the log–log points with their fitted lines, and on the right, the vocabulary growth curves.

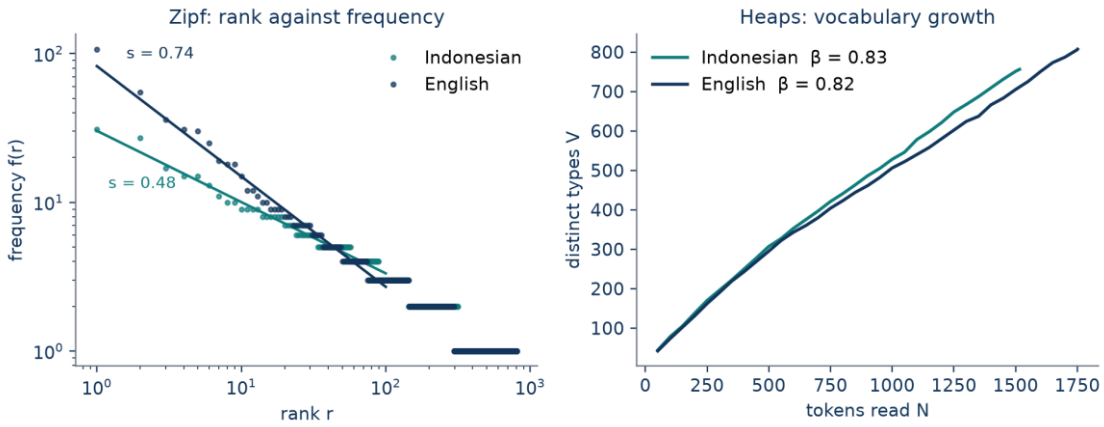

Figure 21.2 Left: rank against frequency on logarithmic axes, with the fitted least-squares lines. Right: the number of distinct types as more tokens are read, with the fitted Heaps exponent.

The Heaps exponents are $\beta = 0.83$ for Indonesian and 0.82 for English. On a corpus this small, almost every news item brings a fresh set of words, so the curves are nearly straight; in corpora of millions of words, β is typically between 0.4 and 0.6 [7]. Rather than a failure, this is a useful lesson: the laws describe large bodies of text, and a small corpus shows their beginning.

21.7 Improving It: Indonesian Clitics and Beyond

21.7.1 The trouble with *-nya*

Indonesian attaches several short words, called **clitics**, directly to the word before or after them. EYD V writes the possessive and object pronouns *-ku*, *-mu* and *-nya* and the particles *-lah* and *-kah* attached to the word [9]: *harganya* (its price), *pelatihnya* (his coach), *bulanlah*. For counting, we often want *harganya* to count as *harga*, because both are about price. The naive solution, "cut *-nya* off every word that ends in it", is a disaster: *hanya* (only) becomes *ha*, *punya* (to own) becomes *pu*, and *tanya* (to ask) becomes *ta*.

The fix in `split_clitics` in **Listing 21.1** is to cut only when what remains is a word we already know, and is longer than two letters. **Listing 21.5** compares the two approaches on eight words, using the Indonesian half of the corpus as the vocabulary.

Listing 21.5 `clitics_demo.py`: naive suffix cutting against cutting only when the stem is a known word.

```
"""clitics_demo.py - naive suffix cutting versus a vocabulary check."""
from tokenizer import split_clitics, words
from wordcount import load_texts

vocabulary = {w for t in load_texts("data/news.tsv", "id") for w in words(t)}
tests = ["harganya", "pelatihnya", "hanya", "punya", "sekolahnya",
         "bulanlah", "meskipun", "tanya"]

print(f"{'word':<12}{'naive cut':<18}{'with vocabulary'}")
for w in tests:
    naive = [w[:-3], "-" + w[-3:]] if w.endswith("nya") else [w]
    smart = split_clitics(w, vocabulary)
    print(f"{w:<12}{' + '.join(naive):<18}{' + '.join(smart)}")
```

```
python clitics_demo.py
```

```
word        naive cut         with vocabulary
harganya    harga + -nya      harga + -nya
pelatihnya  pelatih + -nya    pelatih + -nya
hanya       ha + -nya         hanya
punya       pu + -nya         punya
sekolahnya  sekolah + -nya    sekolah + -nya
bulanlah    bulanlah          bulan + -lah
meskipun    meskipun          meskipun
tanya       ta + -nya         tanya
```

The vocabulary check keeps *hanya*, *punya* and *tanya* whole and still splits *harganya*, *pelatihnya*, *sekolahnya* and *bulanlah*. *Meskipun* (although) stays whole because *meski* is not in our small vocabulary; that happens to be correct, since EYD V lists *meskipun* among the words in which *pun* is written attached [9], while in most other cases *pun* is written as a separate word (*apa pun*, *mana pun*). The method is only as good as its vocabulary: with a larger word list, the rule would be right more often, and a real Indonesian stemmer goes further by removing prefixes such as *me-*, *ber-* and *di-* as well [11]. The spell checker of Chapter 22 builds exactly such a word list from counts.

21.7.2 From words to subwords

Our tokenizer has a fixed idea of what a word is, and anything it has never seen, such as a new brand name or a misspelling, still becomes a token, but one that later stages know nothing about. Modern neural language models avoid unknown tokens altogether with **subword tokenization**. Byte-pair encoding, for example, starts from single characters and repeatedly merges the most frequent adjacent pair into a new symbol, until it has a vocabulary of a chosen size [2]. Frequent words end up as a single symbol and rare words as a few pieces, such as *pelatih* + *nya*, learned from data rather than written by hand [1]. Chapter 39 builds a tiny Transformer language model, and the same reasoning about units applies there.

21.7.3 Other improvements worth making

- **Normalization before tokenization.** Text copied from phones often contains curly quotes (’), non-breaking spaces and different Unicode forms of the same letter. Python’s

`unicodedata.normalize("NFC", text)` puts letters into one standard form; the `WORD` pattern already accepts both the straight and the curly apostrophe.

- **Keeping case information.** Lowercasing loses the difference between *Apple* the company and *apple* the fruit. The named-entity finder of Chapter 28 needs that difference, so it works on tokens before `words` lowercases them.
- **Speed.** One precompiled pattern, run once over the text by `finditer`, is fast: the 96 items of this chapter's corpus are tokenized in about 10 milliseconds on the machine used for this book. Tokenizing millions of documents calls for the same design, only on more machines.

21.8 Testing the Tokenizer

A tokenizer is exactly the kind of code that breaks silently when someone "improves" a pattern. A few automatic tests protect the cases we care about. **Listing 21.6** uses pytest; each test function states one fact that must stay true.

Listing 21.6 `tests/test_tokenizer.py`: four tests for money and numbers, reduplication and contractions, abbreviations, and clitics.

```
"""Run with:  python -m pytest -q"""
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from tokenizer import split_clitics, split_sentences, tokenize, words  # noqa: E402

def test_money_and_numbers():
    text = "Rp80.000 dan 0,3 persen, skor 4-0"
    kinds = [(t.text, t.kind) for t in tokenize(text)]
    assert ("Rp80.000", "MONEY") in kinds
    assert ("0,3", "NUMBER") in kinds
    assert ("4-0", "NUMBER") in kinds

def test_reduplication_and_contraction():
    assert words("Anak-anak don't care") == ["anak-anak", "don't", "care"]

def test_abbreviation_does_not_split():
    s = split_sentences("Kami di Jl. Kenari No. 21. Buka setiap hari.")
    assert s == ["Kami di Jl. Kenari No. 21.", "Buka setiap hari."]

def test_clitic_needs_known_stem():
    vocab = {"harga", "ha"}
    assert split_clitics("harganya", vocab) == ["harga", "-nya"]
    assert split_clitics("hanya", vocab) == ["hanya"]   # stem too short
```

```
python -m pytest -q
```

```
....                                                                     [100%]
4 passed in 0.01s
```

The line `sys.path.insert(0, ...)` lets the test find `tokenizer.py` in the folder above it, so the tests run from the chapter folder without any packaging. Whenever you change `TOKEN_RE`, run the tests again. If you find a sentence that the tokenizer handles badly, add it as a new test *before* you fix the pattern; the test then proves that the fix works and keeps working.

21.9 Common Mistakes, and How to Avoid Them

Splitting on spaces only. `text.split()` leaves punctuation stuck to words, so *kilogram.* and *kilogram* become different types. *Avoid it:* use a tokenizer that treats punctuation as tokens of its own.

Putting the general pattern first. If `WORD` comes before `MONEY`, *Rp* is taken as a word and *Rp80.000* never matches as money. *Avoid it:* order the alternatives from the most specific to the most general, as in **Table 21.1**.

Forgetting that `\w` includes digits and the underscore. A pattern `\w+` for "word" swallows *5G* and *snake_case* whole. *Avoid it:* say what you mean, as `[^\W\d_]` does for letters.

Cutting at every period. *Jl.*, *No.* and *dll.* are not sentence ends. *Avoid it:* keep an abbreviation list and check the next character, and accept that some cases, like *dll.* at the real end of a sentence, stay ambiguous.

Stripping *-nya* blindly. It turns *hanya* into *ha*. *Avoid it:* split a clitic only when the remaining stem is a known word, as `split_clitics` does.

Reading files without an encoding. The default encoding differs between Windows, macOS and Linux. *Avoid it:* always pass `encoding="utf-8"`.

Comparing type–token ratios of texts of different lengths. By Heaps' law, longer texts always have lower TTR. *Avoid it:* compare texts of equal length, or compare the TTR of equal-sized slices.

Removing stop words that carry meaning. Dropping *tidak* or *not* turns "tidak enak" (not tasty) into "enak" (tasty). *Avoid it:* keep negations whenever meaning matters, as it will for the sentiment work of Chapter 15.

Trusting a law fitted on a tiny corpus. Our s and β come from about 1,500 tokens per language. *Avoid it:* report the corpus size with every statistic, as this chapter does.

21.10 Chapter Summary

- A **token** is one occurrence of a unit of text; a **type** is a distinct unit. N counts tokens, V counts types, and the **type–token ratio** is V/N (Equation (21.1)). The **relative frequency** of a type is its count divided by N (Equation (21.2)); a type seen once is a **hapax**.
- A regular-expression tokenizer with **one named alternative per kind of token**, tried from the most specific to the most general (**Table 21.1**), cuts and classifies text in one pass (**Listing 21.1**, **Figure 21.1**). One pattern handles Indonesian and English numbers, rupiah amounts, reduplicated words and contractions.
- **Sentence splitting** needs rules against abbreviations such as *Jl.*, *No.* and *dll.*, and a check that the next sentence starts with a capital.
- **Stop words** are frequent function words; removing them reveals content words, but negations must be kept when meaning matters (**Listing 21.2**, **Listing 21.3**).
- **Zipf's law** says frequency falls as a power of rank (Equation (21.3)); on log–log axes that is a straight line (Equation (21.4)), fitted by least squares (Equation (21.5)). **Heaps' law** says the vocabulary grows as KN^{β} (Equation (21.6)). Our corpus shows both, with the small-corpus effects visible in **Figure 21.2**.

- Indonesian **clitics** such as *-nya* and *-lah* can be split safely only when the remaining stem is a known word (**Listing 21.5**). Modern language models use **subword tokenization** learned from data.
- Automatic **tests** (**Listing 21.6**) protect a tokenizer from well-meant changes.

21.11 Exercises

Exercise 21.1. Tokenize by hand, following **Table 21.1**, the sentence "Bu Sari membeli 2,5 kg beras seharga Rp32.500 di Jl. Rungkut." List each token with its kind. Then compute N, V and the TTR of its *word* tokens after lowercasing.

Exercise 21.2. Text A has 200 word tokens and 150 types; text B has 2,000 word tokens and 900 types. (a) Compute the TTR of both. (b) Can we conclude that the writer of A uses a richer vocabulary? Use Equation (21.6) with $\beta = 0.8$ to estimate how many types a text like A would have at 2,000 tokens, and explain.

Exercise 21.3. Extend the tokenizer pattern so that it recognizes Indonesian mobile numbers written as `0812-3456-7890`, times written as `07.30` or `19:45`, and hashtags such as `#Surabaya`. Test it on "Buka 07.30, tutup 19:45. Hubungi 0812-3456-7890 #Surabaya Rp8.000/kg".

Exercise 21.4. In the English half of the corpus, `zipf.py` found $C = 82.4$ and $s = 0.74$. Use Equation (21.3) to predict the count of the word at rank 10. The real word at rank 10 is *from*, with 15 tokens. How close is the prediction?

Exercise 21.5. The text "Kami menjual sabun, deterjen, dll. Semua barang baru." contains two sentences, but `split_sentences` returns one. Explain why, and propose a rule that would split it correctly without breaking "Kami di Jl. Kenari No. 21."

Exercise 21.6. After stop-word removal, the Indonesian top ten contains the numerals *dua* and *tiga*, and the English top five contains *new* and *every*. Should they be stop words? Answer for two different applications: finding the topic of a news item, and extracting prices and quantities from customer messages.

21.12 Solutions to the Exercises

Solution 21.1. The tokens are: *Bu* WORD, *Sari* WORD, *membeli* WORD, *2,5* NUMBER, *kg* WORD, *beras* WORD, *seharga* WORD, *Rp32.500* MONEY, *di* WORD, *Jl* WORD, *.* PUNCT, *Rungkut* WORD, *.* PUNCT. Note that *Jl.* becomes the word *Jl* followed by a period token; the sentence splitter, not the tokenizer, knows that this period is not a sentence end. The word tokens are *bu, sari, membeli, kg, beras, seharga, di, jl, rungkut*, so $N = 9$, and all nine are different, so $V = 9$ and $\text{TTR} = 9/9 = 1$ by Equation (21.1). A short sentence almost always has a TTR of 1, which is one more reason not to compare TTRs across lengths.

Solution 21.2. (a) $\text{TTR}_A = 150/200 = 0.75$ and $\text{TTR}_B = 900/2000 = 0.45$. (b) No. From Equation (21.6), $V(2000)/V(200) \approx (2000/200)^{0.8} = 10^{0.8} \approx 6.31$, so a text like A would have about $150 \times 6.31 \approx 946$ types at 2,000 tokens, and a TTR of about $946/2000 = 0.47$. That is almost exactly B's 0.45. The two writers are about equally varied; A only looked richer because it is shorter.

Solution 21.3. Three alternatives are added in front of the others, most specific first, as **Listing 21.7** shows. The time pattern accepts hours 00 to 23 and minutes 00 to 59, and `(?!\d)`

makes sure that a longer number such as *07.305* is not cut into a time and a digit. The phone pattern must come before `NUMBER`, which would otherwise take *0812-3456* as a score-like number.

Listing 21.7 `solutions/phone_tokens.py`: extra token kinds for phone numbers, times and hashtags.

```
"""phone_tokens.py - Exercise 21.3: phone numbers, times and hashtags."""
import re

EXTRA_RE = re.compile(r"""
    (?P<PHONE>   0\d{2,3}-\d{4}-\d{3,4} )                # 0812-3456-7890
  | (?P<TIME>    (?:[01]\d|2[0-3])[.:][0-5]\d(?!\d) )     # 07.30  19:45
  | (?P<HASHTAG> \#\w+ )                                   # #Surabaya
  | (?P<MONEY>   (?:Rp|\$)\s?\d+(?:[.,]\d+)* )
  | (?P<NUMBER>  \d+(?:[.,]\d+)*(?:-\d+)? )
  | (?P<WORD>    [^\W\d_]+(?:[-'’][^\W\d_]+)* )
  | (?P<PUNCT>   [^\w\s] )
""", re.VERBOSE)

text = "Buka 07.30, tutup 19:45. Hubungi 0812-3456-7890 #Surabaya Rp8.000/kg"
for m in EXTRA_RE.finditer(text):
    print(f"{m.lastgroup:<8}{m.group()}")
```

```
python solutions/phone_tokens.py
```

```
WORD    Buka
TIME    07.30
PUNCT   ,
WORD    tutup
TIME    19:45
PUNCT   .
WORD    Hubungi
PHONE   0812-3456-7890
HASHTAG #Surabaya
MONEY   Rp8.000
PUNCT   /
WORD    kg
```

Solution 21.4. By Equation (21.3), $f(10) \approx 82.4/10^{0.74}$. Since $10^{0.74} \approx 5.50$, the prediction is $82.4/5.50 \approx 15.0$. The real count is 15, so the prediction is essentially exact at this rank. It will be much worse deep in the tail, where many words share counts of 1 or 2, as the flat steps in **Figure 21.2** show.

Solution 21.5. The word before the period is *dll*, which is in `ABBREVIATIONS`, so the candidate boundary is skipped. The problem is genuine ambiguity: *dll.* can end a sentence or sit inside one. A reasonable extra rule is to treat abbreviations of the "and so on" kind (*dll*, *dsb*, *etc*) differently from abbreviations that are always followed by a name or a number (*Jl*, *No*, *dr*, *Mr*): for the first group, split when the next word starts with a capital; for the second group, never split. "Kami di Jl. Kenari No. 21." is unaffected, because *Jl* and *No* belong to the second group. The rule will still be wrong for "…dll. Toko X…" when the capital word is a name inside the same sentence, which is why sentence splitters for demanding work are trained on data [10].

Solution 21.6. For **topic finding**, numerals and vague words such as *new* and *every* say little about whether a text is about sports or health, so adding them to a domain stop list is reasonable; Chapter 23 shows that TF-IDF weighting pushes such words down automatically. For **extracting prices and quantities**, the numerals are the very information we want: "dua kilo" and "tiga potong" must be kept, and so must the `NUMBER` and `MONEY` tokens. A stop list therefore belongs to an application, not to a language.

Chapter 22
Spell Checker

A customer types “cucain saya sudah selesai?” and a search for *cucian* finds nothing. A shop assistant enters “detergant” in the stock list and the monthly report counts two different products. Small slips of the finger are everywhere, and a program that trusts every letter it is given is easily fooled. By the end of this chapter you will be able to measure how far apart two words are with the edit distance, computed by dynamic programming in a table you can fill in by hand; generate every word one or two slips away from a typo; choose the most likely correction using word frequencies; improve the choice with a *noisy channel* that knows which slips are common on a keyboard; and measure the result honestly, on typos that were written after the program was designed. The corrector works for Indonesian and English with the same code, runs offline on a vocabulary built from our own corpus, and needs nothing beyond the Python standard library.

22.1 Why a Spell Checker?

Profitina Laundry’s cashier types fast, and so do its customers on their phones. In the messages of a single week you will find *hraga* for *harga*, *setrka* for *setrika*, *pelnggan* for *pelanggan*, and in English *laundyr*, *recieve* and *custmer*. Every one of them is obvious to a human reader, and every one of them breaks a program that looks words up exactly: the word counter of Chapter 21 counts *hraga* as a new type, the FAQ bot of Chapter 29 cannot find the answer about prices, and a report that groups orders by service name shows *Setrika* and *Setrka* as two services.

A spell checker repairs the input before anything else uses it. It is also one of the oldest applications of language technology, and one of the most instructive, because it combines three ideas that appear again and again in this book: a **distance** between two objects, a **search** over candidates, and a **probability** that chooses among them [1]. The distance is the edit distance of Levenshtein [2] and Damerau [3]; the search is the candidate generator made famous by Peter Norvig’s short essay on spelling correction [4]; and the probability is the noisy-channel model that Kernighan, Church and Gale used for the Unix spell checker [5].

22.2 The Idea in Plain Words

Think of a becak driver who hears a passenger say “Jalan Kenar Raya”. There is no Jalan Kenar in Surabaya, so he thinks: which streets I know sound almost like that? *Kenari Raya* is one letter away. *Kenjeran* is further. He also knows that *Kenari Raya* is a street he drives through every day, so it is a likely destination. He takes the passenger to Kenari Raya. A spell checker does exactly those three things:

1. **Is the word known?** If *harga* is in our vocabulary, we leave it alone.
2. **Which known words are close?** We list every string that is one small slip away from the typo, and keep those that are real words. If none is found, we try two slips.
3. **Which of them is most likely?** Among the close words, we choose the one that people write most often, and, in the improved version, the one whose slip is most typical.

The "small slips" are four operations on letters: **delete** a letter (*deterjeen* → *deterjen*), **insert** a letter (*setrka* → *setrika*), **substitute** one letter for another (*kemija* → *kemeja*), and **transpose** two neighboring letters (*hraga* → *harga*). Studies of real typing errors found long ago that most misspellings are exactly one of these four operations [3], which is why checking one or two slips away finds nearly every intended word.

22.3 The Mathematics, Gently

22.3.1 Edit distance

> **DEFINITION.** The *Levenshtein distance* between two strings a and b is the smallest number of single-letter deletions, insertions and substitutions that turn a into b. The *Damerau distance* also allows the transposition of two adjacent letters as a single operation.

Some examples: *sepda* → *sepeda* needs one insertion, so its distance is 1, and *kemija* → *kemeja* needs one substitution, so its distance is also 1. *hraga* → *harga* is more interesting. The two words differ only in the order of their second and third letters. With a swap, one operation is enough, so the Damerau distance is 1; without swaps we must substitute r by a and then a by r, so the Levenshtein distance is 2. For short words we can find such answers by looking. For longer words, or for a program, we need a method that computes the distance without guessing, and that is the subject of the next section.

22.3.2 The table

Write $a = a_1 a_2 \ldots a_m$ and $b = b_1 b_2 \ldots b_n$, and let $D[i][j]$ be the distance between the first i letters of a and the first j letters of b. The distance we want is $D[m][n]$. Two edges of the table are easy. Turning i letters into nothing takes i deletions, and turning nothing into j letters takes j insertions:

$$D[i][0] = i, \qquad D[0][j] = j \tag{22.1}$$

For any other cell, think about the *last* letter of each prefix. The cheapest way to turn $a_1 \ldots a_i$ into $b_1 \ldots b_j$ must end with one of three moves: delete a_i (after turning $a_1 \ldots a_{i-1}$ into $b_1 \ldots b_j$), insert b_j (after turning $a_1 \ldots a_i$ into $b_1 \ldots b_{j-1}$), or match a_i with b_j, which is free if they are equal and costs one substitution if they are not. So

$$D[i][j] = \min \begin{cases} D[i-1][j] + 1 \\ D[i][j-1] + 1 \\ D[i-1][j-1] + [a_i \neq b_j] \end{cases} \tag{22.2}$$

where $[a_i \neq b_j]$ is 1 if the letters differ and 0 if they are equal. Equation (22.2) computes each cell from three cells that are already known: the one above, the one to the left, and the one diagonally above-left. Filling the table row by row, starting from the edges of Equation (22.1), therefore computes every cell exactly once. This way of solving a problem, building the answer for large inputs out of stored answers for smaller ones, is **dynamic programming**, and this particular table is the Wagner–Fischer algorithm [6]. It takes $m \times n$ steps, which for words of ten letters is a hundred tiny additions.

Transpositions add one more candidate to the minimum. If the last two letters of a's prefix are the last two letters of b's prefix in the opposite order, that is, $a_i = b_{j-1}$ and $a_{i-1} = b_j$, then

$$D[i][j] = \min(D[i][j],\ D[i-2][j-2] + 1) \tag{22.3}$$

This version is called the *optimal string alignment* distance, a simple and widely used form of the Damerau distance [1]. With it, *hraga* → *harga* costs 1, as a human would say; plain Levenshtein charges 2, because it must substitute twice.

22.3.3 How many candidates?

For a word of n letters there are n ways to delete a letter, $n-1$ ways to swap two neighbors, $26n$ ways to replace a letter by one of the 26 letters (including itself), and $26(n+1)$ ways to insert a letter into one of the $n+1$ gaps. In total

$$|E_1(w)| \le n + (n-1) + 26n + 26(n+1) = 54n + 25 \tag{22.4}$$

strings at most one edit away. For *pasr*, with $n = 4$, that is at most 241; some of them coincide, so the actual set has a few fewer. Two edits away there are tens of thousands, roughly the square, because every one of the first-level strings has its own $54n + 25$ neighbors. That quadratic growth is the reason a corrector tries one edit first and two edits only when one edit finds nothing.

22.3.4 Choosing among candidates

Several known words may be equally close. For the typo *iorning*, both *morning* (substitute *i* by *m*) and *ironing* (swap *o* and *r*) are one edit away. We need a way to prefer one. The simplest is **word frequency**. Let $c(w)$ be the number of times word w occurs in our corpus and N the total number of tokens; the estimate of the probability of w is

$$P(w) = \frac{c(w)}{N} \tag{22.5}$$

and the frequency corrector returns, among the known candidates at the smallest distance, the one with the largest $P(w)$.

A better answer asks a sharper question. We saw the typo x; which intended word w is most probable *given* x? Bayes' rule turns this around:

$$P(w \mid x) = \frac{P(x \mid w)\,P(w)}{P(x)} \tag{22.6}$$

$P(x)$ is the same for every candidate, so it cannot change which candidate wins, and we may drop it:

$$\hat{w} = \operatorname*{argmax}_{w}\ P(x \mid w)\,P(w) \tag{22.7}$$

Read Equation (22.7) as a story. A writer intends the word w, chosen with probability $P(w)$, the **prior**. The word then passes through a noisy channel, the writer's fingers and keyboard, which turns it into x with probability $P(x \mid w)$, the **channel model** or **error model**. We see only x, and we look for the w that best explains it [5]. The frequency corrector is the special case in which all slips are considered equally likely.

How can we estimate $P(x \mid w)$ without a large collection of real typos? A simple and effective choice is to let the probability fall exponentially with a *weighted* distance $d(x, w)$ in which likely slips are cheap:

$$P(x \mid w) \propto e^{-\lambda\, d(x,w)} \tag{22.8}$$

where $\lambda > 0$ controls how strongly distance is punished. Taking the logarithm of Equation (22.7) with Equation (22.8) gives the score our improved corrector maximizes:

$$\text{score}(w) = \log P(w) - \lambda\, d(x, w) \tag{22.9}$$

With $\lambda = 4$, one extra unit of distance costs a factor of $e^4 \approx 55$ in probability, so a word must be about 55 times more frequent to win with one more slip. Section 22.6 chooses the costs that go into $d(x, w)$.

22.4 Building the Edit-Distance Module

Listing 22.1 implements Equation (22.1), Equation (22.2) and Equation (22.3) in the function `distance_table`, which returns the whole table so that we can print it and walk back through it. `alignment` performs that walk: starting from the bottom-right cell, it asks which of the three moves of Equation (22.2) produced the value in the cell, records the move, and steps to the cell that move came from, until it reaches the top-left corner.

Listing 22.1 `edit_distance.py`: the dynamic-programming table, Levenshtein and Damerau distances, and the alignment.

```
"""edit_distance.py - Levenshtein and Damerau (OSA) distance with a DP table."""

def distance_table(a, b, transpositions=False):
    """Return the table D of size (len(a)+1) x (len(b)+1).

    D[i][j] is the cheapest way to turn a[:i] into b[:j]."""
    m, n = len(a), len(b)
    d = [[0] * (n + 1) for _ in range(m + 1)]
    for i in range(m + 1):
        d[i][0] = i                       # delete all i letters
    for j in range(n + 1):
        d[0][j] = j                       # insert all j letters
    for i in range(1, m + 1):
        for j in range(1, n + 1):
            same = 0 if a[i - 1] == b[j - 1] else 1
            d[i][j] = min(d[i - 1][j] + 1,           # delete a[i-1]
                          d[i][j - 1] + 1,           # insert b[j-1]
                          d[i - 1][j - 1] + same)    # keep or substitute
            if (transpositions and i > 1 and j > 1 and a[i - 1] == b[j - 2]
                    and a[i - 2] == b[j - 1]):
                d[i][j] = min(d[i][j], d[i - 2][j - 2] + 1)   # swap two
    return d

def levenshtein(a, b):
    return distance_table(a, b)[len(a)][len(b)]

def damerau(a, b):
    """Optimal string alignment: Levenshtein plus swaps of adjacent letters."""
    return distance_table(a, b, transpositions=True)[len(a)][len(b)]

def alignment(a, b):
    """Walk back through the table and list the edit operations."""
    d = distance_table(a, b)
    i, j, ops = len(a), len(b), []
    while i > 0 or j > 0:
        same = i > 0 and j > 0 and a[i - 1] == b[j - 1]
        if i > 0 and j > 0 and d[i][j] == d[i - 1][j - 1] + (not same):
            ops.append(("keep" if same else "sub", a[i - 1], b[j - 1]))
            i, j = i - 1, j - 1
        elif i > 0 and d[i][j] == d[i - 1][j] + 1:
            ops.append(("del", a[i - 1], "-"))
            i -= 1
```

Listing 22.1 (Continued) *edit_distance.py: the dynamic-programming table, Levenshtein and Damerau distances, and the alignment.*

```
        else:
            ops.append(("ins", "-", b[j - 1]))
            j -= 1
    return ops[::-1]

def print_alignment(a, b):
    """Print a over b with a line of marks: = keep, * sub, - del, + ins."""
    ops = alignment(a, b)
    mark = {"keep": "=", "sub": "*", "del": "-", "ins": "+"}
    print("  " + "".join(x for _, x, _ in ops))
    print("  " + "".join(y for _, _, y in ops))
    print("  " + "".join(mark[op] for op, _, _ in ops))

def print_table(a, b):
    d = distance_table(a, b)
    print("    " + " ".join(f"{c:>2}" for c in " " + b))
    for i in range(len(a) + 1):
        label = " " if i == 0 else a[i - 1]
        print(f"  {label} " + " ".join(f"{x:2d}" for x in d[i]))

if __name__ == "__main__":
    print_table("sepda", "sepeda")
    print_alignment("sepda", "sepeda")
    print_alignment("kemija", "kemeja")
    for a, b in [("sepda", "sepeda"), ("hraga", "harga"), ("kemija", "kemeja"),
                 ("recieve", "receive"), ("laundry", "laundry")]:
        print(f"{a:>8} -> {b:<8} Levenshtein {levenshtein(a, b)}  "
              f"Damerau {damerau(a, b)}")
```

Run it:

```
python edit_distance.py
```

```
      s  e  p  e  d  a
   0  1  2  3  4  5  6
 s  1  0  1  2  3  4  5
 e  2  1  0  1  2  3  4
 p  3  2  1  0  1  2  3
 d  4  3  2  1  1  1  2
 a  5  4  3  2  2  2  1
 sep-da
 sepeda
 ===+==
 kemija
 kemeja
 ===*==
  sepda -> sepeda   Levenshtein 1  Damerau 1
  hraga -> harga    Levenshtein 2  Damerau 1
 kemija -> kemeja   Levenshtein 1  Damerau 1
recieve -> receive  Levenshtein 2  Damerau 1
laundry -> laundry  Levenshtein 0  Damerau 0
```

Check one cell by hand to make sure the recurrence is clear. The cell in row *d* and column *e* (the fourth letter of *sepeda*) holds 1. It is the minimum of: the cell above plus one, $1 + 1 = 2$; the cell to the left plus one, $0 + 1 = 1$; and the diagonal cell plus one because $d \neq e$, $1 + 1 = 2$. The minimum is 1, and it came from the left, that is, from inserting *e*. **Figure 22.1** shades the path that `alignment` follows back from the corner; each diagonal step on the path is a kept letter, and the single horizontal step is the inserted *e*.

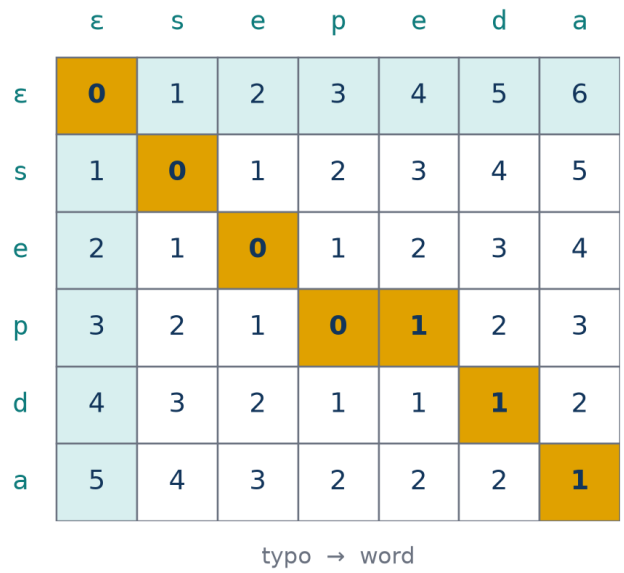

Figure 22.1 The Levenshtein table for turning the typo *sepda* into *sepeda*. The shaded cells are the path found by walking back from the bottom-right corner; the one horizontal step is the insertion of *e*.

The last five lines of the output compare the two distances. For *hraga* and *recieve*, Levenshtein says 2 and Damerau says 1, because both typos are a single swap of neighbors. Swaps are among the most common typing slips, so the Damerau version is the better measure for spelling correction.

22.5 Building the Corrector

The corrector needs a vocabulary with counts. We build it from the 96 news items of Chapter 21 plus `data/laundry.txt`, a short text in both languages about laundry services, so that words such as *setrika*, *deterjen* and *ironing* are known. Tokens are produced by the tokenizer of Chapter 21, copied unchanged into this chapter's folder.

Listing 22.2 is the complete frequency corrector. `edits1` builds the set of Equation (22.4) with four list comprehensions over all ways of splitting the word into a left and a right part; `edits2` applies `edits1` to every result of `edits1`. The heart is two lines:

- `candidates` returns the first non-empty set among: the word itself if it is known; the known words one edit away; the known words two edits away; and, if all else fails, the word unchanged.
- `correct` returns the candidate with the largest probability Equation (22.5). The key `(self.prob(w), w)` breaks ties by alphabetical order, so the result never depends on the order in which Python happens to store the set.

Listing 22.2 `spell.py`: the frequency-based corrector and a function that corrects whole texts.

```
"""spell.py - a spelling corrector for Indonesian and English."""
import csv
import math
import sys
from collections import Counter

from edit_distance import distance_table
from tokenizer import tokenize, words

LETTERS = "abcdefghijklmnopqrstuvwxyz"

def load_counts(news="data/news.tsv", extra="data/laundry.txt"):
    """Count every word of the news corpus and of the laundry text."""
    counts = Counter()
    with open(news, encoding="utf-8", newline="") as f:
        for row in csv.DictReader(f, delimiter="\t"):
            counts.update(words(row["title"] + ". " + row["text"]))
    with open(extra, encoding="utf-8") as f:
        counts.update(words(f.read()))
    return counts

def edits1(word):
    """Every string one delete, swap, substitution or insertion away."""
    splits = [(word[:i], word[i:]) for i in range(len(word) + 1)]
    deletes = [left + right[1:] for left, right in splits if right]
    swaps = [left + right[1] + right[0] + right[2:]
             for left, right in splits if len(right) > 1]
    subs = [left + c + right[1:] for left, right in splits if right
            for c in LETTERS]
    inserts = [left + c + right for left, right in splits for c in LETTERS]
    return set(deletes + swaps + subs + inserts)

def edits2(word):
    return {e2 for e1 in edits1(word) for e2 in edits1(e1)}

class SpellChecker:
    """Nearest known words first; among them the most frequent wins."""

    def __init__(self, counts):
        self.counts = counts
        self.total = sum(counts.values())
```

Listing 22.2 (Continued) *spell.py: the frequency-based corrector and a function that corrects whole texts.*

```
    def prob(self, w):
        return self.counts[w] / self.total

    def known(self, candidates):
        return {w for w in candidates if w in self.counts}

    def candidates(self, word):
        return (self.known([word]) or self.known(edits1(word))
                or self.known(edits2(word)) or {word})

    def correct(self, word):
        return max(self.candidates(word), key=lambda w: (self.prob(w), w))

    def correct_text(self, text):
        """Correct every word of text, keeping punctuation and capitals."""
        out, last = [], 0
        for t in tokenize(text):
            fixed = t.text
            if t.kind == "WORD" and t.text.isalpha():
                fixed = self.correct(t.text.lower())
                if t.text[0].isupper():
                    fixed = fixed.capitalize()
            out.append(text[last:t.start] + fixed)
            last = t.start + len(t.text)
        return "".join(out) + text[last:]

if __name__ == "__main__":
    checker = SpellChecker(load_counts())
    print(f"vocabulary: {len(checker.counts)} types, {checker.total} tokens")
    for w in sys.argv[1:] or ["hraga", "setrka", "laundyr", "teh"]:
        print(f"{w:>10} -> {checker.correct(w)}")
```

`correct_text` corrects a whole sentence. It walks through the tokens of Chapter 21, corrects only alphabetic words, restores a capital first letter, and copies everything between tokens, spaces and punctuation, exactly as it was. That is why the tokenizer kept the start position of every token.

```
python spell.py
```

```
vocabulary: 1631 types, 3589 tokens
     hraga -> harga
    setrka -> setrika
   laundyr -> laundry
       teh -> teh
```

The vocabulary has 1,631 types from 3,589 tokens. Three typos are repaired, and *teh* is left alone, for a reason we will come back to: *teh* is an Indonesian word (tea), and it occurs in our corpus in *es teh manis* and *noda teh*. Now four harder words:

```
python spell.py iorning stian pasr blanket
```

```
vocabulary: 1631 types, 3589 tokens
   iorning -> morning
     stian -> setiap
      pasr -> pasar
   blanket -> blankets
```

Two answers are wrong. *iorning* became *morning* instead of *ironing*: both are one edit away and both occur exactly twice, so the tie was broken alphabetically, and *m* comes after *i*. *blanket* was "corrected" to *blankets*, because only the plural occurs in our vocabulary. *stian* became *setiap* because *stain* is not in our vocabulary either; only *stains* is. The corrector is only as good as the words it knows.

22.6 Improving It: A Keyboard-Aware Noisy Channel

The frequency corrector treats every slip as equally likely. People do not type like that. Three kinds of slip are especially common, and each gets a cost of 0.5 instead of 1 in the weighted distance $d(x, w)$ of Equation (22.8):

- **a neighboring key**: *hatga* for *harga*, because *t* touches *r* on a QWERTY keyboard. The first letter is excluded, since people rarely miss the key they start with;
- **two swapped letters**: *hraga* for *harga*, *iorning* for *ironing*;
- **a vowel left out**: *pasr* for *pasar*, *pelnggan* for *pelanggan*. Indonesian writers often drop vowels when typing quickly, as in the familiar *yg* and *dgn* of text messages.

Listing 22.3 implements this. `neighbors` computes, from the three letter rows of a keyboard, the set of keys that touch each key. `weighted_distance` is the table of Equation (22.2) and Equation (22.3) with the cheaper costs. `NoisyChannel` inherits everything from `SpellChecker` and replaces only `correct`: it keeps known words, gathers all known candidates up to two edits away, and picks the one with the highest score of Equation (22.9).

Listing 22.3 `noisy_channel.py`: a weighted distance with cheaper keyboard slips, swaps and dropped vowels, and the noisy-channel corrector.

```
"""noisy_channel.py - rank candidates by prior times a keyboard-aware channel."""
import math

from spell import SpellChecker, edits1, edits2

ROWS = ["qwertyuiop", "asdfghjkl", "zxcvbnm"]
VOWELS = set("aeiou")

def neighbors():
    """Map each letter to the letters that touch it on a QWERTY keyboard."""
    pos = {c: (r, i) for r, row in enumerate(ROWS) for i, c in enumerate(row)}
    near = {}
    for c, (r, i) in pos.items():
        near[c] = {d for d, (r2, i2) in pos.items()
                   if d != c and abs(r - r2) <= 1 and abs(i - i2) <= 1}
    return near

NEAR = neighbors()

def weighted_distance(a, b):
    """Damerau-like distance from typo a to word b with cheaper likely slips:
    a neighboring key (not on the first letter), two swapped letters, and a
    vowel left out (pasr for pasar) each cost 0.5 instead of 1."""
    m, n = len(a), len(b)
    d = [[0.0] * (n + 1) for _ in range(m + 1)]
    for i in range(m + 1):
        d[i][0] = float(i)
    for j in range(n + 1):
        d[0][j] = float(j)
    for i in range(1, m + 1):
        for j in range(1, n + 1):
            x, y = a[i - 1], b[j - 1]
            near = i > 1 and y in NEAR.get(x, ())
            sub = 0.0 if x == y else (0.5 if near else 1.0)
            dropped = 0.5 if y in VOWELS else 1.0    # b has a letter a lacks
            d[i][j] = min(d[i - 1][j] + 1, d[i][j - 1] + dropped,
                          d[i - 1][j - 1] + sub)
            if i > 1 and j > 1 and x == b[j - 2] and a[i - 2] == y:
                d[i][j] = min(d[i][j], d[i - 2][j - 2] + 0.5)   # swapped keys
    return d[m][n]
```

Listing 22.3 (Continued) *noisy_channel.py: a weighted distance with cheaper keyboard slips, swaps and dropped vowels, and the noisy-channel corrector.*

```
class NoisyChannel(SpellChecker):
    """Choose w maximizing log P(w) - penalty * weighted_distance(typo, w)."""

    def __init__(self, counts, penalty=4.0):
        super().__init__(counts)
        self.penalty = penalty

    def score(self, typo, w):
        return math.log(self.prob(w)) - self.penalty * weighted_distance(typo, w)

    def correct(self, word):
        if word in self.counts:
            return word
        cands = self.known(edits1(word)) | self.known(edits2(word))
        if not cands:
            return word
        return max(cands, key=lambda w: (self.score(word, w), w))
```

Work the *iorning* example by hand. Both *morning* and *ironing* occur twice among 3,589 tokens, so $\log P(w) = \log(2/3589) \approx -7.49$ for both. The weighted distance to *ironing* is 0.5 (one swap), and to *morning* it is 1.0 (a substitution of the first letter, which gets no discount). With $\lambda = 4$, Equation (22.9) gives $-7.49 - 2 = -9.49$ for *ironing* and $-7.49 - 4 = -11.49$ for *morning*. *ironing* wins by 2 in log score, which is a factor of $e^2 \approx 7.4$ in probability.

22.7 Measuring It

A corrector must be judged on a list of typos whose correct answers are known. `data/typos.tsv` has 46 of them, 25 Indonesian and 21 English, labeled with the kind of slip, and including three words that are already correct, which the corrector must leave alone. **Listing 22.4** runs both correctors on a typo file, reports the accuracy per language (or per kind of slip for the generated file of Section 22.8), and lists the misses.

Listing 22.4 `evaluate.py`: accuracy of the frequency and noisy-channel correctors on a file of typos.

```
"""evaluate.py - accuracy of both correctors on a file of typos."""
import csv
import sys
import time
from collections import Counter

from noisy_channel import NoisyChannel
from spell import SpellChecker, load_counts

path = sys.argv[1] if len(sys.argv) > 1 else "data/typos.tsv"
with open(path, encoding="utf-8", newline="") as f:
    tests = list(csv.DictReader(f, delimiter="\t"))
counts = load_counts()

for name, checker in [("frequency", SpellChecker(counts)),
                      ("noisy channel", NoisyChannel(counts))]:
    start = time.perf_counter()
    right, total, misses = Counter(), Counter(), []
    for t in tests:
        group = t["lang"] if t["lang"] != "-" else t["kind"]
        guess = checker.correct(t["typo"])
        total[group] += 1
        if guess == t["correct"]:
            right[group] += 1
        else:
            misses.append(f"{t['typo']}->{guess} (want {t['correct']})")
    secs = time.perf_counter() - start
    groups = "  ".join(f"{g} {right[g]}/{total[g]}" for g in total)
    acc = sum(right.values()) / len(tests)
    print(f"{name}: {acc:.1%} correct  ({secs:.1f} s)")
    print(f"    {groups}")
    for m in misses[:6]:
        print("    miss:", m)
    if len(misses) > 6:
        print(f"    ... and {len(misses) - 6} more")
```

```
python evaluate.py
```

```
frequency: 91.3% correct  (0.0 s)
    id 25/25  en 17/21
    miss: iorning->morning (want ironing)
    miss: blanket->blankets (want blanket)
    miss: stian->setiap (want stain)
    miss: teh->teh (want the)
noisy channel: 93.5% correct  (2.7 s)
    id 25/25  en 18/21
    miss: blanket->blankets (want blanket)
    miss: stian->setiap (want stain)
    miss: teh->teh (want the)
```

The frequency corrector gets 42 of 46 right, 91.3%; the noisy channel gets 43, 93.5%, because it repairs *iorning*. The three misses that remain have causes that no choice of costs can fix:

- *blanket* and *stian* fail because the intended word is **missing from the vocabulary**. The cure is more text, or a user dictionary, as Exercise 22.5 discusses.
- *teh* for *the* is a **real-word error**: the typo is itself a correct word of Indonesian. No corrector that looks at one word at a time can know that "led teh gains" is English, a problem studied since the early days of statistical spelling correction [7]. The cure is context, and Exercise 22.4 builds it with the word pairs of the corpus.

The noisy channel is also much slower, a few seconds against a fraction of a second on the machine used for this book, because it always explores two edits. Section 22.9 returns to speed.

22.8 Testing Honestly

There is a problem with the result above, and it is important enough for a section of its own. The costs in `weighted_distance` were chosen *after* looking at the misses in `data/typos.tsv`. The vowel rule, for example, exists because *pasr* was once corrected to *past*. A method tuned on its own test data always looks better on that data than it will on new data. This is the same trap as testing a student with the exact questions used for practice.

Two fairer checks are therefore needed. The first is a fresh set, `data/typos_new.tsv`, with 16 typos written only after the code was frozen:

```
python evaluate.py data/typos_new.tsv
```

```
frequency: 100.0% correct  (0.0 s)
    id 8/8  en 8/8
noisy channel: 100.0% correct  (0.9 s)
    id 8/8  en 8/8
```

Both correctors get all 16 right, which says that these typos were easy rather than that the methods are perfect. The second check is larger: **Listing 22.5** generates 200 artificial typos from random vocabulary words of at least five letters, 50 each of four kinds (a swap, a neighboring key, a deleted letter, a doubled letter), never touching the first letter. The seed `22` makes the file identical on every run.

Listing 22.5 `make_typos.py`: a reproducible generator of artificial typos.

```
"""make_typos.py - generate a reproducible set of artificial typos."""
import random

from noisy_channel import NEAR
from spell import load_counts

KINDS = ["swap", "neighbor", "delete", "double"]

def make_typo(word, kind, rng):
    i = rng.randrange(1, len(word) - 1)          # never the first letter
    if kind == "swap":
        return word[:i] + word[i + 1] + word[i] + word[i + 2:]
    if kind == "neighbor" and NEAR.get(word[i]):
        return word[:i] + rng.choice(sorted(NEAR[word[i]])) + word[i + 1:]
    if kind == "delete":
        return word[:i] + word[i + 1:]
    return word[:i] + word[i] + word[i:]          # a doubled letter

if __name__ == "__main__":
    rng = random.Random(22)
    counts = load_counts()
    pool = sorted(w for w in counts if len(w) >= 5 and w.isalpha())
    with open("data/typos_generated.tsv", "w", encoding="utf-8") as f:
        f.write("typo\tcorrect\tlang\tkind\n")
        for n in range(200):
            word, kind = rng.choice(pool), KINDS[n % 4]
            typo = make_typo(word, kind, rng)
            if typo != word:
                f.write(f"{typo}\t{word}\t-\t{kind}\n")
    print("wrote data/typos_generated.tsv")
```

```
python make_typos.py
python evaluate.py data/typos_generated.tsv
```

```
frequency: 97.0% correct  (0.0 s)
    swap 48/50  neighbor 48/50  delete 48/50  double 50/50
    miss: hana->hand (want hanya)
    miss: slstem->system (want sistem)
    miss: movels->novels (want models)
    miss: burku->buku (want buruk)
    miss: kouta->kota (want kuota)
    miss: lapanan->layanan (want lapangan)
noisy channel: 98.0% correct  (16.0 s)
    swap 49/50  neighbor 50/50  delete 47/50  double 50/50
    miss: hana->hand (want hanya)
    miss: kouta->kota (want kuota)
    miss: heps->hopes (want helps)
    miss: lapanan->layanan (want lapangan)
```

The frequency corrector reaches 97.0% and the noisy channel 98.0%. Look at the misses: *hana* was meant to be *hanya* but *hand* is also one edit away and more frequent in English; *kouta* could be *kuota* or *kota*, and *kota* is far more common. These are genuinely ambiguous, and a human without context would often guess the same way. One warning belongs with the generated set: it contains exactly the slips that the noisy channel was designed for, so it favors that model. **Figure 22.2** puts the three results side by side; the honest summary is that the noisy channel helps by about one or two points, and that the remaining errors come from missing words and missing context.

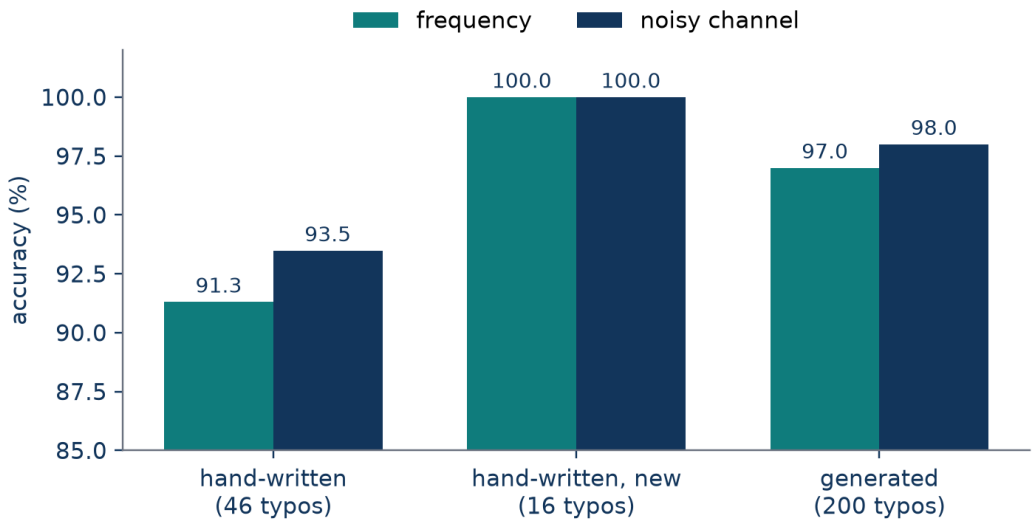

Figure 22.2 Accuracy of the two correctors on the three typo sets. The vertical axis starts at 85% so that the differences are visible.

22.9 Speed and Scale

Generating candidates costs about $54n + 25$ strings for one edit and tens of thousands for two, as Equation (22.4) predicts; for *pasr* the program builds 234 and 24,254 strings. That is fine for a sentence, slow for a book, and hopeless for a search engine that must answer in milliseconds. Two classic remedies turn the search around, so that it starts from the vocabulary rather than from the typo:

- A **BK-tree** stores the vocabulary in a tree organized by edit distance. Because the edit distance obeys the triangle inequality, a query for "all words within distance 2" can skip whole branches of the tree [8].
- **Symmetric deletion**, used by the SymSpell library, precomputes every deletion of every vocabulary word once; at query time it generates only the deletions of the typo and looks them up in a dictionary, avoiding insertions and substitutions entirely [9].

A cheap filter helps any method: two words whose lengths differ by more than k cannot be within distance k, because every edit changes the length by at most one. Exercise 22.6 uses this.

22.10 Testing the Code

Listing 22.6 checks distances computed by hand in this chapter, the presence of each kind of edit in `edits1`, the cheaper costs of the weighted distance, and a full sentence correction that keeps capitals and punctuation.

Listing 22.6 `tests/test_spell.py`: tests for the distances, the candidate generator, the weighted distance and the corrector.

```
"""Run with:  python -m pytest -q"""
import os
import sys

HERE = os.path.dirname(os.path.dirname(os.path.abspath(__file__)))
sys.path.insert(0, HERE)
os.chdir(HERE)

22.11 Common Mistakes, and How to Avoid Them

Filling the DP table in the wrong order. A cell needs its upper, left and upper-left neighbors. *Avoid it:* fill row by row, left to right, after initializing the first row and column with Equation (22.1).

Off-by-one between string positions and table positions. Row i of the table corresponds to the letter `a[i - 1]`. *Avoid it:* keep the extra row and column for the empty prefix, and write `a[i - 1]` deliberately.

Correcting words that are already right. A corrector that always looks for a "more frequent" neighbor turns rare but correct words into common ones. *Avoid it:* return a known word unchanged, as both correctors do.

Relying on Python's set order. Iterating over a set gives an order that can change between runs. *Avoid it:* break ties explicitly, as the `(score, w)` keys do.

Trusting accuracy on the data you tuned with. *Avoid it:* keep a test set you never look at while designing, or generate a new one, and say which is which, as Section 22.8 does.

Using a vocabulary that is too small. Every missing word will be "corrected" into a wrong one. *Avoid it:* build the vocabulary from a large amount of text of the same kind as the input, and let users add their own words.

Ignoring real-word errors. *teh* and *the* are both words. *Avoid it:* use context, as in Exercise 22.4, when the cost of such errors matters.

Generating two-edit candidates for every word. It multiplies the running time by a hundred. *Avoid it:* try one edit first, and use a BK-tree or symmetric deletion when the vocabulary is large.

22.12 Chapter Summary

- The **edit distance** counts the fewest deletions, insertions and substitutions (Levenshtein) and, optionally, swaps of neighbors (Damerau) that turn one string into another. It is computed by **dynamic programming** in an $(m+1) \times (n+1)$ table from Equation (22.1), Equation (22.2) and Equation (22.3) (**Listing 22.1**, **Figure 22.1**).
- A **candidate generator** lists all strings one edit away, about $54n + 25$ of them (Equation (22.4)), and two edits away when needed, and keeps the known words.
- The **frequency corrector** chooses the most frequent nearest candidate by Equation (22.5) (**Listing 22.2**). The **noisy-channel corrector** chooses $\text{argmax}_w P(x \mid w)P(w)$ (Equation (22.6), Equation (22.7)), with a channel that decays with a weighted distance (Equation (22.8), Equation (22.9)) in which keyboard neighbors, swaps and dropped vowels are cheap (**Listing 22.3**).
- On our hand-written typos the two correctors reach 91.3% and 93.5%; on 200 generated typos 97.0% and 98.0% (**Listing 22.4**, **Listing 22.5**, **Figure 22.2**). The remaining errors come from **missing words**, **ambiguity** and **real-word errors**.
- Tuning and testing on the same data inflates results; always keep an independent test.
- For large vocabularies, **BK-trees** and **symmetric deletion** make candidate search fast.

22.13 Exercises

Exercise 22.1. Fill in by hand the Levenshtein table for turning *teh* into *the*, using Equation (22.1) and Equation (22.2). What is the distance? What is the Damerau distance, by Equation (22.3)?

Exercise 22.2. Use Equation (22.4) to compute the maximum number of strings one edit away from *cucian*. Explain why `len(edits1("cucian"))` is smaller than that number, giving one concrete pair of operations that produce the same string.

Exercise 22.3. Section 22.5 says the frequency corrector turned *iorning* into *morning* because of a tie. Show exactly how `max` with the key `(self.prob(w), w)` resolves the tie, and compute the scores of Equation (22.9) for *morning* and *ironing* with $\lambda = 2$ instead of 4. Does the noisy channel still choose *ironing*?

Exercise 22.4. Write a corrector for real-word errors that looks at the previous and the next word. Use the word pairs (bigrams) of the corpus with add-k smoothing, $P(w \mid v) = \frac{c(v,w)+k}{c(v)+kV}$ with $k = 0.01$, and a channel that says the typed word is right with probability 0.95. Test it on "banking shares led teh gains", "segelas es teh manis", "noda teh dan kopi" and "a friendly match agaist thailand".

Exercise 22.5. The word *blanket* is correct English but is "corrected" to *blankets*. Give two ways to prevent this, and explain the risk each one brings.

Exercise 22.6. Prove that if $|m - n| > k$ then the Levenshtein distance between a word of length m and a word of length n is greater than k. How many words of the vocabulary would this filter remove, for a five-letter typo and $k = 2$, if vocabulary lengths were spread evenly between 2 and 14 letters?

22.14 Solutions to the Exercises

Solution 22.1. With rows for *t, e, h* and columns for *t, h, e*, the first row is 0,1,2,3 and the first column 0,1,2,3 by Equation (22.1). Row *t*: $D[1][1] = \min(2,2,0+0) = 0$; $D[1][2] = \min(3,0+1,1+1) = 1$; $D[1][3] = \min(4,2,2+1) = 2$. Row *e*: $D[2][1] = \min(0+1,3,1+1) = 1$; $D[2][2] = \min(1+1,1+1,0+1) = 1$ $(e \neq h)$; $D[2][3] = \min(2+1,1+1,1+0) = 1$ $(e = e)$. Row *h*: $D[3][1] = \min(1+1,4,2+1) = 2$; $D[3][2] = \min(1+1,2+1,1+0) = 1$ $(h = h)$; $D[3][3] = \min(1+1,1+1,1+1) = 2$. The Levenshtein distance is 2. For Damerau, at cell (3,3) we have $a_3 = h = b_2$ and $a_2 = e = b_3$, so Equation (22.3) allows $D[1][1] + 1 = 0 + 1 = 1$. The Damerau distance is 1: one swap.

Solution 22.2. *cucian* has $n = 6$, so Equation (22.4) gives at most $54 \cdot 6 + 25 = 349$ strings. Many operations produce the same string. Substituting a letter by itself gives the original word back, and there are six such substitutions, one per letter. Inserting a letter next to an identical letter also coincides: inserting *c* just before or just after the first *c* gives the same *ccucian*. Because `edits1` returns a set, each distinct string is kept only once, so the set is smaller than 349; the program reports the exact size if you run `len(edits1("cucian"))`.

Solution 22.3. Both candidates have probability 2/3589, so the first element of the key is equal, and `max` compares the second element, the word itself. Strings compare alphabetically, and *morning* > *ironing* because *m* > *i*, so *morning* is the maximum. The tie-break is deterministic but carries no meaning. With $\lambda = 2$, Equation (22.9) gives $-7.49 - 2 \times 0.5 = -8.49$ for *ironing* and $-7.49 - 2 \times 1.0 = -9.49$ for *morning*: *ironing* still wins, because the priors are equal and only the distances decide. λ matters only when the candidates have different frequencies.

Solution 22.4. **Listing 22.7** scores each candidate *c* for the word at position *i* by $\log P(\text{channel}) + \log P(c \mid w_{i-1}) + \log P(w_{i+1} \mid c)$, the context version of Equation (22.7). The typed word keeps probability 0.95; the remaining 0.05 is shared among its known neighbors one edit away. An unknown word, such as *agaist*, is never kept.

Listing 22.7 `solutions/context.py`: a context-aware corrector for real-word errors.

```
"""context.py - Exercise 22.4: fix real-word errors with the previous word."""
import csv
import math
import os
import sys
from collections import Counter

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from spell import edits1, load_counts  # noqa: E402
from tokenizer import words  # noqa: E402

counts = load_counts()
pairs = Counter()
with open("data/news.tsv", encoding="utf-8", newline="") as f:
    for row in csv.DictReader(f, delimiter="\t"):
        ws = words(row["title"] + ". " + row["text"])
        pairs.update(zip(ws, ws[1:]))
with open("data/laundry.txt", encoding="utf-8") as f:
    ws = words(f.read())
    pairs.update(zip(ws, ws[1:]))

def p_next(prev, w, k=0.01):
    """P(w | prev) with add-k smoothing over the vocabulary."""
    return (pairs[(prev, w)] + k) / (counts[prev] + k * len(counts))

def correct_in_context(sentence, keep=0.95):
    """Noisy channel with context: the typed word is right with P = keep."""
    ws, out = words(sentence), []
    for i, w in enumerate(ws):
        others = {c for c in edits1(w) if c in counts} - {w}

        def score(c):
            channel = keep if c == w else (1 - keep) / max(len(others), 1)
            s = math.log(channel)
            if i > 0:
                s += math.log(p_next(ws[i - 1], c))
            if i + 1 < len(ws):
                s += math.log(p_next(c, ws[i + 1]))
            return s
        pool = others | {w} if w in counts else others or {w}
        out.append(max(pool, key=lambda c: (score(c), c)))
    return " ".join(out)
```

Listing 22.7 (Continued) *solutions/context.py: a context-aware corrector for real-word errors.*

```
for s in ["banking shares led teh gains", "segelas es teh manis",
          "noda teh dan kopi", "a friendly match agaist thailand"]:
    print(f"{s:<34} -> {correct_in_context(s)}")
```

```
python solutions/context.py
```

```
banking shares led teh gains       -> banking shares led the gains
segelas es teh manis               -> segelas es teh manis
noda teh dan kopi                  -> noda teh dan kopi
a friendly match agaist thailand   -> a friendly match against thailand
```

In “led teh gains”, the pair *led the* and the pair *the gains* both occur in the corpus, while *led teh* and *teh gains* do not, so *the* wins despite the channel’s preference for keeping the typed word. In “es teh manis” and “noda teh dan kopi” the pairs *es teh*, *teh manis* and *noda teh* are known, and *teh* stays. That is exactly the behavior we want. The small smoothing constant matters: with add-one

smoothing, the 1,631-word vocabulary drowns the few observed pairs and nothing is ever changed.

Solution 22.5. (1) Add *blanket* to the vocabulary, either by adding more text or through a **user dictionary** of words that are always accepted. The risk is that a misspelling added by mistake is accepted forever. (2) **Lemmatize** or **stem** the vocabulary so that *blankets* also makes *blanket* known. The risk is that stemming creates non-words or merges different words, as the *-nya* example of Chapter 21 showed. In both cases the corrector should only *suggest* corrections for words it does not know, and let the person decide.

Solution 22.6. Each deletion or insertion changes the length by exactly one, and a substitution does not change it. To go from length m to length n we therefore need at least $|m - n|$ deletions or insertions, so the distance is at least $|m - n|$. If $|m - n| > k$, the distance is greater than k. For a five-letter typo and $k = 2$, only lengths 3 to 7 can be within distance 2: that is 5 of the 13 lengths from 2 to 14, so about $8/13 \approx 62\%$ of the vocabulary is removed without computing a single table.

Chapter 23

Keyword Extractor (TF-IDF)

Chapter 21 counted words and found that the most frequent ones say almost nothing: *di*, *dan*, *the*, *of*. This chapter turns that observation into one of the most useful formulas in language technology. By the end of it you will be able to explain term frequency, document frequency and inverse document frequency in plain words and in symbols; compute TF-IDF weights by hand for a small example; write a keyword extractor from scratch that picks the five words that best describe a news item; check that your implementation agrees with scikit-learn to sixteen decimal places; measure keyword quality against headlines; and double that quality with one idea borrowed from journalism, the lead sentence. The same weights reappear in the summarizer of Chapter 24, the topic classifier of Chapter 25 and the FAQ bot of Chapter 29.

23.1 Why Extract Keywords?

The owner of Profitina Laundry reads a local news site every morning and wants to know, at a glance, what each item is about. A list of tags under every headline would do: *cabai, harga, Lebaran*; *QRIS, binatu, pembayaran*; *demam berdarah, puskesmas*. Nobody has time to tag hundreds of items by hand, but a program can, if it can decide which words of a text are *characteristic* of it.

The same need appears everywhere. A library catalog wants subject terms for every book. A customer-service inbox wants to route “noda kopi di kemeja saya tidak hilang” to the stain specialist. A search engine wants to know that a document about *kecerdasan buatan* is a good answer for a query containing those words, even though *yang* and *di* appear in the document far more often. All of these rest on the same question: how important is a word *to this document*, compared with how common it is *everywhere*?

The answer that has served search engines for half a century is **TF-IDF**, *term frequency times inverse document frequency*. The idea of weighting a word by how rare it is across a collection was published by Karen Spärck Jones in 1972 [1], and the combination with term frequency became the standard weighting of the vector-space model of Salton and his colleagues [2]. It remains a strong baseline today, and it is the first thing to try before anything more complicated [3].

23.2 The Idea in Plain Words

Imagine a pile of 48 newspaper clippings. Pick one about a laundry app that uses artificial intelligence. Which words describe it?

- A word that appears **many times in this clipping** is probably important to it. *Cucian* (laundry) and *kecerdasan* (intelligence) each appear twice. That is the **term frequency**.
- But *memakai* (to use) also appears twice, and it appears in seven of the 48 clippings; it is a general verb. *Di* appears in 21 clippings and *dan* in 26. A word that appears in **many clippings** cannot distinguish one clipping from another. The rarer a word is across the pile, the more it tells us. That is the **inverse document frequency**.

TF-IDF multiplies the two. A word scores high when it is frequent *here* and rare *elsewhere*. *Kecerdasan* appears twice in this clipping and in no other: it gets the highest score. *Dan* may appear often, but it is everywhere: its score is low. The keywords of a text are simply its highest-scoring words.

A becak driver in Surabaya would understand at once. If a passenger says “Tugu Pahlawan” twice, that is where he wants to go; if he says “tolong” (please) twice, that tells the driver nothing, because every passenger says it.

23.3 The Mathematics, Gently

We need four quantities. Let the **corpus** be a collection of N documents $d_1, \dots, d_N$, and let t be a **term**, which in this chapter is a content word or, in Section 23.6, a two-word phrase.

23.3.1 Term frequency

The **term frequency** of t in document d is the number of times t occurs in d:

$$\mathrm{tf}(t, d) = \text{count of } t \text{ in } d \tag{23.1}$$

In *“Aplikasi binatu memakai kecerdasan buatan. Sebuah aplikasi binatu … memakai kecerdasan buatan …”*, $\mathrm{tf}(\text{kecerdasan}, d) = 2$.

Raw counts reward repetition without limit: a word that appears ten times gets ten times the weight of a word that appears once, though it is hardly ten times as important. A common remedy is the **sublinear** or logarithmic term frequency

$$\mathrm{tf}_{\log}(t, d) = 1 + \log \mathrm{tf}(t, d) \quad \text{for } \mathrm{tf}(t, d) > 0 \tag{23.2}$$

so that ten occurrences count about 3.3 times as much as one, not ten times [3].

23.3.2 Document frequency and its inverse

The **document frequency** $\mathrm{df}(t)$ is the number of documents that contain t at least once. It counts documents, not occurrences: a word that appears five times in one document has $\mathrm{df} = 1$. The **inverse document frequency** is

$$\mathrm{idf}(t) = \log \frac{N}{\mathrm{df}(t)} \tag{23.3}$$

Look at its two extremes. A word that occurs in every document has $\mathrm{df} = N$ and $\mathrm{idf} = \log 1 = 0$: it carries no information about which document we are in. A word that occurs in a single document has $\mathrm{idf} = \log N$, the largest possible value. The logarithm makes the scale gentle: halving the document frequency adds a constant $\log 2$ to the idf, instead of doubling it.

Why a logarithm, and why this particular fraction? Think of drawing a document at random. The probability that it contains t is $\mathrm{df}(t)/N$. Learning that a document contains a word that almost every document contains tells us almost nothing; learning that it contains a word that only one document in N contains narrows it down to one. The quantity $\log \frac{N}{\mathrm{df}}$ is exactly the “surprise” of that event in information theory, which is one of the explanations Robertson gives for why idf works so well [4].

Equation (23.3) has two practical flaws. It divides by zero for a term that appears in no document of the corpus, such as a word in a new query, and it gives weight zero to a word that occurs in every document, which can make a document vector entirely zero. scikit-learn therefore uses a **smoothed** version by default [5]:

$$\mathrm{idf}_s(t) = \log\frac{1+N}{1+\mathrm{df}(t)} + 1 \tag{23.4}$$

Adding one to the numerator and denominator behaves as if one extra document contained every term, so the fraction is never zero or infinite; adding one at the end keeps every weight positive. **Figure 23.1** compares the two curves for our $N = 48$ Indonesian documents and marks a few words. *Kecerdasan* sits at the top left, rare and heavy; *di* and *dan* sit at the bottom right, common and light.

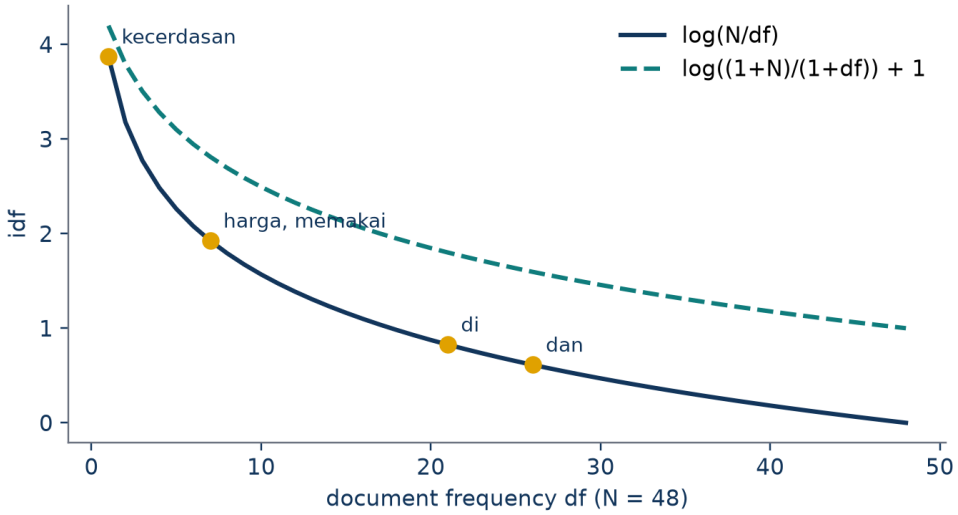

Figure 23.1 The inverse document frequency as a function of document frequency for $N = 48$ documents, plain and smoothed. The dots mark words of the Indonesian corpus.

23.3.3 TF-IDF and normalization

The weight of term t in document d is the product

$$w(t,d) = \mathrm{tf}(t,d) \cdot \mathrm{idf}(t) \tag{23.5}$$

A document then becomes a **vector**: a list of weights, one per term of the vocabulary, mostly zeros. Long documents have larger counts and therefore larger weights, which is unfair when we compare documents of different lengths. The usual cure is to divide the vector by its length, its **Euclidean norm**:

$$\hat{w}(t,d) = \frac{w(t,d)}{\sqrt{\sum_u w\,(u,d)^2}} \tag{23.6}$$

where the sum runs over all terms u of the document. After this step every document vector has length exactly 1, and only the *proportions* of the weights matter. Normalization does not change which words of a single document are its keywords, because every weight of the document is divided by the same number; it matters when documents are compared, as in Exercise 23.4 and in Chapter 29.

23.3.4 A worked example

Take a tiny corpus of $N = 3$ documents: d_1 = "cabai naik", d_2 = "harga cabai naik", d_3 = "harga emas naik". The document frequencies are df(naik) $= 3$, df(cabai) $= 2$, df(harga) $= 2$, df(emas) $= 1$. With Equation (23.3) and natural logarithms:

- idf(naik) $= \log(3/3) = 0$;
- idf(cabai) $=$ idf(harga) $= \log(3/2) \approx 0.405$;
- idf(emas) $= \log(3/1) \approx 1.099$.

In d_3 every term occurs once, so by Equation (23.5) the weights are 0.405 for *harga*, 1.099 for *emas* and 0 for *naik*. The best keyword of d_3 is *emas*, which is right: gold is what makes this document different from the other two. The length of the vector is $\sqrt{0.405^2 + 1.099^2 + 0^2} = \sqrt{0.164 + 1.208} \approx 1.171$, so by Equation (23.6) the normalized weights are 0.346 and 0.938. The tests of Section 23.8 check exactly these facts.

23.3.5 Measuring keyword quality

To compare methods we need a number. Our corpus gives us a free reference: every news item has a **headline** written by a person. If we extract keywords from the *body* only, a good method should find words that the headline also uses. For a document with extracted keywords K ($|K| = k$) and headline content words H, the **precision at** k is

$$P@k = \frac{|K \cap H|}{k} \tag{23.7}$$

the fraction of keywords that appear in the headline, and the **headline recall** $|K \cap H|/|H|$ is the fraction of headline words that the keywords found. Both are averaged over all documents. This is an imperfect reference, because headlines often use synonyms of body words, but it is automatic, honest, and the same for every method.

23.4 Building the Keyword Extractor

Listing 23.1 implements Section 23.3 as a small class. It reuses the tokenizer and stop-word lists of Chapter 21, copied into this chapter's folder.

Listing 23.1 `tfidf.py`: TF-IDF weights and keywords, written from scratch.

```
"""tfidf.py - TF-IDF weighting written from scratch."""
import math
from collections import Counter

from stopwords import STOPWORDS
from tokenizer import split_sentences, words

def terms(text, ngrams=1):
    """Content words of text, plus two-word phrases when ngrams == 2."""
    ws = words(text)
    out = [w for w in ws if w not in STOPWORDS and not w.isdigit()]
    if ngrams == 2:
        out += [a + " " + b for a, b in zip(ws, ws[1:])
                if a not in STOPWORDS and b not in STOPWORDS]
    return out

class TfIdf:
    """Learn document frequencies from a corpus; weigh the terms of a text."""

    def __init__(self, ngrams=1, smooth=True, sublinear=False):
        self.ngrams, self.smooth, self.sublinear = ngrams, smooth, sublinear

    def fit(self, texts):
        self.n_docs = len(texts)
        self.df = Counter()
        for text in texts:
            self.df.update(set(terms(text, self.ngrams)))   # once per document
        return self

    def idf(self, term):
        df = self.df[term]
        if self.smooth:                      # as scikit-learn: never divides by 0
            return math.log((1 + self.n_docs) / (1 + df)) + 1
        return math.log(self.n_docs / df) if df else 0.0
```

Listing 23.1 (Continued) *tfidf.py: TF-IDF weights and keywords, written from scratch.*

```
    def weights(self, text):
        """Return {term: tf-idf}, scaled so that the vector has length 1."""
        tf = Counter(terms(text, self.ngrams))
        w = {}
        for t, c in tf.items():
            f = 1 + math.log(c) if self.sublinear else c
            w[t] = f * self.idf(t)
        norm = math.sqrt(sum(x * x for x in w.values())) or 1.0
        return {t: x / norm for t, x in w.items()}

    def keywords(self, text, k=5, lead_boost=1.0):
        """The k heaviest terms; terms of the first sentence count lead_boost
        times as much, because news puts the main point first."""
        w = self.weights(text)
        if lead_boost != 1.0:
            lead = set(terms(split_sentences(text)[0], self.ngrams))
            w = {t: x * (lead_boost if t in lead else 1.0) for t, x in w.items()}
        return sorted(w.items(), key=lambda item: (-item[1], item[0]))[:k]
```

The pieces map onto the equations one to one.

- `terms` turns a text into its content words: lowercased words from the tokenizer, minus stop words and pure numbers. With `ngrams=2` it also adds every pair of adjacent words in which neither word is a stop word, such as *artificial intelligence*.

- `fit` learns the document frequencies. The line `self.df.update(set(terms(text, self.ngrams)))` is the whole definition of df: `set` removes repetitions, so each document adds at most one to each term.
- `idf` is Equation (23.4) by default and Equation (23.3) with `smooth=False`.
- `weights` computes Equation (23.5), optionally with the logarithmic tf of Equation (23.2), and normalizes by Equation (23.6). The expression `or 1.0` protects an empty text from a division by zero.
- `keywords` sorts the terms by weight, breaking ties alphabetically so that the output is reproducible, and returns the top k. We will come back to its `lead_boost` parameter in Section 23.6.

Listing 23.2 wraps the class in a command-line program. It fits the model on the documents of the same language only, because an Indonesian document frequency tells us nothing about English words.

Listing 23.2 `keywords.py`: a command-line keyword extractor with an explanation mode.

```
"""keywords.py - print the keywords of a news item, or of your own text."""
import argparse
import csv
from collections import Counter

from tfidf import TfIdf, terms

def load(path="data/news.tsv"):
    with open(path, encoding="utf-8", newline="") as f:
        return list(csv.DictReader(f, delimiter="\t"))

def main():
    ap = argparse.ArgumentParser(description=__doc__)
    ap.add_argument("doc", nargs="?", default="id25", help="document id")
    ap.add_argument("--text", help="your own text instead of a document")
    ap.add_argument("--lang", default=None, help="id or en (for --text)")
    ap.add_argument("--k", type=int, default=5)
    ap.add_argument("--ngrams", type=int, default=1, choices=[1, 2])
    ap.add_argument("--lead", type=float, default=1.0,
                    help="weight of first-sentence terms, e.g. 2")
    ap.add_argument("--explain", action="store_true")
    args = ap.parse_args()

    rows = load()
    if args.text:
        text, lang = args.text, args.lang or "id"
    else:
        row = next(r for r in rows if r["id"] == args.doc)
        text, lang = row["title"] + ". " + row["text"], row["lang"]
        print(f"[{row['id']}] {row['title']}")
    corpus = [r["title"] + ". " + r["text"] for r in rows if r["lang"] == lang]
    model = TfIdf(ngrams=args.ngrams).fit(corpus)

    if args.explain:
        tf = Counter(terms(text, args.ngrams))
        print(f"N = {model.n_docs} documents")
        print(f"{'term':<14}{'tf':>3}{'df':>4}{'idf':>7}{'tf-idf':>8}{'weight':>8}")
        for t, w in model.keywords(text, args.k):
            idf = model.idf(t)
            print(f"{t:<14}{tf[t]:>3}{model.df[t]:>4}{idf:>7.3f}"
                  f"{tf[t] * idf:>8.3f}{w:>8.3f}")
    else:
        for t, w in model.keywords(text, args.k, args.lead):
            print(f"  {w:.3f}  {t}")
```

Listing 23.2 (Continued) *keywords.py: a command-line keyword extractor with an explanation mode.*

```
if __name__ == "__main__":
    main()
```

23.5 Running It

The default document is the one about the laundry app:

```
python keywords.py
```

```
[id25] Aplikasi binatu memakai kecerdasan buatan
  0.354  buatan
  0.354  cucian
  0.354  kecerdasan
  0.320  aplikasi
  0.320  binatu
```

The five keywords are exactly how a person would tag the item: *buatan*, *cucian*, *kecerdasan*, *aplikasi*, *binatu*. The `--explain` option shows where the numbers come from:

```
python keywords.py id25 --explain --k 8
```

```
[id25] Aplikasi binatu memakai kecerdasan buatan
N = 48 documents
term           tf  df    idf  tf-idf  weight
buatan          2   1  4.199   8.397   0.354
cucian          2   1  4.199   8.397   0.354
kecerdasan      2   1  4.199   8.397   0.354
aplikasi        2   2  3.793   7.586   0.320
binatu          2   2  3.793   7.586   0.320
memakai         2   7  2.812   5.625   0.237
deterjen        1   1  4.199   4.199   0.177
harian          1   1  4.199   4.199   0.177
```

Verify one row with Equation (23.4). For *buatan*, $N = 48$ and $\mathrm{df} = 1$, so $\mathrm{idf}_s = \log(49/2) + 1 = 3.199 + 1 = 4.199$, and with $\mathrm{tf} = 2$ the product of Equation (23.5) is 8.397. *Memakai* also occurs twice, but it appears in seven documents, so its idf is only $\log(49/8) + 1 = 2.812$ and it falls to sixth place. The last column is the normalized weight of Equation (23.6); dividing 8.397 by 0.354 shows that the length of this document's vector is about 23.7. **Figure 23.2** makes the effect of idf visible: on the left, raw counts without a stop list, where *memakai* and even *dan* compete with the real topic words; on the right, TF-IDF.

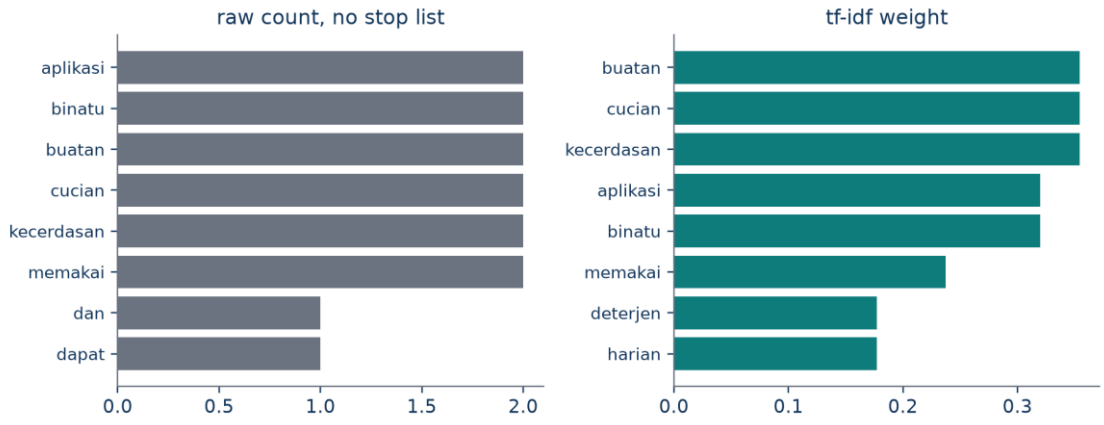

Figure 23.2 The top eight words of item id25 by raw count (left) and by TF-IDF weight (right). The inverse document frequency pushes general words such as *memakai* and *dan* down.

The program also accepts any text. Here is a customer message:

```
python keywords.py --text "Noda kopi di kemeja saya tidak hilang" --lang id
```

```
  0.459  hilang
  0.459  kemeja
  0.459  noda
  0.459  saya
  0.394  kopi
```

Two lessons hide in this output. First, words that never occur in the corpus, such as *noda*, *kemeja* and *hilang*, get the maximum idf, because $\mathrm{df} = 0$ in Equation (23.4); *kopi*, which appears in the coffee-export item, is slightly lower. Second, *saya* (I) is ranked as high as *noda* (stain), because our

stop list does not contain it. News items rarely say *saya*, but customer messages say it constantly. A corpus of customer messages would give *saya* a low idf automatically; a corpus of news cannot. The weights are only as good as the corpus they are learned from.

23.6 Improving It

23.6.1 Phrases

Many ideas are two words: *kecerdasan buatan*, *artificial intelligence*, *demam berdarah*, *mobil listrik*. With `--ngrams 2`, `terms` adds adjacent pairs of content words as terms of their own:

```
python keywords.py en25 --ngrams 2
```

```
[en25] Laundry app uses artificial intelligence
  0.380  laundry
  0.281  artificial
  0.281  artificial intelligence
  0.281  intelligence
  0.281  laundry app
```

artificial intelligence and *laundry app* now appear as keywords. Pairs are rarer than single words, so they get high idf, and the list fills up quickly with overlapping terms (*artificial*, *intelligence* and *artificial intelligence*). A practical extractor usually removes a single word when a phrase containing it is already on the list.

23.6.2 The lead sentence

Journalists write news as an *inverted pyramid*: the most important facts go into the first sentence, the **lead**, and the details follow. That an early position in a text signals importance was noticed in early research on automatic abstracting [6], and it is still one of the strongest signals for news. The `lead_boost` parameter of `keywords` multiplies the weight of every term that appears in the first sentence:

$$w'(t,d) = \begin{cases} \beta\,\hat{w}(t,d) & \text{if } t \text{ is in the first sentence of } d \\ \hat{w}(t,d) & \text{otherwise} \end{cases} \tag{23.8}$$

with $\beta = 2$, "a word of the lead counts double". Because the command-line program joins the headline and the body, the first sentence of a whole item is its headline:

```
python keywords.py id01
python keywords.py id01 --lead 2
```

```
[id01] Harga cabai naik menjelang Lebaran
  0.535  cabai
  0.298  naik
  0.239  harga
  0.178  beralih
  0.178  deras
[id01] Harga cabai naik menjelang Lebaran
  1.070  cabai
  0.595  naik
  0.478  harga
  0.357  lebaran
  0.322  menjelang
```

Without the boost, two incidental words of the last sentence, *beralih* (switch) and *deras* (heavy, of rain), make the list; with it, *Lebaran* and *menjelang* (approaching) take their place. The weights are no longer normalized, which is harmless for ranking.

23.7 Measuring It

Listing 23.3 runs the comparison of Section 23.3.5 honestly: it fits each model on the bodies only, extracts five keywords from each body, and compares them with the words of the headline, which the model never saw. A two-word keyword counts as a hit when both of its words are in the headline. The baseline "tf only" ranks words by raw count, with stop words removed.

Listing 23.3 `evaluate.py`: precision at 5 and headline recall of five keyword methods.

```
"""evaluate.py - do the keywords of the body match the words of the title?"""
from collections import Counter

from keywords import load
from tfidf import TfIdf, terms

def tf_only(text, k):
    counts = Counter(terms(text))
    return [t for t, _ in sorted(counts.items(), key=lambda x: (-x[1], x[0]))[:k]]

def hit(keyword, title_terms):
    return all(part in title_terms for part in keyword.split())

rows = load()
K = 5
print(f"{'method':<22}{'lang':<6}{'precision@5':>12}{'title recall':>14}")
for lang in ("id", "en"):
    docs = [r for r in rows if r["lang"] == lang]
    bodies = [r["text"] for r in docs]
    models = {"tf-idf": TfIdf().fit(bodies),
              "tf-idf, log tf": TfIdf(sublinear=True).fit(bodies),
              "tf-idf + bigrams": TfIdf(ngrams=2).fit(bodies)}
    methods = {"tf only": lambda text: tf_only(text, K)}
    for name, m in models.items():
        methods[name] = lambda text, m=m: [t for t, _ in m.keywords(text, K)]
    methods["tf-idf + lead x2"] = lambda text: [
        t for t, _ in models["tf-idf"].keywords(text, K, lead_boost=2.0)]
    for name, extract in methods.items():
        prec = rec = 0.0
        for r in docs:
            title = set(terms(r["title"]))
            keys = extract(r["text"])
            hits = sum(hit(t, title) for t in keys)
            prec += hits / len(keys)
            found = {w for t in keys if hit(t, title) for w in t.split()}
            rec += len(found) / len(title)
        n = len(docs)
        print(f"{name:<22}{lang:<6}{prec / n:>12.3f}{rec / n:>14.3f}")
```

```
python evaluate.py
```

```
method                lang   precision@5  title recall
tf only               id           0.246         0.269
tf-idf                id           0.279         0.309
tf-idf, log tf        id           0.279         0.309
tf-idf + bigrams      id           0.233         0.242
tf-idf + lead x2      id           0.513         0.556
tf only               en           0.196         0.207
tf-idf                en           0.213         0.231
tf-idf, log tf        en           0.213         0.231
tf-idf + bigrams      en           0.200         0.225
tf-idf + lead x2      en           0.429         0.458
```

Read the table from top to bottom. TF-IDF beats plain counting in both languages, from 0.246 to 0.279 in Indonesian and from 0.196 to 0.213 in English, by Equation (23.7). The logarithmic tf of Equation (23.2) changes nothing, for a simple reason: in items of three sentences, almost every word occurs once, and $1 + \log 1 = 1$. Bigrams slightly *lower* precision, because a phrase is a hit only if both words are in the headline. The lead boost of Equation (23.8) is the big winner: precision roughly doubles, to 0.513 and 0.429, and so does recall. Three sentences are not much text, and knowing *where* a word appears tells us more than counting it.

A word of caution about the lead boost: it was chosen by reasoning about news, and values from 1.5 to 3 give almost the same result on this corpus, so the improvement is not a lucky setting. It would not help for a text whose first sentence is a greeting, such as a customer message that begins “Selamat pagi, Kak”. Always ask whether a trick fits the kind of text you have.

23.7.1 Agreement with scikit-learn

Writing TF-IDF from scratch is the best way to understand it; using a tested library is the best way to deploy it. **Listing 23.4** checks that our numbers are the same as those of scikit-learn’s `TfidfVectorizer` [5], given the same tokens (our `terms` function is passed as the `analyzer`), the same smoothed idf, and the same normalization.

Listing 23.4 `compare_sklearn.py`: our weights against scikit-learn’s `TfidfVectorizer`.

```
"""compare_sklearn.py - our TF-IDF against scikit-learn's TfidfVectorizer."""
import sklearn
from sklearn.feature_extraction.text import TfidfVectorizer

from keywords import load
from tfidf import TfIdf, terms

texts = [r["title"] + ". " + r["text"] for r in load() if r["lang"] == "id"]
ours = TfIdf().fit(texts)
vec = TfidfVectorizer(analyzer=terms, smooth_idf=True, norm="l2")
matrix = vec.fit_transform(texts)
vocab = vec.get_feature_names_out()

worst = 0.0
for i, text in enumerate(texts):
    mine = ours.weights(text)
    row = matrix[i].toarray()[0]
    theirs = {vocab[j]: row[j] for j in row.nonzero()[0]}
    assert mine.keys() == theirs.keys()
    worst = max(worst, max(abs(mine[t] - theirs[t]) for t in mine))
print(f"scikit-learn {sklearn.__version__}: {matrix.shape[0]} documents, "
      f"{matrix.shape[1]} terms")
print(f"largest difference between the two: {worst:.1e}")
```

```
python compare_sklearn.py
```

```
scikit-learn 1.9.1: 48 documents, 717 terms
largest difference between the two: 1.1e-16
```

The largest difference over all 48 documents and 717 terms is about 10^{-16}, the rounding error of floating-point arithmetic. The two implementations compute the same thing. scikit-learn 1.9.1 is the current release at the time of writing [7], and it stores the vectors as sparse matrices, which matters when the vocabulary has a million terms.

23.8 Testing

Listing 23.5 turns the worked example of Section 23.3.4 into tests: a word that appears in every document gets idf zero, a word that appears in one of three documents gets log3, the normalized vector has length one, and the rare word *emas* ranks first.

Listing 23.5 `tests/test_tfidf.py`: tests based on the worked example.

```
"""Run with:  python -m pytest -q"""
import math
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from tfidf import TfIdf, terms  # noqa: E402

DOCS = ["cabai naik", "harga cabai naik", "harga emas naik"]

def test_terms_drop_stopwords_and_numbers():
    assert terms("Harga cabai di pasar naik 5 persen") == [
        "harga", "cabai", "pasar", "naik", "persen"]

def test_idf_by_hand():
    m = TfIdf(smooth=False).fit(DOCS)
    assert m.idf("naik") == 0.0                      # in every document
    assert math.isclose(m.idf("emas"), math.log(3))  # in one of three

def test_weights_have_unit_length():
    w = TfIdf().fit(DOCS).weights("harga emas naik naik")
    assert math.isclose(sum(x * x for x in w.values()), 1.0)

def test_rare_word_ranks_first():
    top = TfIdf().fit(DOCS).keywords("harga emas naik", k=1)
    assert top[0][0] == "emas"
```

```
python -m pytest -q
```

```
....                                                                     [100%]
4 passed in 0.01s
```

23.9 Keywords for Profitina Laundry's Inbox

Suppose Profitina Laundry wants to tag every incoming customer message so that the right person answers it: prices go to the cashier, stains and damage to the washing supervisor, pickup times to the courier. How would the ideas of this chapter be put to work?

First, collect the right corpus. Section 23.5 showed that news gives *saya* a high idf because journalists rarely write "I". A few hundred past messages, even without any labels, are a far better corpus: *saya*, *kak*, *mohon* and *terima kasih* occur in almost every message, so their idf falls close to its minimum by Equation (23.4), and the words that remain heavy are the ones that differ from message to message: *noda*, *luntur*, *jemput*, *harga*, *kilat*. No stop list has to be written by hand; the corpus writes it.

Second, pick a position rule that fits the genre. As Solution 23.6 argues, messages often start with a greeting and end with the request, so a boost for the last sentence, or for a sentence with a question mark, plays the role that the lead boost of Equation (23.8) plays for news.

Third, keep the vocabulary clean. Customer messages are full of typos, and a typo such as *hraga* has df = 1 and therefore the highest possible idf. Left alone, typos become "keywords". Running the spell checker of Chapter 22 before counting solves most of this, which is a good example of how the applications of this part are meant to be chained: tokenize (Chapter 21), correct (Chapter 22), weigh (this chapter).

Fourth, let a person decide. The keywords are a suggestion for routing, shown next to the message, not an automatic decision. When a message is tagged wrongly, the correction is itself useful data: Chapter 25 shows how a few hundred such labeled messages train a classifier that assigns topics directly.

23.10 Where TF-IDF Stops

TF-IDF knows only the surface of words. It cannot see that *mobil listrik* and *electric car* mean the same thing, that *memakai* and *pakai* share a root, or that "tidak mahal" means cheap. Stemming helps with the second problem; the word embeddings of Chapter 37 and the semantic search of Chapter 54 address the first; and modern keyword extractors such as YAKE combine statistics like ours with position and co-occurrence features [8]. Yet TF-IDF remains the first thing to try: it needs no training, no labels and no GPU, it explains every number it produces, and on many retrieval tasks it is surprisingly hard to beat.

23.11 Common Mistakes, and How to Avoid Them

Counting occurrences instead of documents for df. If a word appears five times in one document, its df is 1, not 5. *Avoid it:* update df with the `set` of a document's terms.

Fitting df on the text you are analyzing. With a corpus of one document, every word has idf zero under Equation (23.3). *Avoid it:* fit on a large collection of similar texts, then weigh the new text.

Mixing languages in one idf. An English word never appears in Indonesian documents, which inflates its idf in a mixed corpus. *Avoid it:* fit one model per language, as `keywords.py` does, or be aware of the effect.

Forgetting smoothing. A query word absent from the corpus makes Equation (23.3) divide by zero. *Avoid it:* use Equation (23.4), or skip unknown terms explicitly.

Comparing unnormalized vectors. Long documents look more similar to everything. *Avoid it:* normalize with Equation (23.6) before computing similarities.

Treating the stop list as universal. *saya* is rare in news and common in chat. *Avoid it:* learn weights from text like yours, or extend the stop list for the domain.

Tuning on the evaluation data. *Avoid it:* choose parameters such as the lead boost by reasoning or on separate data, and check that nearby values give similar results.

23.12 Chapter Summary

- **Term frequency** (Equation (23.1)) counts a term in a document; the **logarithmic** version (Equation (23.2)) tames repetition. **Document frequency** counts the documents that contain a term; the **inverse document frequency** (Equation (23.3)) is high for rare terms and zero for

universal ones, and the **smoothed** version (Equation (23.4)) avoids division by zero (**Figure 23.1**).

- **TF-IDF** multiplies the two (Equation (23.5)); normalizing by the Euclidean length (Equation (23.6)) makes documents of different lengths comparable. The **keywords** of a text are its highest-weighted terms (**Listing 23.1**, **Listing 23.2**, **Figure 23.2**).
- Our implementation agrees with scikit-learn's `TfidfVectorizer` to about 10^{-16} (**Listing 23.4**).
- Measured by **precision at 5** against headlines (Equation (23.7), **Listing 23.3**), TF-IDF beats raw counts, and a **lead-sentence boost** (Equation (23.8)) roughly doubles precision for news.
- TF-IDF is a strong, explainable baseline, limited to the surface of words.

23.13 Exercises

Exercise 23.1. For the corpus d_1 = "cabai naik", d_2 = "harga cabai naik", d_3 = "harga emas naik", compute the smoothed idf of Equation (23.4) for every term. Which term of d_2 is its best keyword under the plain idf, and which under the smoothed idf?

Exercise 23.2. A term occurs in every one of N documents. What are its plain and smoothed idf? Explain in one sentence each why both answers make sense.

Exercise 23.3. In the output of `keywords.py --text "Noda kopi di kemeja saya tidak hilang"`, all words except *kopi* have the same weight, 0.459. Show with Equation (23.4), Equation (23.5) and Equation (23.6) that this value is correct.

Exercise 23.4. Two documents are similar when their normalized TF-IDF vectors point in the same direction. Their **cosine similarity** is $\cos(\mathbf{u}, \mathbf{v}) = \sum_t \hat{u}_t \, \hat{v}_t$, the dot product of the unit vectors. Write a program that fits one TF-IDF model on all 96 items and lists the four items most similar to id25 and to en37. What happens to items in the other language, and why?

Exercise 23.5. The word *memakai* (to use) has $\mathrm{df} = 7$ in the Indonesian corpus, but the related forms *pakai*, *dipakai* and *pemakaian* would each have their own df. Explain how a stemmer that reduces all of them to *pakai* would change the idf of the group and the keywords of id25.

Exercise 23.6. Explain why the lead boost of Equation (23.8) helps for news items but could hurt for (a) customer messages and (b) recipes. Propose a different position rule for each.

23.14 Solutions to the Exercises

Solution 23.1. With $N = 3$: *naik* has $\mathrm{df} = 3$, so $\mathrm{idf}_s = \log(4/4) + 1 = 1$; *cabai* and *harga* have $\mathrm{df} = 2$, so $\mathrm{idf}_s = \log(4/3) + 1 \approx 1.288$; *emas* has $\mathrm{df} = 1$, so $\mathrm{idf}_s = \log(4/2) + 1 \approx 1.693$. In d_2 = "harga cabai naik", all three words occur once. Under the plain idf, *harga* and *cabai* tie at $\log(3/2) \approx 0.405$ and *naik* gets 0; alphabetical tie-breaking makes *cabai* the first keyword. Under the smoothed idf the ranking is the same, 1.288 for both against 1 for *naik*, and *naik* is no longer zero, only lower. Smoothing changes the numbers but rarely the order.

Solution 23.2. Plain: $\mathrm{idf} = \log(N/N) = 0$, which is right, because a word found everywhere cannot tell documents apart. Smoothed: $\log\frac{1+N}{1+N} + 1 = 1$, the smallest value that Equation (23.4) can take; the word still counts a little, so that a document made only of such words does not become a zero vector.

Solution 23.3. The terms of the message, after removing the stop words *di* and *tidak*, are *noda*, *kopi*, *kemeja*, *saya* and *hilang*, each with $\mathrm{tf} = 1$. Four of them never occur in the 48 Indonesian

items, so $\text{idf}_s = \log(49/1) + 1 = 3.892 + 1 = 4.892$. *kopi* occurs in exactly one item (id03, coffee exports), so $\text{idf}_s = \log(49/2) + 1 = 4.199$. The vector length is $\sqrt{4 \times 4.892^2 + 4.199^2} = \sqrt{95.73 + 17.63} = \sqrt{113.36} \approx 10.647$. The normalized weights are $4.892/10.647 \approx 0.459$ and $4.199/10.647 \approx 0.394$, exactly as printed.

Solution 23.4. **Listing 23.6** computes all 96 unit vectors and ranks the others by the dot product.

Listing 23.6 `solutions/similar.py`: the most similar news items by cosine similarity of TF-IDF vectors.

```
"""similar.py - Exercise 23.4: the news items most similar to a given one."""
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from keywords import load  # noqa: E402
from tfidf import TfIdf  # noqa: E402

def cosine(u, v):
    """Dot product of two unit-length sparse vectors stored as dicts."""
    return sum(x * v[t] for t, x in u.items() if t in v)

rows = load()
texts = {r["id"]: r["title"] + ". " + r["text"] for r in rows}
model = TfIdf().fit(list(texts.values()))          # both languages together
vectors = {i: model.weights(t) for i, t in texts.items()}

for query in ("id25", "en37"):
    ranked = sorted(((cosine(vectors[query], vectors[i]), i)
                     for i in texts if i != query), reverse=True)
    print(query, "->", ", ".join(f"{i} ({s:.2f})" for s, i in ranked[:4]))
```

```
python solutions/similar.py
```

```
id25 -> id02 (0.20), id35 (0.06), id36 (0.05), id28 (0.04)
en37 -> en47 (0.18), en41 (0.15), en35 (0.10), en38 (0.10)
```

The laundry-app item id25 is closest to id02, the item about laundries accepting QR payments, which shares *binatu*, *Surabaya*, *pemilik* (owner), *menerima* (receive) and *memakai*. The dengue item en37 is closest to en47, the blood-donation item, with which it shares *blood*, *health*, *free* and *residents*, and then to en41, another health item. Items in the other language never appear: an Indonesian and an English text share almost no terms, so their dot product is zero. TF-IDF compares *words*, not meanings, which is why the English twin of id25, en25, is invisible to it. Chapter 54 fixes this with embeddings.

Solution 23.5. Today the three forms are separate terms, each rarer than the group, so each gets a higher idf than the group would. After stemming, *pakai* would have the df of the union of the documents containing any form, at least 7, so its idf would fall. In id25, *memakai* would become *pakai*, with a lower idf, and would fall further below *kecerdasan* and *cucian*; the keywords would become slightly cleaner. The general rule: stemming merges counts, which lowers the idf of common roots and raises the tf of the merged term within a document.

Solution 23.6. (a) Customer messages often start with a greeting (“Selamat pagi, Kak”) and put the request at the end, so boosting the first sentence would promote *selamat* and *pagi*. A better rule is to boost the *last* sentence, or the sentence that contains a question mark. (b) A recipe starts with a title and an ingredient list; the steps come later. Boosting the title is useful, but boosting the ingredient list would favor quantities and units. A better rule is to boost the title only, and

down-weight lines that start with a number. Position rules are knowledge about a genre, and every genre has its own.

Chapter 24

Extractive Summarizer

A summary saves the reader's time: three sentences instead of twenty. This chapter builds a program that writes such summaries by *choosing* the most important sentences of a text, which is called **extractive** summarization. By the end of it you will be able to score sentences in four ways (by position, by word frequency, by similarity to the whole text, and by TextRank, the PageRank algorithm applied to a graph of sentences); reduce repetition with maximal marginal relevance; measure summaries against human references with ROUGE, which you will implement yourself; and interpret the results honestly, including the uncomfortable fact that for news, simply taking the first three sentences is very hard to beat. Everything runs offline on four articles written for this book, two in Indonesian and two in English, each with a reference summary written by a person.

24.1 Why Summarize?

Profitina Laundry's owner does not have time to read every report, complaint and news item that crosses her desk. A long message from a customer, the monthly report of an outlet, an article about the rainy season and what it does to laundry businesses: each would be easier to handle if it came with three sentences on top saying what matters. The same is true for anyone who reads for work: a lawyer with a stack of rulings, a doctor with patient notes, a student with a reading list.

Automatic summarization is one of the oldest dreams of computing. In 1958 Hans Peter Luhn at IBM published a method that picked the sentences of a technical paper with the most "significant" words, where significance was measured by frequency [1]. A decade later Edmundson added the position of a sentence and cue words such as "in conclusion" [2]. In 2004 Mihalcea and Tarau, and independently Erkan and Radev, recast the problem as ranking sentences in a graph, with the same idea Google used to rank web pages [3], [4]. Today large language models write *abstractive* summaries in their own words, and Chapter 85 shows how to run one locally; but extractive methods remain valuable because they never invent a fact: every sentence of the summary is a sentence of the original.

24.2 The Idea in Plain Words

Imagine a becak driver who has listened to a long story from a passenger and is asked by his friend at the pangkalan, "So, what was it about?" He will not repeat the whole story. He will pick the few sentences that carry the main points. How does he know which ones?

- **Position.** The passenger said the most important thing first: "My laundry business is overflowing because of the rain." News is written the same way.
- **Frequency.** The words that kept coming back, *binatu*, *cucian*, *hujan*, are what the story was about. A sentence full of those words is probably central.
- **Centrality.** Some sentences echo many others; they are like the hub of the story. A sentence that shares words with most of the other sentences summarizes them.

- **No repetition.** Having said "the owner receives three hundred kilograms a day", he will not add "the owner now washes much more than before". Two sentences saying the same thing waste the listener's time.

Our summarizer will give every sentence a score according to one of the first three ideas, take the three best, apply the fourth idea when asked, and print the chosen sentences in their original order so that the summary reads naturally.

Why choose sentences instead of writing new ones? Because choosing is safe. A chosen sentence comes from the text itself, so it cannot contain a fact that the text does not contain; the worst an extractive summary can do is leave out something important or pick a sentence that makes little sense without its neighbors. A generated summary can say things more briefly and smoothly, but it can also state, fluently and wrongly, that the laundry doubled its prices when the article said it doubled its *orders*. For a business owner reading a digest, a clumsy but faithful summary is better than an elegant but unfaithful one. That is the reason extractive methods are still used as a first step, and as a check on generated summaries, even now that language models can write.

24.3 The Mathematics, Gently

Let a text consist of sentences $s_1, s_2, \ldots, s_n$. Every method computes a score $\text{score}(s_i)$, and the summary is the k sentences with the highest scores, printed in order of i.

24.3.1 Sentence vectors and similarity

We turn each sentence into a TF-IDF vector with the code of Chapter 23, treating every *sentence* as a "document". A word that appears in many sentences of this text therefore gets a low weight, and a word that appears in only one sentence gets a high one. For two sentence vectors $\mathbf{u}$ and $\mathbf{v}$ the **cosine similarity** is

$$\cos(\mathbf{u}, \mathbf{v}) = \frac{\sum_t u_t \, v_t}{\sqrt{\sum_t u_t^2} \, \sqrt{\sum_t v_t^2}} \tag{24.1}$$

It is the cosine of the angle between the two vectors: 1 when they point the same way (the sentences use the same words in the same proportions) and 0 when they share no word at all. Because TF-IDF weights are never negative, the cosine is never negative either.

24.3.2 Position

The simplest score says that earlier is more important:

$$\text{score}_{\text{lead}}(s_i) = \frac{1}{i} \tag{24.2}$$

Taking the three highest scores simply takes the first three sentences. This **lead** baseline is our yardstick.

24.3.3 Word frequency

Following Luhn [1], let $c(t)$ be the number of times content word t occurs in the whole text, and $c_{\max}$ the largest such count. Let T_i be the list of content words of sentence s_i. The frequency score is the average relative frequency of those words:

$$\text{score}_{\text{freq}}(s_i) = \frac{1}{|T_i|} \sum_{t \in T_i} \frac{c(t)}{c_{\max}} \tag{24.3}$$

Dividing by $|T_i|$ keeps long sentences from winning just because they contain more words.

24.3.4 Centroid

Add up all the sentence vectors to obtain the **centroid** of the text, $\mathbf{c} = \sum_{j=1}^{n} \mathbf{v}_j$, a vector that says which words the text as a whole is about. A central sentence points in almost the same direction:

$$\text{score}_{\text{centroid}}(s_i) = \cos(\mathbf{v}_i, \mathbf{c}) \tag{24.4}$$

This is the idea of centroid-based summarization [5].

24.3.5 TextRank

TextRank builds a **graph**: every sentence is a node, and every pair of sentences is joined by an edge whose weight is their similarity, $w_{ij} = \cos(\mathbf{v}_i, \mathbf{v}_j)$ for $i \neq j$. It then imagines a reader who starts at a random sentence and repeatedly jumps to another sentence, choosing sentence i from sentence j with probability proportional to w_{ji}; with probability $1 - d$ the reader gets bored and jumps to a random sentence instead. The score of a sentence is the fraction of time the reader spends there in the long run. It satisfies the PageRank equation of Brin and Page [6]:

$$S(i) = \frac{1 - d}{n} + d \sum_{j \neq i} \frac{w_{ji}}{\sum_k w_{jk}} S(j) \tag{24.5}$$

with the **damping factor** $d = 0.85$. Read it aloud: a sentence is important if important sentences point to it strongly. The fraction $w_{ji} / \sum_k w_{jk}$ is the share of sentence j's "vote" that goes to i; sentence j divides its own importance $S(j)$ among the sentences it resembles.

Equation (24.5) defines S in terms of itself, but it can be solved by **power iteration**: start with $S(i) = 1/n$ for every i, compute the right-hand side to get a new S, and repeat. Because $d < 1$, every round shrinks the difference between successive answers by at least a factor d, so after fifty rounds the error is below $0.85^{50} \approx 3 \times 10^{-4}$ of where it started, and in practice much smaller. The scores always add up to 1, which one of the tests in Section 24.10 checks.

24.3.6 Maximal marginal relevance

The three best-scored sentences may say nearly the same thing. **Maximal marginal relevance** (MMR) picks sentences one at a time. At each step it chooses, among the sentences not yet chosen, the one that maximizes

$$\text{MMR}(i) = \lambda \frac{\text{score}(s_i)}{\max_j \text{score}(s_j)} - (1 - \lambda) \max_{j \in C} \cos(\mathbf{v}_i, \mathbf{v}_j) \tag{24.6}$$

where C is the set of sentences chosen so far and λ balances importance against novelty [7]. With $\lambda = 0.7$, importance matters more, but a sentence that repeats a chosen one is pushed down.

24.3.7 ROUGE

How good is a summary? The standard automatic answer is **ROUGE**, *Recall-Oriented Understudy for Gisting Evaluation* [8]. It compares the words of a system summary with those of a reference summary written by a person. Let an n-gram be a sequence of n consecutive words, and let $\text{Count}_{\text{match}}(g)$ be the number of times the n-gram g occurs in both summaries (clipped to the smaller count). Then

$$R_n = \frac{\sum_g \text{Count}_{\text{match}}(g)}{\sum_{g \in \text{ref}} \text{Count}(g)}, \qquad P_n = \frac{\sum_g \text{Count}_{\text{match}}(g)}{\sum_{g \in \text{sys}} \text{Count}(g)} \tag{24.7}$$

R_n, the **recall**, is the fraction of the reference's n-grams that the system found; P_n, the **precision**, is the fraction of the system's n-grams that are in the reference. The **F1** score combines them with the harmonic mean:

$$F_1 = \frac{2 R_n P_n}{R_n + P_n} \tag{24.8}$$

ROUGE-1 counts single words and measures content; ROUGE-2 counts pairs of words and rewards fluent, matching phrases. Neither understands meaning: a summary that uses synonyms of the reference's words is punished. ROUGE is useful for comparing systems on the same references, not as an absolute judgment of quality.

24.4 The Data

`data/articles.txt` holds four articles of 18 to 21 sentences each: the rainy season and laundries in Surabaya (`id-hujan`), traders at a traditional market switching to QR payments (`id-pasar`), a city library launching digital loans (`en-library`), and a neighborhood fighting dengue fever (`en-dengue`). Each has a reference summary of three sentences, written by a person *in their own words*, not copied from the article. That makes the task hard in an honest way: no extractive method can reach a ROUGE of 1, because the reference contains phrasing that does not appear in the article at all.

The file uses a simple format that is easy to read and to edit by hand:

```
@id id-hujan
@lang id
@title Musim Hujan, Musim Sibuk bagi Usaha Binatu
@summary Musim hujan membuat pesanan usaha binatu ... (three sentences)
Musim hujan tahun ini membuat usaha binatu di Surabaya kebanjiran pesanan. ...
@end
```

24.5 Building the Summarizer

Listing 24.1 contains the whole method. It reuses the tokenizer and sentence splitter of Chapter 21 and the TF-IDF class of Chapter 23, copied into this chapter's folder.

Listing 24.1 `summarizer.py`: four sentence scorers, maximal marginal relevance, and the summarize function.

```python
"""summarizer.py - pick the most important sentences of a text."""
import math
from collections import Counter

from tfidf import TfIdf, terms
from tokenizer import split_sentences

def read_articles(path="data/articles.txt"):
    """Parse the @id/@lang/@title/@summary ... @end blocks of the data file."""
    articles, cur, body = [], None, []
    with open(path, encoding="utf-8") as f:
        for line in f:
            line = line.rstrip("\n")
            if line.startswith("@id "):
                cur, body = {"id": line[4:]}, []
            elif line == "@end":
                cur["text"] = " ".join(x for x in body if x)
                articles.append(cur)
            elif line.startswith("@"):
                key, _, value = line[1:].partition(" ")
                cur[key] = value
            else:
                body.append(line.strip())
    return articles

def cosine(u, v):
    """Cosine of two sparse vectors stored as {term: weight}."""
    dot = sum(x * v[t] for t, x in u.items() if t in v)
    nu = math.sqrt(sum(x * x for x in u.values()))
    nv = math.sqrt(sum(x * x for x in v.values()))
    return dot / (nu * nv) if nu and nv else 0.0

def lead_scores(sentences, vectors):
    """Baseline: earlier sentences score higher."""
    return [1.0 / (i + 1) for i in range(len(sentences))]
```

Listing 24.1 (Continued) *summarizer.py: four sentence scorers, maximal marginal relevance, and the summarize function.*

```
def frequency_scores(sentences, vectors):
    """Luhn-style: the average relative frequency of a sentence's words."""
    counts = Counter(t for s in sentences for t in terms(s))
    top = max(counts.values())
    scores = []
    for s in sentences:
        ts = terms(s)
        scores.append(sum(counts[t] / top for t in ts) / len(ts) if ts else 0.0)
    return scores

def centroid_scores(sentences, vectors):
    """Cosine between each sentence and the sum of all sentence vectors."""
    centre = Counter()
    for v in vectors:
        centre.update(v)
    return [cosine(v, centre) for v in vectors]

def textrank_scores(sentences, vectors, d=0.85, iterations=50):
    """PageRank on the graph whose edge weights are sentence similarities."""
    n = len(sentences)
    w = [[cosine(vectors[i], vectors[j]) if i != j else 0.0 for j in range(n)]
         for i in range(n)]
    out = [sum(row) or 1.0 for row in w]
    score = [1.0 / n] * n
    for _ in range(iterations):
        score = [(1 - d) / n + d * sum(w[j][i] / out[j] * score[j]
                                       for j in range(n))
                 for i in range(n)]
    return score

METHODS = {"lead": lead_scores, "frequency": frequency_scores,
           "centroid": centroid_scores, "textrank": textrank_scores}
```

Listing 24.1 (Continued) *summarizer.py: four sentence scorers, maximal marginal relevance, and the summarize function.*

```
def mmr_select(scores, vectors, k, lam=0.7):
    """Maximal marginal relevance: good sentences that repeat little."""
    top = max(scores) or 1.0
    chosen = []
    while len(chosen) < min(k, len(scores)):
        def value(i):
            overlap = max((cosine(vectors[i], vectors[j]) for j in chosen),
                          default=0.0)
            return lam * scores[i] / top - (1 - lam) * overlap
        best = max((i for i in range(len(scores)) if i not in chosen),
                   key=lambda i: (value(i), -i))
        chosen.append(best)
    return chosen

def summarize(text, method="textrank", k=3, mmr=False):
    """Return the k chosen sentences, in their original order."""
    sentences = split_sentences(text)
    model = TfIdf().fit(sentences)          # each sentence is a "document"
    vectors = [model.weights(s) for s in sentences]
    scores = METHODS[method](sentences, vectors)
    if mmr:
        chosen = mmr_select(scores, vectors, k)
    else:
        chosen = sorted(range(len(sentences)), key=lambda i: (-scores[i], i))[:k]
    return [sentences[i] for i in sorted(chosen)], scores
```

The structure is worth noticing. Every scorer has the same signature, `(sentences, vectors)`, and returns a list of scores, so the four methods can live in one dictionary, `METHODS`, and `summarize` can call any of them by name. Adding a fifth method means writing one function and adding one line to the dictionary.

- `read_articles` parses the data file line by line: a line starting with `@id` opens an article, other `@` lines set a field, plain lines are collected as the body, and `@end` closes the article.
- `cosine` is Equation (24.1). The vectors from `TfIdf.weights` are already unit length, but computing the norms again keeps the function correct for any vectors, such as the centroid.
- `frequency_scores` is Equation (24.3); `centroid_scores` is Equation (24.4); `lead_scores` is Equation (24.2).
- `textrank_scores` first builds the $n \times n$ weight matrix `w`, then applies Equation (24.5) fifty times. `out[j]` is the denominator $\sum_k w_{jk}$; the `or 1.0` protects a sentence that shares no word with any other from a division by zero.
- `mmr_select` is Equation (24.6), applied greedily. Ties are broken toward the earlier sentence by the key `(value(i), -i)`.
- `summarize` splits the text, fits TF-IDF on its sentences, scores, selects, and returns the chosen sentences *sorted by position*, together with all scores.

Listing 24.2 is the command-line front end; it wraps long sentences so that they fit on a terminal.

Listing 24.2 `summarize.py`: the command-line summarizer.

```
"""summarize.py - summarize an article from the data file, or any text file."""
import argparse
import textwrap

from summarizer import METHODS, read_articles, summarize

def main():
    ap = argparse.ArgumentParser(description=__doc__)
    ap.add_argument("article", nargs="?", default="id-hujan")
    ap.add_argument("--file", help="summarize this UTF-8 text file instead")
    ap.add_argument("--method", default="textrank", choices=sorted(METHODS))
    ap.add_argument("--k", type=int, default=3)
    ap.add_argument("--mmr", action="store_true", help="avoid repetition")
    ap.add_argument("--scores", action="store_true")
    args = ap.parse_args()

    if args.file:
        with open(args.file, encoding="utf-8") as f:
            text = f.read()
    else:
        text = next(a for a in read_articles() if a["id"] == args.article)["text"]
    chosen, scores = summarize(text, args.method, args.k, args.mmr)
    if args.scores:
        cells = [f"{i:2d}: {s:.3f}" for i, s in enumerate(scores, 1)]
        for row in range(0, len(cells), 6):
            print("   ".join(cells[row:row + 6]))
    for s in chosen:
        print(textwrap.fill(s, 78, initial_indent="- ", subsequent_indent="  "))

if __name__ == "__main__":
    main()
```

24.6 Running It

The default is TextRank on the rainy-season article:

```
python summarize.py
```

```
- Seorang pemilik binatu di Rungkut mengatakan bahwa ia kini menerima sekitar
  tiga ratus kilogram cucian setiap hari.
- Pemilik binatu kini mengirim pesan kepada pelanggan jika cucian diperkirakan
  terlambat.
- Pemilik usaha menyarankan pelanggan memesan lebih awal selama musim hujan.
```

These are reasonable sentences: the volume of laundry, the owner informing customers of delays, and the advice to order early. The reference summary also mentions the new driers, the higher electricity bill and the delivery service, so ROUGE will not be perfect. To see the scores behind a choice, ask for them:

```
python summarize.py id-pasar --scores
```

```
 1: 0.071    2: 0.048    3: 0.065    4: 0.046    5: 0.008    6: 0.068
 7: 0.046    8: 0.042    9: 0.061   10: 0.029   11: 0.045   12: 0.074
13: 0.051   14: 0.050   15: 0.065   16: 0.054   17: 0.058   18: 0.071
- Pedagang di sebuah pasar tradisional di Sidoarjo mulai menerima pembayaran
  dengan kode QR.
- Sebaliknya, sebagian pembeli lanjut usia masih memilih uang tunai, sehingga
  pedagang tetap menyediakan uang kembalian.
- Tujuannya agar semua pedagang, tua maupun muda, bisa ikut menikmati manfaat
  pembayaran digital.
```

The three highest scores belong to sentences 12, 1 and 18. The lowest, 0.008, belongs to sentence 5, “Ia takut uangnya hilang atau tidak masuk ke rekening.” It shares almost no content word with any other sentence, so in Equation (24.5) it receives only the random-jump share $(1-d)/n = 0.15/18 \approx 0.008$. **Figure 24.1** draws the graph of this article: the thicker the line, the more similar the two sentences; the larger the circle, the higher the TextRank score; the three chosen sentences are highlighted.

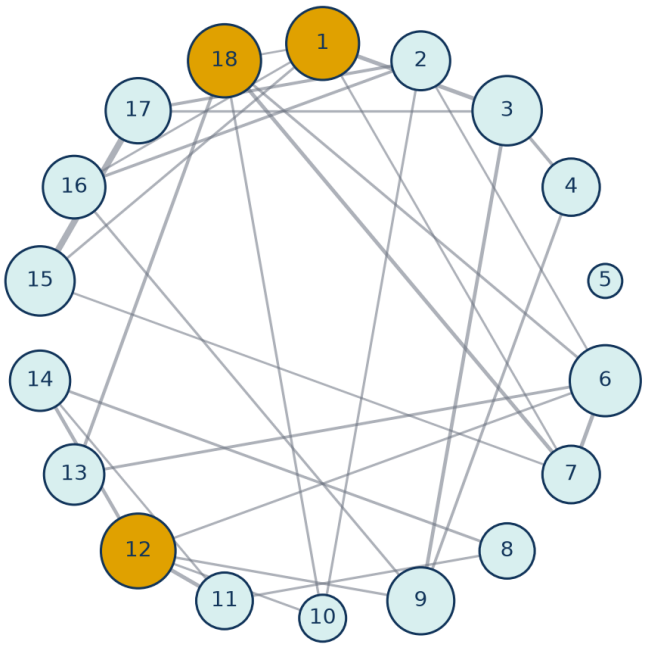

Figure 24.1 The sentence graph of the article id-pasar. Lines join similar sentences, circle size shows the TextRank score, and the three highlighted sentences form the summary. Sentence 5 is almost isolated.

Now compare the lead baseline with TextRank on the dengue article:

```
python summarize.py en-dengue --method lead
```

```
- Dengue fever cases rose sharply in one Surabaya neighborhood at the start of
  the rainy season.
- Within three weeks, eleven residents had been treated at the local health
  center.
- Two of them were children who needed to stay in hospital for several days.
```

```
python summarize.py en-dengue
```

```
- Dengue fever cases rose sharply in one Surabaya neighborhood at the start of
  the rainy season.
- Within three weeks, eleven residents had been treated at the local health
  center.
- Within two months, new cases in the neighborhood fell from eleven to one.
```

The lead summary tells only the beginning of the story, the outbreak. TextRank keeps the first two sentences and replaces the detail about the children with the outcome, “new cases in the neighborhood fell from eleven to one”, which is arguably what a reader most wants to know.

24.7 Measuring It

Listing 24.3 implements Equation (24.7) and Equation (24.8). The clipping `min(c, ref[g])` matters: if the system says *pedagang* four times and the reference only twice, only two of the four count as matches.

Listing 24.3 `rouge.py`: ROUGE-N recall, precision and F1.

```
"""rouge.py - ROUGE-N overlap between a summary and a reference."""
from collections import Counter

from tokenizer import words

def ngrams(tokens, n):
    return Counter(tuple(tokens[i:i + n]) for i in range(len(tokens) - n + 1))

def rouge_n(candidate, reference, n=1):
    """Return (recall, precision, F1) of the n-grams of two texts."""
    cand, ref = ngrams(words(candidate), n), ngrams(words(reference), n)
    overlap = sum(min(c, ref[g]) for g, c in cand.items())   # clipped counts
    recall = overlap / max(sum(ref.values()), 1)
    precision = overlap / max(sum(cand.values()), 1)
    f1 = 2 * recall * precision / (recall + precision) if overlap else 0.0
    return recall, precision, f1
```

Listing 24.4 summarizes each article with every method, with and without MMR, and reports ROUGE-1 F1 per article and ROUGE-1 and ROUGE-2 means. A **random** baseline picks three sentences at random, averaged over ten draws per article with a fixed seed, so that we know what "no method at all" scores.

Listing 24.4 `evaluate.py`: ROUGE of every method, with an option to shuffle the sentences.

```
"""evaluate.py - ROUGE of every method against the reference summaries.

    python evaluate.py            the articles as written
    python evaluate.py --shuffle  sentences in random order (20 shuffles each)
"""
import random
import sys

from rouge import rouge_n
from summarizer import METHODS, read_articles, summarize
from tokenizer import split_sentences

shuffle = "--shuffle" in sys.argv
rng = random.Random(24)
articles = read_articles()
rows = {}

def add(label, i, summary, ref, weight):
    vals = rows.setdefault(label, [[0.0, 0.0] for _ in articles])
    vals[i][0] += rouge_n(summary, ref, 1)[2] * weight
    vals[i][1] += rouge_n(summary, ref, 2)[2] * weight

for i, a in enumerate(articles):
    for _ in range(20 if shuffle else 1):
        sents = split_sentences(a["text"])
        if shuffle:
            rng.shuffle(sents)
        text, w = " ".join(sents), 1 / (20 if shuffle else 1)
        for _ in range(10):                                  # random baseline
            pick = sorted(rng.sample(range(len(sents)), 3))
            add("random", i, " ".join(sents[j] for j in pick), a["summary"], w / 10)
        for name in METHODS:
            for mmr in (False, True):
                label = name + (" + mmr" if mmr else "")
                summary = " ".join(summarize(text, name, 3, mmr)[0])
                add(label, i, summary, a["summary"], w)

print(f"{'ROUGE-1 F1':<16}" + "".join(f"{a['id']:>11}" for a in articles)
      + f"{'mean R1':>8}{'mean R2':>8}")

          + f"{r1:>8.3f}{r2:>8.3f}")
```

```
python evaluate.py
```

```
ROUGE-1 F1         id-hujan   id-pasar en-library  en-dengue mean R1 mean R2
random                0.307      0.264      0.248      0.273   0.273   0.077
lead                  0.404      0.430      0.547      0.303   0.421   0.244
lead + mmr            0.404      0.430      0.547      0.303   0.421   0.244
frequency             0.286      0.416      0.452      0.347   0.375   0.233
frequency + mmr       0.395      0.416      0.452      0.347   0.402   0.248
centroid              0.276      0.559      0.455      0.347   0.409   0.243
centroid + mmr        0.276      0.559      0.383      0.347   0.391   0.237
textrank              0.276      0.559      0.455      0.347   0.409   0.243
textrank + mmr        0.276      0.559      0.383      0.347   0.391   0.237
```

Three things stand out.

1. **Every method beats random.** Random selection reaches a mean ROUGE-1 of 0.273; all methods score between 0.375 and 0.421.
2. **The lead baseline is the best on average**, with 0.421. This is not a bug: news is written so that the first sentences carry the main facts, and researchers regularly report that the first three

sentences are a strong baseline for news summarization that many sophisticated systems fail to beat [9].

3. **Centroid and TextRank choose exactly the same sentences** on all four articles. That is not a coincidence either, as Exercise 24.4 shows: on a small, densely connected graph, the PageRank score of a sentence is almost proportional to its total similarity to the other sentences, which is what the centroid measures [4].

Four articles are a small test. A difference of 0.01 or 0.02 in the mean could reverse with four other articles, and we should say so rather than declare a winner.

24.7.1 When position is not a clue

Is TextRank then useless? Try the same evaluation on texts in which the important sentences are *not* at the top. We can simulate such texts by shuffling the sentences of each article, twenty times with a fixed seed:

```
python evaluate.py --shuffle
```

```
ROUGE-1 F1          id-hujan   id-pasar en-library  en-dengue mean R1 mean R2
random                 0.295      0.312      0.291      0.271   0.292   0.113
lead                   0.268      0.285      0.253      0.275   0.271   0.090
lead + mmr             0.268      0.285      0.253      0.275   0.271   0.090
frequency              0.286      0.416      0.452      0.347   0.375   0.233
frequency + mmr        0.395      0.416      0.452      0.347   0.402   0.248
centroid               0.276      0.559      0.455      0.347   0.409   0.243
centroid + mmr         0.276      0.559      0.383      0.347   0.391   0.237
textrank               0.276      0.559      0.455      0.347   0.409   0.243
textrank + mmr         0.276      0.559      0.383      0.347   0.391   0.237
```

The lead baseline collapses to 0.271, the level of random selection, because the first three sentences are now random sentences. The frequency, centroid and TextRank methods do not change at all: they never look at the order of the sentences. **Figure 24.2** puts the two tables side by side. The lesson is about matching the method to the text. For news written as an inverted pyramid, position is the best single clue. For meeting notes, customer complaints, forum threads and other texts without that structure, the graph and centroid methods keep working while position fails.

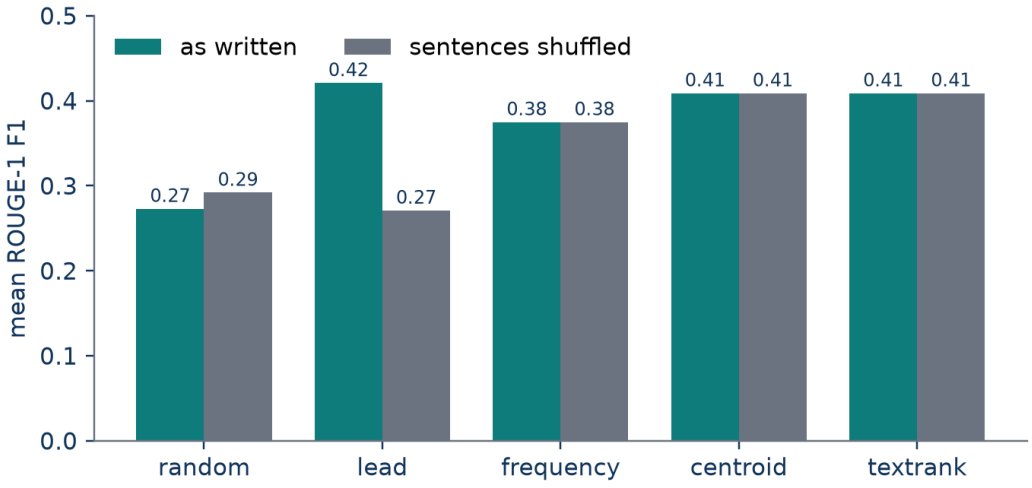

Figure 24.2 Mean ROUGE-1 F1 of each method on the four articles as written and with their sentences shuffled. Only the lead baseline depends on sentence order.

24.8 Improving It

24.8.1 Less repetition

MMR changed one summary for the better: the frequency method on `id-hujan` rose from 0.286 to 0.395. Compare the two outputs:

```
python summarize.py id-hujan --method frequency
```

```
- Pemilik binatu kini mengirim pesan kepada pelanggan jika cucian diperkirakan
  terlambat.
- Pemilik usaha menyarankan pelanggan memesan lebih awal selama musim hujan.
- Dengan perencanaan yang baik, katanya, musim hujan justru menjadi musim
  panen bagi usaha binatu.
```

```
python summarize.py id-hujan --method frequency --mmr
```

```
- Musim hujan tahun ini membuat usaha binatu di Surabaya kebanjiran pesanan.
- Pemilik binatu kini mengirim pesan kepada pelanggan jika cucian diperkirakan
  terlambat.
- Pemilik usaha menyarankan pelanggan memesan lebih awal selama musim hujan.
```

Without MMR, the last sentence repeats *musim hujan* and *usaha* from the sentence before it. MMR penalizes that overlap by Equation (24.6) and chooses the opening sentence instead, which states the main fact. On the other methods MMR helped nowhere, and it hurt the centroid and TextRank summaries of `en-library`, because their top sentences were already different from one another and the replacement was a less central sentence. MMR is a remedy for a specific illness, repetition, and should be judged by whether that illness is present.

24.8.2 Other improvements worth trying

- **Combine clues.** A weighted sum of a position score and a TextRank score is easy to build; the weight should be chosen on a separate set of articles, not on the four used for testing.
- **Compress sentences.** Extractive summaries inherit long sentences. Removing parenthetical phrases and attributions such as “katanya” shortens them without changing the facts.
- **Summarize for a question.** If the reader asks “what should customers do?”, add the similarity to the question to each sentence’s score. The FAQ bot of Chapter 29 uses the same idea to find answers.
- **Generate.** An abstractive model rewrites the chosen facts in fluent new sentences. Chapter 85 does this with a local language model, and uses an extractive summary like ours as a factual anchor.

24.9 A Morning Digest for Profitina Laundry

Put the pieces of this chapter together for the owner of Profitina Laundry, who wants a short digest every morning: the three most important sentences of each long customer message received overnight, and of any news item that mentions laundry, rain, electricity prices or the neighborhoods where the outlets are.

Choose the method per genre. News items follow the inverted pyramid, so the lead baseline is a sound choice for them, as Section 24.7 showed. Customer messages do not, so they get TextRank with MMR, the combination Solution 24.6 recommends. The code of **Listing 24.1** supports both through the `method` and `mmr` arguments, so the digest simply calls `summarize` with different settings for different sources.

Choose the length by the text. Three sentences suit a twenty-sentence article; a four-sentence message needs one. A simple rule, $k = \max(1, \lceil n/6 \rceil)$ for a text of n sentences, keeps summaries proportional. Very short messages should not be summarized at all.

Keep the link to the whole. Every summary in the digest carries a link to the full text. Extractive summaries never invent facts, but they always leave facts out, and the owner must be able to read the rest with one click, especially for complaints, where a detail omitted by the summary (a date, an order number) may be exactly what is needed.

Clean the input first. Customer messages contain typos and informal spellings. Running the spell checker of Chapter 22 before building the TF-IDF vectors makes sentences that talk about the same thing look similar to each other, which is what TextRank needs. This is the pipeline of Part 3 at work again: tokenize, correct, weigh, and only then choose.

Measure on your own data. Our four articles are a demonstration, not a benchmark. Before relying on the digest, the owner could write short reference summaries for twenty real messages, and the evaluation of **Listing 24.4** would then say, with numbers that belong to this business, which method to trust.

24.10 Testing

Listing 24.5 checks ROUGE on a case small enough to do by hand ("the cat sat" against "the cat sat down": three of four reference words found, recall 0.75, precision 1), that TextRank scores form a probability distribution, that summaries keep the original order, and that the lead method returns the first sentences.

Listing 24.5 `tests/test_summarizer.py`: tests for ROUGE, TextRank and the summarizer.

```
"""Run with:  python -m pytest -q"""
import math
import os
import sys

HERE = os.path.dirname(os.path.dirname(os.path.abspath(__file__)))
sys.path.insert(0, HERE)
os.chdir(HERE)
from rouge import rouge_n  # noqa: E402
from summarizer import read_articles, summarize, textrank_scores  # noqa: E402
from tfidf import TfIdf  # noqa: E402
from tokenizer import split_sentences  # noqa: E402

def test_rouge_by_hand():
    r, p, f = rouge_n("the cat sat", "the cat sat down", 1)
    assert (r, p) == (0.75, 1.0)
    assert math.isclose(f, 2 * 0.75 / 1.75)

def test_textrank_is_a_distribution():
    text = read_articles()[0]["text"]
    sents = split_sentences(text)
    m = TfIdf().fit(sents)
    scores = textrank_scores(sents, [m.weights(s) for s in sents])
    assert math.isclose(sum(scores), 1.0, rel_tol=1e-9)

def test_summary_keeps_original_order():
    text = read_articles()[1]["text"]
    chosen, _ = summarize(text, "textrank", 3)
    sents = split_sentences(text)
    positions = [sents.index(s) for s in chosen]
    assert len(chosen) == 3 and positions == sorted(positions)

def test_lead_takes_first_sentences():
    text = read_articles()[2]["text"]
    assert summarize(text, "lead", 2)[0] == split_sentences(text)[:2]
```

```
  python -m pytest -q
```

```
....                                                                     [100%]
4 passed in 0.02s
```

24.11 Common Mistakes, and How to Avoid Them

Printing the chosen sentences in score order. The summary then jumps back and forth in time. *Avoid it:* sort the chosen sentences by position, as `summarize` does.

Letting long sentences win. A sum of word scores grows with sentence length. *Avoid it:* average, as in Equation (24.3), or normalize the vectors, as the cosine does.

Forgetting the isolated sentence. A sentence that shares no word with any other makes a row of zeros and a division by zero in Equation (24.5). *Avoid it:* guard the denominator, as `out` does.

Reporting ROUGE without baselines. A ROUGE-1 of 0.41 means nothing alone. *Avoid it:* always report random and lead baselines next to your method.

Declaring a winner on four documents. *Avoid it:* report the per-document numbers, note how small the test is, and prefer conclusions that hold on every document, such as “every method beats random” and “only lead depends on order”.

Treating ROUGE as meaning. ROUGE counts shared words; a correct summary in different words scores low. *Avoid it:* read the summaries as well as scoring them.

Using an extractive summary as if it were complete. Three sentences out of twenty always leave facts out. *Avoid it:* link the summary to the full text, and let the reader decide when to read more.

24.12 Chapter Summary

- **Extractive** summarization chooses sentences; every method gives each sentence a score and returns the top k in their original order (**Listing 24.1**, **Listing 24.2**).
- Four scores: **position** (Equation (24.2)), **word frequency** (Equation (24.3)), **similarity to the centroid** (Equation (24.4)) and **TextRank**, PageRank on a graph of sentence similarities (Equation (24.1), Equation (24.5), **Figure 24.1**), solved by power iteration.
- **Maximal marginal relevance** (Equation (24.6)) trades importance against repetition.
- **ROUGE** (Equation (24.7), Equation (24.8), **Listing 24.3**) measures word and phrase overlap with a reference summary.
- On our four news articles every method beats random, the **lead baseline** is best, and centroid and TextRank agree exactly (**Listing 24.4**). When sentence order carries no information, lead falls to random while the other methods are unaffected (**Figure 24.2**).
- Match the method to the genre, report baselines, and read the summaries.

24.13 Exercises

Exercise 24.1. Compute ROUGE-1 recall, precision and F1 by hand for the system summary “harga cabai naik tajam” against the reference “harga cabai rawit naik”.

Exercise 24.2. Consider three sentences whose similarities are $w_{12} = 0.5$, $w_{13} = 0.5$ and $w_{23} = 0$. Run two rounds of power iteration of Equation (24.5) by hand with $d = 0.85$, starting from $S = (1/3,1/3,1/3)$. Which sentence is most central, and why?

Exercise 24.3. Why does the frequency score of Equation (24.3) divide by $|T_i|$? Give an example of a sentence that would win without the division and explain why that would be a poor choice.

Exercise 24.4. Section 24.7 claims that TextRank and centroid scores are almost proportional on our articles. Write a program that computes the Pearson correlation between the two lists of scores for each article.

Exercise 24.5. The reference summaries were written in the writer’s own words. Explain why that caps the ROUGE-1 of any extractive method below 1, and name two kinds of difference between a good extractive summary and the reference that ROUGE-1 punishes.

Exercise 24.6. Profitina Laundry receives long complaint messages from customers. Which of the four scores would you use to summarize them for the owner, and would you add MMR? Justify your answer with the results of Section 24.7.1.

24.14 Solutions to the Exercises

Solution 24.1. The system words are *harga, cabai, naik, tajam* and the reference words *harga, cabai, rawit, naik*. Three words match: *harga*, *cabai*, *naik*. By Equation (24.7), $R_1 = 3/4 = 0.75$ and $P_1 = 3/4 = 0.75$, and by Equation (24.8), $F_1 = 2 \times 0.75 \times 0.75/1.5 = 0.75$.

Solution 24.2. The out-weights are $\sum_k w_{1k} = 1$, $\sum_k w_{2k} = 0.5$, $\sum_k w_{3k} = 0.5$. Sentence 2 sends its whole vote to sentence 1 ($0.5/0.5 = 1$), and so does sentence 3; sentence 1 splits its vote equally between 2 and 3. Round 1: $S(1) = 0.05 + 0.85(1/3 + 1/3) = 0.05 + 0.567 = 0.617$; $S(2) = S(3) = 0.05 + 0.85 \times 0.5 \times 1/3 = 0.05 + 0.142 = 0.192$. (The constant term is $(1 - 0.85)/3 = 0.05$.) Round 2: $S(1) = 0.05 + 0.85(0.192 + 0.192) = 0.376$; $S(2) = S(3) = 0.05 + 0.85 \times 0.5 \times 0.617 = 0.312$. The scores oscillate toward their fixed point, $S(1) \approx 0.486$ and $S(2) = S(3) \approx 0.257$ (check: $0.05 + 0.85 \times 0.514 \approx 0.487$). In every round the total is 1. Sentence 1 is the most central because it is the only one similar to both others: it is the hub.

Solution 24.3. Without the division, the score would be the *sum* of the relative frequencies of the sentence's words, and a long sentence that lists many ordinary words would beat a short sentence made only of key words. For example, "Pemilik usaha, pegawai, kurir, dan pelanggan binatu di Rungkut, Keputih, dan Medokan semuanya merasakan hujan tahun ini" contains many words, each with some frequency, and would outscore the short and central "Mesin pengering menjadi kunci pada musim seperti ini." Averaging measures how *dense* in important words a sentence is, not how long it is.

Solution 24.4. **Listing 24.6** computes both score lists and their Pearson correlation, $r = \frac{\sum(x-\bar{x})(y-\bar{y})}{\sqrt{\sum(x-\bar{x})^2 \sum(y-\bar{y})^2}}$.

Listing 24.6 `solutions/compare_scores.py`: correlation between TextRank and centroid scores.

```
"""compare_scores.py - Exercise 24.4: how close are TextRank and centroid?"""
import math
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from summarizer import (centroid_scores, read_articles,  # noqa: E402
                        textrank_scores)
from tfidf import TfIdf  # noqa: E402
from tokenizer import split_sentences  # noqa: E402

def pearson(x, y):
    mx, my = sum(x) / len(x), sum(y) / len(y)
    sxy = sum((a - mx) * (b - my) for a, b in zip(x, y))
    sxx = sum((a - mx) ** 2 for a in x)
    syy = sum((b - my) ** 2 for b in y)
    return sxy / math.sqrt(sxx * syy)

for a in read_articles():
    sents = split_sentences(a["text"])
    model = TfIdf().fit(sents)
    vectors = [model.weights(s) for s in sents]
    tr = textrank_scores(sents, vectors)
    ce = centroid_scores(sents, vectors)
    r = pearson(tr, ce)
    print(f"{a['id']:<11} {len(sents)} sentences  correlation {r:.3f}")
```

```
python solutions/compare_scores.py
```

```
id-hujan    21 sentences  correlation 0.996
id-pasar    18 sentences  correlation 0.999
en-library  18 sentences  correlation 0.996
en-dengue   18 sentences  correlation 0.986
```

The correlations are between 0.986 and 0.999. When nearly every sentence is connected to nearly every other, the random walk of Equation (24.5) visits each sentence in proportion to how

strongly it is connected, its weighted degree $\sum_j w_{ij}$, and that sum is almost the dot product of $\mathbf{v}_i$ with the centroid. On large, sparse graphs, such as the web or long documents with distinct sections, the two scores differ more, and PageRank's ability to pass importance along chains of sentences matters.

Solution 24.5. An extractive summary can only use words that appear in the article, while the reference may use words that do not: "sulit menjemur pakaian" in the reference of `id-hujan` matches the article, but "Binatu menambah jam kerja" (the article says "menambah satu sif kerja") and "keterlambatan juga meningkat" appear nowhere in it. ROUGE-1 punishes (1) **synonyms and paraphrases**, a correct idea in different words, and (2) **extra detail**, since every word of a long extracted sentence that is not in the reference lowers precision. A reference written by copying sentences would give higher numbers, but would reward extraction for the wrong reason.

Solution 24.6. Complaint messages rarely put the main point first: they often begin with a greeting or a story and state the problem later. Section 24.7.1 showed that lead falls to random when position carries no information, while frequency, centroid and TextRank are unaffected. A complaint is also repetitive ("sudah tiga kali", "lagi-lagi"), so MMR is worth adding. TextRank or centroid with MMR is therefore the better choice, with the whole message one click away, because the owner, not the program, decides what to do about a complaint.

Chapter 25

News Topic Classifier

The keyword extractor of Chapter 23 describes a text; it does not decide anything. This chapter builds a program that reads a news item and decides which of four sections it belongs to: business, sports, technology or health. By the end of it you will be able to derive the multinomial naive Bayes classifier from Bayes' rule, including Laplace smoothing and the switch to logarithms; implement it from scratch and check it against scikit-learn prediction by prediction; evaluate a classifier properly with stratified cross-validation, a confusion matrix, and precision, recall and F1 for each class; say how much an accuracy measured on 96 documents can be trusted; compare it with logistic regression and a linear support vector machine; read a learning curve; and explain what happens when a model trained on Indonesian meets English. Chapter 15 met naive Bayes for sentiment with two classes; here we go deeper, with four classes, two languages and a careful look at evaluation.

25.1 Why Classify Topics?

A news portal in Surabaya publishes a hundred short items a day. Each must be placed in a section so that readers who only care about sports, or only about health, find what they want. An editor does it by hand today, and it takes an hour. The same problem appears at Profitina Laundry in a different dress: every customer message must go to the right person, the cashier for prices, the supervisor for stains, the courier for pickups. A support desk, an e-mail filter, a library catalog and a complaint system all do the same thing: they read a text and put it into one of a fixed set of boxes. That is **text classification**, and **topic classification** is its most common form.

Unlike the methods of Chapters 21 to 24, a classifier must **learn**. We give it examples that a person has already labeled, and it discovers which words go with which label. That makes two new questions central to this chapter: how does the program learn from the examples, and how do we know that what it learned will work on texts it has never seen?

25.2 The Idea in Plain Words

Think of a becak driver who has driven around Surabaya for years. When a passenger climbs in with a racket bag and sports shoes, he guesses "GOR" (the sports hall) before a word is said. When the passenger carries a medical file, he guesses the hospital. He has learned, from hundreds of trips, which clues go with which destination, and he combines several clues at once.

Our classifier does the same with words. From the labeled training items it learns, for each topic, how often each word appears: *pertandingan*, *pelatih*, *medali* are frequent in sports; *harga*, *pedagang*, *ekspor* in business; *puskesmas*, *dokter*, *vaksinasi* in health; *aplikasi*, *jaringan*, *data* in technology. Given a new item, it asks, for each topic: "if a text came from this topic, how likely would these exact words be?" It multiplies the evidence of all the words, adjusts for how common each topic is, and picks the topic with the highest result.

The method is called **naive Bayes**: *Bayes* because it uses Bayes' rule, and *naive* because it pretends that the words of a text are independent of each other, as if each word were drawn from

a bag without looking at the others. That assumption is plainly false: *demam* and *berdarah* travel together. Yet the method works remarkably well for choosing among topics, it trains in a blink, and every decision can be explained by pointing at words [1].

25.3 The Mathematics, Gently

25.3.1 Bayes' rule for documents

Let c be a class (a topic) and d a document. We want the class with the highest probability given the document. Bayes' rule rewrites that probability as

$$P(c \mid d) = \frac{P(d \mid c)\, P(c)}{P(d)} \tag{25.1}$$

$P(c)$ is the **prior**, how common the class is before we read anything. $P(d \mid c)$ is the **likelihood**, how probable this document would be if it came from class c. $P(d)$ is the same for every class, so it can be ignored when we only want the best class.

25.3.2 The naive assumption

A document is a sequence of terms $t_1, t_2, \ldots, t_m$ (the content words of Chapter 23). Computing $P(t_1, \ldots, t_m \mid c)$ exactly would require having seen this exact sequence before, which never happens. The naive assumption treats every word as an independent draw from the class's bag of words:

$$P(d \mid c) \approx \prod_{i=1}^{m} P\,(t_i \mid c) \tag{25.2}$$

Each factor is easy to estimate from data, and that is the whole trick. Because a document is treated as a sequence of draws that may repeat the same word, this version is called the **multinomial** model; it is the one that works best for topics [2].

25.3.3 Estimating the probabilities

With N training documents, N_c of which belong to class c, the prior is estimated as

$$P(c) = \frac{N_c}{N} \tag{25.3}$$

For the word probabilities, let $\text{count}(t, c)$ be the number of times term t occurs in all training documents of class c, and V the vocabulary, the set of all terms seen in training. The plain estimate $\text{count}(t, c) / \sum_u \text{count}\,(u, c)$ has a fatal flaw: a word never seen in class c gets probability zero, and by Equation (25.2) a single such word makes the whole product zero, no matter how strong the other evidence is. **Laplace smoothing**, or add-α smoothing, pretends that every word was seen α extra times in every class:

$$P(t \mid c) = \frac{\text{count}(t, c) + \alpha}{\sum_{u \in V} \text{count}\,(u, c) + \alpha\,|V|} \tag{25.4}$$

With $\alpha = 1$, a word never seen in a class gets a small but positive probability, and the probabilities of all words in V still add up to 1, because the numerators add up to the denominator.

25.3.4 Working in logarithms

A news item has thirty or forty terms, and each $P(t \mid c)$ is small, around 0.001. Their product is around 10^{-120}, close to the smallest number a computer can store; a longer document underflows to exactly zero. The cure is to add logarithms instead of multiplying probabilities. Since the logarithm is increasing, the class with the largest product also has the largest sum of logarithms:

$$\hat{c} = \operatorname*{argmax}_c \left[\log P(c) + \sum_{i=1}^{m} \log P(t_i \mid c) \right] \tag{25.5}$$

This is the rule the program uses. When we want probabilities to show a person, we turn the scores s_c of Equation (25.5) back into probabilities that add up to one:

$$P(c \mid d) = \frac{e^{s_c - s_{\max}}}{\sum_k e^{s_k - s_{\max}}} \tag{25.6}$$

Subtracting the largest score $s_{\max}$ changes nothing mathematically, because it multiplies the numerator and the denominator by the same factor $e^{-s_{\max}}$, but it keeps the exponentials from underflowing.

25.3.5 A worked example

Train on four tiny documents: sports = “gol tim” and “tim juara”; business = “harga naik” and “harga pasar”. Both classes have $N_c = 2$, so $P(\text{sports}) = P(\text{business}) = 0.5$. The vocabulary has $|V| = 6$ terms, and each class has 4 tokens, so by Equation (25.4) with $\alpha = 1$ the denominator is $4 + 6 = 10$ for both classes. For sports: $P(\text{tim}) = (2 + 1)/10 = 0.3$, $P(\text{gol}) = P(\text{juara}) = 0.2$, and each business word gets 0.1. For business: $P(\text{harga}) = 0.3$, $P(\text{naik}) = P(\text{pasar}) = 0.2$, and each sports word gets 0.1.

Classify “tim gol”. Sports: $0.5 \times 0.3 \times 0.2 = 0.030$. Business: $0.5 \times 0.1 \times 0.1 = 0.005$. By Equation (25.6), $P(\text{sports} \mid d) = 0.030/0.035 \approx 0.86$. The tests of Section 25.8 check these numbers.

25.3.6 Measuring a classifier

Accuracy is the fraction of test documents classified correctly. It hides which classes are confused with which, so we also count, for each class c, the true positives TP_c (documents of class c predicted as c), the false positives FP_c (other documents predicted as c) and the false negatives FN_c (documents of class c predicted as something else). Then

$$\text{precision}_c = \frac{\text{TP}_c}{\text{TP}_c + \text{FP}_c}, \qquad \text{recall}_c = \frac{\text{TP}_c}{\text{TP}_c + \text{FN}_c} \tag{25.7}$$

Precision answers “when the classifier says *sports*, how often is it right?”; recall answers “of all sports items, how many did it find?”. Their harmonic mean, $F_1 = 2PR/(P + R)$, is high only when both are high. A **confusion matrix** shows all the counts at once: row i, column j is the number of documents of true class i predicted as class j; the diagonal holds the correct answers.

With only 96 documents we cannot afford to set a quarter of them aside once and for all. **k-fold cross-validation** splits the data into k parts, trains on $k-1$ parts and tests on the remaining one, and repeats k times so that every document is tested exactly once by a model that never saw it [3]. **Stratified** folds keep the share of every class the same in every part.

Finally, how precise is an accuracy measured on n documents? If the true accuracy is p, the number of correct answers behaves like a sum of n coin flips that come up "correct" with probability p, and the measured accuracy has a **standard error** of

$$\mathrm{SE} = \sqrt{\frac{p\,(1-p)}{n}} \tag{25.8}$$

Roughly 95% of the time, the measured accuracy lies within two standard errors of the true one. Keep this formula in mind; Section 25.7 uses it to avoid being fooled.

25.4 Building the Classifier

Listing 25.1 implements Section 25.3. It takes documents that are already lists of terms, so it knows nothing about tokens or languages; the `terms` function of Chapter 23 provides them.

Listing 25.1 `naive_bayes.py`: multinomial naive Bayes with Laplace smoothing, from scratch.

```
"""naive_bayes.py - multinomial naive Bayes for text, written from scratch."""
import math
from collections import Counter, defaultdict

class NaiveBayes:
    def __init__(self, alpha=1.0):
        self.alpha = alpha                      # add-alpha (Laplace) smoothing

    def fit(self, docs, labels):
        """docs: lists of terms; labels: one class name per document."""
        self.classes = sorted(set(labels))
        n_docs = Counter(labels)
        self.log_prior = {c: math.log(n_docs[c] / len(labels))
                          for c in self.classes}
        self.counts = defaultdict(Counter)      # counts[c][term]
        for terms, c in zip(docs, labels):
            self.counts[c].update(terms)
        self.vocab = {t for c in self.classes for t in self.counts[c]}
        v = len(self.vocab)
        self.total = {c: sum(self.counts[c].values()) for c in self.classes}
        self.log_unseen, self.log_like = {}, {}
        for c in self.classes:
            denom = self.total[c] + self.alpha * v
            self.log_unseen[c] = math.log(self.alpha / denom)
            self.log_like[c] = {t: math.log((n + self.alpha) / denom)
                                for t, n in self.counts[c].items()}
        return self

    def log_p(self, c, term):
        return self.log_like[c].get(term, self.log_unseen[c])

    def scores(self, terms):
        """log P(c) + sum of log P(term | c), for every class c."""
        known = [t for t in terms if t in self.vocab]  # unknown words: ignored
        return {c: self.log_prior[c] + sum(self.log_p(c, t) for t in known)
                for c in self.classes}

    def predict(self, terms):
        """The most probable class, or "?" when no term is known at all."""
        if not any(t in self.vocab for t in terms):
            return "?"
        s = self.scores(terms)
        return max(self.classes, key=lambda c: (s[c], c))
```

Listing 25.1 (Continued) *naive_bayes.py: multinomial naive Bayes with Laplace smoothing, from scratch.*

```
    def proba(self, terms):
        """Turn the log scores into probabilities that add up to one."""
        s = self.scores(terms)
        top = max(s.values())
        e = {c: math.exp(x - top) for c, x in s.items()}   # safe exponent
        z = sum(e.values())
        return {c: x / z for c, x in e.items()}

    def top_terms(self, c, n=6):
        """Terms that most favour class c over the average other class."""
        others = [k for k in self.classes if k != c]

        def lift(t):
            rest = sum(self.log_p(k, t) for k in others) / len(others)
            return self.log_p(c, t) - rest
        return sorted(self.counts[c], key=lambda t: (-lift(t), t))[:n]
```

- `fit` counts documents per class for the prior of Equation (25.3) and terms per class for the likelihoods, then stores every $\log P(t \mid c)$ of Equation (25.4). `log_unseen[c]` is the log-probability of a term that is in the vocabulary but never occurred in class c: the case smoothing exists for.
- `scores` is the bracket of Equation (25.5). Terms that never appeared in training at all are ignored: they carry no information about any class, and including them would only add the same constant to every score.
- `predict` returns the class with the highest score, breaking ties by name so that the result is reproducible. If the document has *no* known term at all, every score equals the prior and any answer would be a pure guess, so it honestly returns `"?"`.
- `proba` is Equation (25.6); `top_terms` lists the terms whose probability in class c most exceeds their average probability in the other classes, which is what we will print to explain decisions.

Listing 25.2 is the evaluation program: stratified folds, a confusion matrix, and precision, recall and F1 by Equation (25.7). Options restrict training or testing to one language, which we need in Section 25.6.

Listing 25.2 `classify.py`: stratified cross-validation, confusion matrix, precision, recall and F1.

```
"""classify.py - cross-validate the topic classifier and classify headlines."""
import argparse
import csv
import random
from collections import Counter

from naive_bayes import NaiveBayes
from tfidf import terms

TOPICS = ["business", "health", "sports", "tech"]

def load(path="data/news.tsv"):
    with open(path, encoding="utf-8", newline="") as f:
        rows = list(csv.DictReader(f, delimiter="\t"))
    return [(r["title"] + ". " + r["text"], r["topic"], r["lang"]) for r in rows]

def folds(labels, k, seed=25):
    """Stratified k-fold: every fold gets its share of every class."""
    rng = random.Random(seed)
    fold_of = [0] * len(labels)
    for c in sorted(set(labels)):
        idx = [i for i, y in enumerate(labels) if y == c]
        rng.shuffle(idx)
        for pos, i in enumerate(idx):
            fold_of[i] = pos % k
    return fold_of

def report(pairs):
    """Accuracy, confusion matrix and per-class precision, recall and F1."""
    acc = sum(t == p for t, p in pairs) / len(pairs)
    conf = Counter(pairs)
    unknown = sum(p == "?" for _, p in pairs)
    print(f"accuracy {acc:.3f} on {len(pairs)} documents"
          f" ({unknown} without a single known word)")
    print("true \\ predicted " + "".join(f"{c:>9}" for c in TOPICS))
    for t in TOPICS:
        print(f"{t:<17}" + "".join(f"{conf[(t, p)]:>9}" for p in TOPICS))
    print(f"{'':<17}{'precision':>10}{'recall':>8}{'F1':>7}")
    for c in TOPICS:
        tp = conf[(c, c)]
        prec = tp / max(sum(conf[(t, c)] for t in TOPICS), 1)
        rec = tp / max(sum(t == c for t, _ in pairs), 1)   # "?" counts as a miss
        f1 = 2 * prec * rec / (prec + rec) if tp else 0.0
```

Listing 25.2 (Continued) *classify.py: stratified cross-validation, confusion matrix, precision, recall and F1.*

```
        print(f"{c:<17}{prec:>10.2f}{rec:>8.2f}{f1:>7.2f}")

def main():
    ap = argparse.ArgumentParser(description=__doc__)
    ap.add_argument("--k", type=int, default=4, help="number of folds")
    ap.add_argument("--train-lang", help="train on one language only")
    ap.add_argument("--test-lang", help="test on one language only")
    args = ap.parse_args()

    data = load()
    docs = [terms(text) for text, _, _ in data]
    labels = [topic for _, topic, _ in data]
    langs = [lang for _, _, lang in data]
    fold_of = folds(labels, args.k)
    pairs = []
    for f in range(args.k):
        train = [i for i in range(len(data)) if fold_of[i] != f
                 and args.train_lang in (None, langs[i])]
        test = [i for i in range(len(data)) if fold_of[i] == f
                and args.test_lang in (None, langs[i])]
        model = NaiveBayes().fit([docs[i] for i in train],
                                 [labels[i] for i in train])
        pairs += [(labels[i], model.predict(docs[i])) for i in test]
    report(pairs)

if __name__ == "__main__":
    main()
```

The fold assignment in `folds` shuffles the documents of each class with a fixed seed and deals them out like cards, 0,1,2,3,0,1, …, so every fold receives six of each topic's 24 documents.

25.5 Running It

```
python classify.py
```

```
accuracy 0.677 on 96 documents (0 without a single known word)
true \ predicted  business   health   sports     tech
business               14        1        2        7
health                  3       19        0        2
sports                  2        1       20        1
tech                    9        3        0       12
                 precision  recall     F1
business              0.50    0.58   0.54
health                0.79    0.79   0.79
sports                0.91    0.83   0.87
tech                  0.55    0.50   0.52
```

The accuracy is 0.677: 65 of 96 items were placed in the right section by a model that had never seen them. Guessing among four balanced topics would give 0.25. **Figure 25.1** shows the confusion matrix. Sports and health are recognized well, with F1 of 0.87 and 0.79; business and technology are confused with each other in both directions (7 business items called tech, 9 tech items called business). Read those items and the reason is clear: QR payments at markets, electric car sales, foldable phones getting cheaper, a port expanding its capacity. They are about money *and* technology, and a person could argue either way. A classifier cannot be more certain than the categories themselves are.

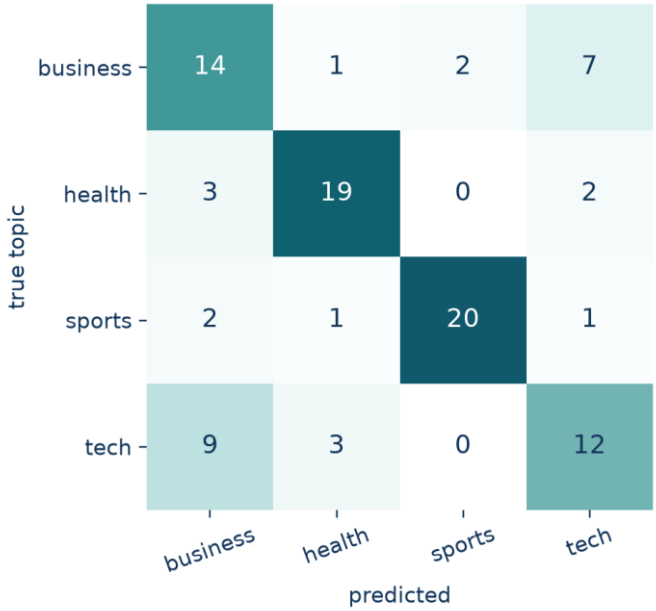

Figure 25.1 Confusion matrix of naive Bayes under 4-fold cross-validation on the 96 news items. Rows are true topics and columns predicted topics; the diagonal holds the correct answers.

25.5.1 Explaining decisions

Listing 25.3 trains on all 96 items and classifies eight new headlines that were written for this chapter, printing the probability of Equation (25.6) and the three words that most favored the chosen topic.

Listing 25.3 `predict.py`: classifying new headlines, with the words that decided.

```
"""predict.py - classify new headlines and show which words decided."""
import csv
import sys

from classify import load
from naive_bayes import NaiveBayes
from tfidf import terms

data = load()
model = NaiveBayes().fit([terms(t) for t, _, _ in data], [y for _, y, _ in data])

if sys.argv[1:] == ["--top"]:                  # the most telling words
    for c in model.classes:
        print(f"{c:<9}", ", ".join(model.top_terms(c, 8)))
    sys.exit()
if len(sys.argv) > 1:
    items = [(" ".join(sys.argv[1:]), "")]
else:
    with open("data/new_headlines.tsv", encoding="utf-8", newline="") as f:
        items = [(r["text"], r["topic"]) for r in csv.DictReader(f, delimiter="\t")]

for text, truth in items:
    ts = terms(text)
    probs = model.proba(ts)
    best = model.predict(ts)
    mark = "" if not truth else ("  ok" if best == truth else f"  WRONG ({truth})")
    print(f"{text}")
    print(f"   -> {best} {probs.get(best, 0):.2f}{mark}")
    if best in model.classes:
        rest = [c for c in model.classes if c != best]
        why = sorted((t for t in set(ts) if t in model.vocab),
                     key=lambda t: (max(model.log_p(c, t) for c in rest)
                                    - model.log_p(best, t), t))
        print(f"      words for it: {', '.join(why[:3])}")
```

```
python predict.py
```

```
Harga beras di Pasar Wonokromo turun menjelang panen raya
   -> business 0.93  ok
      words for it: harga, beras, turun
Tim voli pantai Jawa Timur melaju ke final kejuaraan nasional
   -> sports 1.00  ok
      words for it: tim, final, kejuaraan
Puskesmas membuka layanan cek gula darah gratis setiap Jumat
   -> health 0.99  ok
      words for it: darah, gula, gratis
Perusahaan rintisan Surabaya meluncurkan aplikasi antrean puskesmas
   -> tech 0.73  ok
      words for it: aplikasi, meluncurkan, perusahaan
Rice prices fall as the harvest begins
   -> business 0.54  ok
      words for it: prices, rice, harvest
Local swimmer sets a new provincial record
   -> sports 0.81  ok
      words for it: swimmer, sets, record
Free blood sugar checks at the health center every Friday
   -> health 1.00  ok
      words for it: blood, health, sugar
Surabaya startup launches a queue app for health centers
   -> health 0.56  WRONG (tech)
      words for it: health, centers, surabaya
```

Seven of eight are right, and the explanations make sense: *harga*, *beras*, *turun* for business; *darah*, *gula*, *gratis* for health. The one mistake is instructive. “Surabaya startup launches a queue app for health centers” is labeled technology, but the words *health* and *centers* are strong health words, while *startup*, *launches* and *queue* never occur in the English training items, and *app* occurs only

twice. Its Indonesian twin, with *aplikasi* and *meluncurkan*, is classified correctly. Notice also the probabilities: 1.00 for two headlines. Naive Bayes is famously **overconfident**, because the independence assumption counts correlated words as separate pieces of evidence; its ranking of classes is much better than its probabilities [1]. Treat those numbers as scores, not as honest chances.

You can classify any headline from the command line:

```
python predict.py Harga ponsel lipat turun lagi bulan ini
```

```
Harga ponsel lipat turun lagi bulan ini
   -> business 0.76
      words for it: harga, turun, bulan
```

"The price of foldable phones fell again this month" goes to business, on the strength of *harga* and *turun*. The training item about foldable phones was labeled technology, so a person might disagree. Once again, the boundary between the two topics is where the errors live.

25.5.2 What the model learned

Explaining single decisions is useful; so is looking at the whole model at once. With the option `--top`, **Listing 25.3** lists for each topic the eight words whose probability in that topic most exceeds their average probability in the other topics, the `top_terms` method of **Listing 25.1**:

```
python predict.py --top
```

```
business  harga, bank, usaha, listrik, menjadi, percent, persen, prices
health    health, blood, darah, kesehatan, dokter, gigi, anak, children
sports    tim, coach, pelatih, team, muda, pemain, tournament, turnamen
tech      data, digital, model, program, robot, bahasa, 5g, students
```

The lists are bilingual, because the model was trained on both languages at once: *harga* and *prices*, *darah* and *blood*, *pelatih* and *coach* sit side by side. Most entries are exactly the words a person would pick to describe each section. A few are accidents of this small corpus. *Menjadi* (to become) appears under business because several business items report that something rose or fell "menjadi" a new level: a price, an interest rate, a waiting time. *Students* appears under technology because the robot and the data-science items mention students. *Anak* (child) appears under health because the health items talk about vaccinating children and brushing their teeth.

Such words are harmless as long as they agree with the real topic words, but they show how a small training set turns coincidence into "evidence": a sports item about a student athlete would get a small push toward technology from *students*. Three remedies exist. More data dilutes coincidences, as the learning curve of Section 25.7.1 will show. A minimum count, ignoring words seen fewer than two or three times, removes the rarest accidents. And a person can read these lists and remove words that obviously do not belong. Reading the top words of every class is one of the fastest checks that a text classifier has learned something sensible, and it costs nothing.

25.6 One Model, Two Languages

Our 96 items are half Indonesian and half English, and the model of Section 25.5 was trained on both. What happens if we train only on Indonesian and test on English?

```
python classify.py --train-lang id --test-lang en
```

```
accuracy 0.542 on 48 documents (17 without a single known word)
true \ predicted  business   health   sports     tech
business                 5        0        1        1
health                   1        6        0        1
sports                   0        0        7        0
tech                     1        0        0        8
                  precision  recall     F1
business               0.71    0.42   0.53
health                 1.00    0.50   0.67
sports                 0.88    0.58   0.70
tech                   0.80    0.67   0.73
```

Accuracy falls to 0.542, and for 17 of the 48 English items the model returns `"?"`: not one of their words occurs in the Indonesian training data. More surprising is that the model is right on 26 items at all. The reason is that the two languages share words: place names (*Surabaya*, *Bromo*, *Sidoarjo*), loanwords (*bank*, *robot*, *data*, *digital*, *final*, *futsal*, *diabetes*) and technical terms (*5G*, *QR*). Exercise 25.4 lists all 44 of them. Most carry the same topic in both languages, which is why they help. A few are **false friends**: Indonesian *air* means water and occurs in a health item about drinking plain water and a technology item about drones finding dry fields, while English *air* occurs in the item about air pollution.

The lesson is general. A bag-of-words model knows words, not meanings, and it will only transfer between languages as far as the vocabularies overlap. Models that transfer across languages properly represent words by meaning, with multilingual embeddings; Chapter 37 trains word embeddings from scratch, and Chapter 54 uses them for search.

25.7 How Good Is Good? Comparing Models Honestly

Listing 25.4 runs three scikit-learn models [4] on exactly the same folds, using `PredefinedSplit` to pass our fold assignment: scikit-learn's own `MultinomialNB`, and logistic regression and a linear support vector machine on TF-IDF vectors [5].

Listing 25.4 `compare_models.py`: our naive Bayes against three scikit-learn models on the same folds.

```
"""compare_models.py - our naive Bayes against three scikit-learn models."""
import warnings

from sklearn.feature_extraction.text import CountVectorizer, TfidfVectorizer
from sklearn.linear_model import LogisticRegression
from sklearn.model_selection import PredefinedSplit, cross_val_predict
from sklearn.naive_bayes import MultinomialNB
from sklearn.pipeline import make_pipeline
from sklearn.svm import LinearSVC

from classify import folds, load
from naive_bayes import NaiveBayes
from tfidf import terms

warnings.filterwarnings("ignore")
data = load()
texts = [t for t, _, _ in data]
labels = [y for _, y, _ in data]
fold_of = folds(labels, 4)
split = PredefinedSplit(fold_of)                # exactly our four folds

ours = []
for f in range(4):
    train = [i for i in range(len(data)) if fold_of[i] != f]
    model = NaiveBayes().fit([terms(texts[i]) for i in train],
                             [labels[i] for i in train])
    ours += [(i, model.predict(terms(texts[i])))
             for i in range(len(data)) if fold_of[i] == f]
ours = [p for _, p in sorted(ours)]

models = {
    "sklearn MultinomialNB": make_pipeline(CountVectorizer(analyzer=terms),
                                           MultinomialNB(alpha=1.0)),
    "tf-idf + LogisticRegression": make_pipeline(
        TfidfVectorizer(analyzer=terms), LogisticRegression(C=10, max_iter=1000)),
    "tf-idf + LinearSVC": make_pipeline(TfidfVectorizer(analyzer=terms),
                                        LinearSVC(C=1.0)),
}
print(f"{'model':<30}{'accuracy':>9}")
acc = sum(p == y for p, y in zip(ours, labels)) / len(labels)
print(f"{'our NaiveBayes':<30}{acc:>9.3f}")
for name, pipe in models.items():
    pred = cross_val_predict(pipe, texts, labels, cv=split)
    acc = sum(p == y for p, y in zip(pred, labels)) / len(labels)
    same = sum(p == q for p, q in zip(pred, ours))
    print(f"{name:<30}{acc:>9.3f}   agrees with ours on {same}/96")
```

```
python compare_models.py
```

```
model                          accuracy
our NaiveBayes                    0.677
sklearn MultinomialNB             0.677   agrees with ours on 96/96
tf-idf + LogisticRegression       0.719   agrees with ours on 89/96
tf-idf + LinearSVC                0.719   agrees with ours on 89/96
```

The first line after ours is a strong check of correctness: scikit-learn's `MultinomialNB`, given the same terms and the same smoothing, makes exactly the same prediction on all 96 items. The two discriminative models reach 0.719, four more documents correct than naive Bayes.

Is 0.719 really better than 0.677? Use Equation (25.8): with $p \approx 0.7$ and $n = 96$, $\text{SE} = \sqrt{0.7 \times 0.3/96} \approx 0.047$. Two standard errors are about 0.09, more than twice the difference we observed. With 96 documents, a difference of four documents is within the noise. The honest statement is "logistic regression and the SVM did slightly better on this data, and the difference is not large enough to be sure". On large text collections, linear models usually do beat naive Bayes

when there is plenty of training data, while naive Bayes is often better when training data is scarce [6].

25.7.1 More data

What would help most? A **learning curve** answers that question by training on growing shares of each training fold and measuring accuracy on the same test folds. **Listing 25.5** averages ten random draws for each size.

Listing 25.5 `learning_curve.py`: accuracy as a function of the number of training items.

```
"""learning_curve.py - how accuracy grows with the number of training items."""
import random

from classify import folds, load
from naive_bayes import NaiveBayes
from tfidf import terms

data = load()
docs = [terms(t) for t, _, _ in data]
labels = [y for _, y, _ in data]
fold_of = folds(labels, 4)
rng = random.Random(25)

print(f"{'training items':>15}{'accuracy':>10}")
for share in (0.25, 0.5, 0.75, 1.0):
    right = total = 0
    for repeat in range(10):
        for f in range(4):
            train = [i for i in range(len(data)) if fold_of[i] != f]
            train = rng.sample(train, round(share * len(train)))
            model = NaiveBayes().fit([docs[i] for i in train],
                                     [labels[i] for i in train])
            test = [i for i in range(len(data)) if fold_of[i] == f]
            right += sum(model.predict(docs[i]) == labels[i] for i in test)
            total += len(test)
    print(f"{round(share * 72):>15}{right / total:>10.3f}")
```

```
python learning_curve.py
```

```
 training items  accuracy
             18     0.467
             36     0.601
             54     0.666
             72     0.677
```

Figure 25.2 plots the result. With 18 training items, the model reaches 0.47; with 72, 0.68. The curve is still rising at the right-hand end, and it has not flattened. That is the most useful single fact in this chapter for anyone who wants a better classifier: before tuning parameters or trying fancier models, label more data. A few hundred items per topic would move this classifier much further than any change of algorithm. Real Indonesian benchmarks, such as those collected in IndoNLU, use thousands of labeled texts for exactly this reason [7].

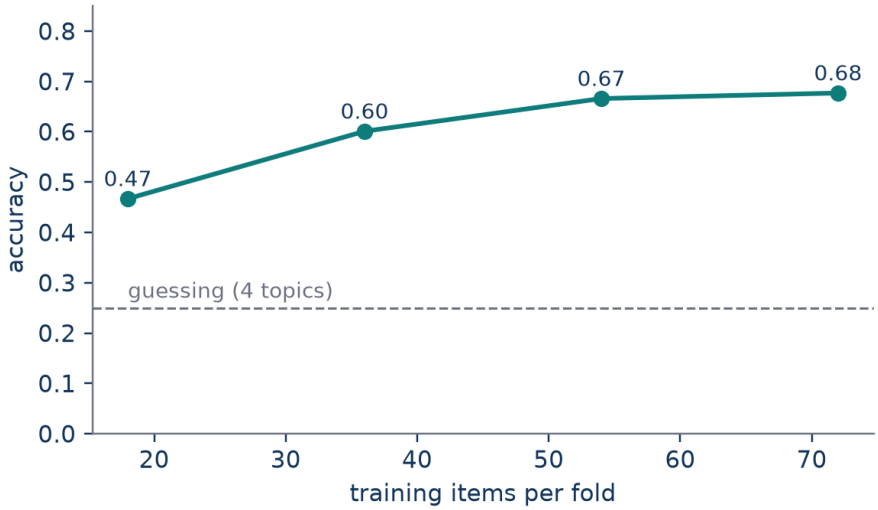

Figure 25.2 Learning curve of naive Bayes: cross-validated accuracy against the number of training items per fold, averaged over ten random draws. The dashed line is the accuracy of guessing.

25.8 Testing

Listing 25.6 turns the worked example of Section 25.3.5 into tests, checks that probabilities add up to one and that a document with no known word gets `"?"`, and checks that the folds are stratified.

Listing 25.6 `tests/test_naive_bayes.py`: tests for smoothing, prediction and stratified folds.

```

3 passed in 0.01s
```

25.9 A Classifier for Profitina Laundry's Messages

The same program can route customer messages. Replace the four news topics by the four desks of Profitina Laundry (price and payment, stains and damage, pickup and delivery, other), label a few hundred past messages, and `classify.py` reports how well the routing would have worked. Three points from this chapter carry over directly.

Measure per class, not only overall. A rare but important class, such as damage complaints, can have poor recall while overall accuracy looks fine, because the common classes dominate the average. Precision and recall by Equation (25.7) reveal it; a complaint routed to the wrong desk is a customer kept waiting.

Keep the "?" answer. A message whose words the model has never seen should go to a person, not to a random desk. Returning `"?"` instead of guessing, as `predict` does, is a small design decision that prevents silent errors.

Let people correct it. Each time a staff member moves a message to the right desk, that correction is a new labeled example. The learning curve of **Figure 25.2** says that such examples are exactly what a small classifier needs most. The program advises; the staff decides, and the program learns from the decision.

25.10 Common Mistakes, and How to Avoid Them

Testing on the training data. A model scores almost perfectly on items it has memorized. *Avoid it:* always evaluate on held-out data, with cross-validation when data is scarce.

Forgetting smoothing. One unseen word turns a class's probability into zero. *Avoid it:* use Equation (25.4) with $\alpha > 0$.

Multiplying probabilities. The product underflows to zero for long texts. *Avoid it:* add logarithms, as in Equation (25.5).

Reporting only accuracy. It hides which classes fail. *Avoid it:* print the confusion matrix and per-class precision, recall and F1.

Believing small differences. Four documents out of 96 are within the noise. *Avoid it:* compute the standard error of Equation (25.8) before declaring a winner.

Trusting naive Bayes probabilities. A probability of 1.00 does not mean certainty. *Avoid it:* use the ranking, and calibrate probabilities on held-out data if you need them.

Guessing when nothing is known. A prediction from the prior alone is a coin toss dressed up as an answer. *Avoid it:* return "unknown" and let a person decide.

Mixing up folds between models. Comparing models evaluated on different splits adds noise to the comparison. *Avoid it:* use the same folds for every model, as `PredefinedSplit` does.

25.11 Chapter Summary

- **Text classification** assigns a text to one of a fixed set of classes by learning from labeled examples.

- **Naive Bayes** applies Bayes' rule (Equation (25.1)) with the assumption that words are independent given the class (Equation (25.2)); it estimates priors by counting documents (Equation (25.3)) and word probabilities with **Laplace smoothing** (Equation (25.4)), and decides with a sum of logarithms (Equation (25.5)), turning scores into probabilities with Equation (25.6) (**Listing 25.1**).
- **Stratified cross-validation**, a **confusion matrix** and **precision, recall and F1** (Equation (25.7)) describe performance honestly (**Listing 25.2**, **Figure 25.1**). The **standard error** (Equation (25.8)) says how much a measured accuracy can be trusted.
- On our 96 items naive Bayes reaches 0.677, identical to scikit-learn's implementation; logistic regression and a linear SVM reach 0.719, a difference within the noise (**Listing 25.4**). Business and technology are confused because the items genuinely overlap.
- Trained on Indonesian alone, the model understands English only through shared names and loanwords (**Listing 25.3**). The **learning curve** is still rising: more labeled data would help most (**Listing 25.5**, **Figure 25.2**).

25.12 Exercises

Exercise 25.1. Using the four training documents of Section 25.3.5, classify the document "harga naik tim" by hand. Give both unnormalized scores and the probability of the winning class by Equation (25.6).

Exercise 25.2. In the confusion matrix of Section 25.5, compute precision, recall and F1 for *business* from the counts, and check them against the printed values.

Exercise 25.3. Two classifiers are tested on 96 documents: A is right on 65, B on 69. Compute the standard error of each accuracy by Equation (25.8). Then suppose the same accuracies were measured on 9,600 documents. Would you now believe that B is better? Explain.

Exercise 25.4. Write a program that lists the terms that occur in both the Indonesian and the English halves of the corpus, and the terms among them whose topics differ between the two languages.

Exercise 25.5. A headline is a dense summary of its item. Modify the training so that the headline's terms are counted two or three times, and measure the cross-validated accuracy. Is the change worth making, given Equation (25.8)?

Exercise 25.6. A fifth topic, *laundry*, is to be added, with items about laundry services. Which existing topic will it be confused with most, judging from the corpus, and what would you do before training?

25.13 Solutions to the Exercises

Solution 25.1. Sports: $P(\text{sports})\,P(\text{harga} \mid \text{sports})\,P(\text{naik} \mid \text{sports})\,P(\text{tim} \mid \text{sports}) = 0.5 \times 0.1 \times 0.1 \times 0.3 = 0.0015$. Business: $0.5 \times 0.3 \times 0.2 \times 0.1 = 0.003$. Business wins, with $P(\text{business} \mid d) = 0.003/(0.003 + 0.0015) = 2/3 \approx 0.67$ by Equation (25.6). Two business words against one sports word, and business is the answer, but not with certainty.

Solution 25.2. For *business*: TP $= 14$; the column *business* holds $14 + 3 + 2 + 9 = 28$ predictions, so FP $= 14$ and precision $= 14/28 = 0.50$; the row holds $14 + 1 + 2 + 7 = 24$ items, so recall $= 14/24 = 0.58$. $F_1 = 2 \times 0.50 \times 0.583/(0.50 + 0.583) = 0.583/1.083 \approx 0.54$. All three match the output.

Solution 25.3. A: $p = 65/96 = 0.677$, SE $= \sqrt{0.677 \times 0.323/96} \approx 0.048$. B: $p = 69/96 = 0.719$, SE $= \sqrt{0.719 \times 0.281/96} \approx 0.046$. The difference, 0.042, is less than one standard error of each, so it could easily be chance. On 9,600 documents both standard errors shrink by $\sqrt{100} = 10$, to about 0.0047; a difference of 0.042 is then about nine standard errors, far too large to be chance, and we would believe that B is better. (A more exact comparison uses McNemar's test, which looks only at the documents on which the two classifiers disagree; the idea is the same.)

Solution 25.4. **Listing 25.7** collects the terms of each language with the topics they occur in, prints the shared ones, and then the shared terms whose topic sets differ.

Listing 25.7 `solutions/shared_words.py`: terms shared by both languages, and those whose topics differ.

```
"""shared_words.py - Exercise 25.4: words used by both halves of the corpus."""
import os
import sys
import textwrap
from collections import Counter

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from classify import load  # noqa: E402
from tfidf import terms  # noqa: E402

vocab = {"id": Counter(), "en": Counter()}
topic_of = {}
for text, topic, lang in load():
    for t in set(terms(text)):
        vocab[lang][t] += 1
        topic_of.setdefault(t, Counter())[topic, lang] += 1

shared = sorted(set(vocab["id"]) & set(vocab["en"]))
print(len(shared), "words occur in both languages:")
print(textwrap.fill(", ".join(shared), 78))
print("same topics in both languages, except:")
for t in shared:
    topics = {lang: {tp for (tp, lg) in topic_of[t] if lg == lang}
              for lang in ("id", "en")}
    if topics["id"] != topics["en"]:
        print(f"  {t:<10} id: {', '.join(sorted(topics['id'])):<24}"
              f"en: {', '.join(sorted(topics['en']))}")
```

```
python solutions/shared_words.py
```

```
44 words occur in both languages:
5g, air, bank, bromo, data, diabetes, digital, donor, final, futsal, garuda,
indonesia, internet, junior, keputih, kilogram, korea, lamongan, madura,
malang, malaysia, mental, meter, model, muda, operator, pencak, per, perak,
program, python, qr, robot, rungkut, semifinal, senior, set, sidoarjo, silat,
stamina, surabaya, tanjung, thailand, video
same topics in both languages, except:
  air        id: health, tech            en: health
  indonesia  id: business, sports        en: business
  madura     id: health, tech            en: health
  muda       id: sports, tech            en: sports
  qr         id: tech                    en: business, tech
```

Of the 44 shared terms, 39 occur with the same topics in both languages, which is why a model trained on one language still gets many English items right. The five exceptions are *air* (a false friend), *indonesia*, *madura*, *muda* and *qr*, which appear in slightly different items in each language.

Solution 25.5. **Listing 25.8** repeats the headline terms before the body terms and reruns the cross-validation.

Listing 25.8 `solutions/title_weight.py`: counting the headline two or three times.

```
"""title_weight.py - Exercise 25.5: count headline words more than once."""
import csv
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from classify import folds  # noqa: E402
from naive_bayes import NaiveBayes  # noqa: E402
from tfidf import terms  # noqa: E402

with open("data/news.tsv", encoding="utf-8", newline="") as f:
    rows = list(csv.DictReader(f, delimiter="\t"))
labels = [r["topic"] for r in rows]
fold_of = folds(labels, 4)

for weight in (1, 2, 3):
    docs = [terms(r["title"]) * weight + terms(r["text"]) for r in rows]
    right = 0
    for f in range(4):
        train = [i for i in range(len(rows)) if fold_of[i] != f]
        model = NaiveBayes().fit([docs[i] for i in train],
                                 [labels[i] for i in train])
        right += sum(model.predict(docs[i]) == labels[i]
                     for i in range(len(rows)) if fold_of[i] == f)
    print(f"headline counted {weight}x: {right}/96 = {right / 96:.3f}")
```

```
python solutions/title_weight.py
```

```
headline counted 1x: 65/96 = 0.677
headline counted 2x: 68/96 = 0.708
headline counted 3x: 68/96 = 0.708
```

Counting the headline twice gains three documents, from 65 to 68. By Equation (25.8) the standard error is about 0.047, and three documents are 0.031, less than one standard error, so the evidence is weak. The change is cheap and has a sound reason (headlines are written to name the topic), so it is reasonable to keep it, but it should be confirmed on more data before anyone claims an improvement.

Solution 25.6. Laundry items talk about prices, payments, customers and small businesses (*harga*, *pelanggan*, *usaha*, *QRIS*), so they will be confused mostly with **business**, and, where apps and QR payments are involved, with **technology**. Before training, write a clear definition of each topic with borderline examples ("an item about a laundry's prices is *laundry*, not *business*"), label enough items that the learning curve flattens, and look at the confusion matrix for the new row and column first. If people cannot agree on the label of an item, no classifier will.

Chapter 26

Language Detector

Every program in this part so far has been told which language it is reading. Real input does not come labeled: a customer writes in Indonesian one day and in English the next, a tourist asks in Dutch, and a message from Johor Bahru is written in Malay, which looks almost exactly like Indonesian. This chapter builds a detector that decides the language of a text from its letters alone. By the end of it you will be able to cut a text into character n-grams; build the classic rank-profile detector of Cavnar and Trenkle; build a naive Bayes detector over character n-grams and explain why it needs smoothing; measure how accuracy depends on the length of the text; see why Indonesian and Malay are hard to tell apart and how a small list of marker words helps; decide when to answer "not sure"; and test your conclusions honestly on sentences written after the program was finished.

26.1 Why Detect Languages?

A language detector is the silent first step of many systems. A search engine must know the language of a page before it can tokenize it, remove stop words or stem it; our keyword extractor of Chapter 23 fitted one model per language for exactly that reason. A translation app must know what to translate from. A support desk must send a Dutch e-mail to someone who reads Dutch. The large text collections used to train language models are sorted by language with detectors before anything else happens to them.

For Profitina Laundry the need is concrete. Its FAQ bot (Chapter 29) has answers in Indonesian and English and should reply in the customer's language. Its spell checker (Chapter 22) should not "correct" an English word into an Indonesian one. And customers who cross the border, from Malaysia or Singapore, write in Malay, which shares most of its words with Indonesian but differs in spelling and vocabulary: *kerana* for *karena*, *wang* for *uang*, *kedai* for *toko*.

The problem sounds easy, and for long texts in very different languages it is. It becomes interesting for short texts, such as a four-word chat message, and for closely related languages, such as Indonesian and Malay. Both situations occur every day, and this chapter meets both.

Indonesia makes the problem especially rich. Besides Indonesian, hundreds of regional languages are spoken across the archipelago, and many people switch between Indonesian, a regional language such as Javanese or Madurese, and English within a single conversation. A customer in Surabaya might greet in Javanese, ask the question in Indonesian and name the service in English. A detector built for such a place must expect short, mixed and informal texts, and must be honest about how sure it is. This chapter works with four languages to keep the experiments small, but the same code extends to any language for which a few pages of text can be collected.

26.2 The Idea in Plain Words

Suppose a becak driver hears a passenger on the phone but cannot make out the words. He can still often tell the language, from the *sounds*: the "-ng" and "-an" endings of Indonesian, the "th" of

English, the "-en" and "ij" of Dutch. Written text has the same kind of fingerprint in its letters. English is full of *th*, *he*, *ing*; Dutch of *en*, *de*, *ij*, *aa*; Indonesian and Malay of *an*, *ng*, *me*, *pe*, *ber*.

So we cut every text into short strings of consecutive characters, called **character n-grams**, and count them. For each language we learn, from a sample text, which n-grams are common. To classify a new text, we ask which language's counts it resembles most. Characters have two big advantages over whole words: a short text of a few words still contains dozens of n-grams, and a word the detector has never seen, such as a name or a misspelling, still contains familiar pieces.

We try two ways of comparing counts. The first, from 1994, compares the *rank order* of the most frequent n-grams, like comparing two top-300 charts. The second is naive Bayes, the method of Chapter 25, applied to n-grams instead of words.

Why not simply look words up in a dictionary of each language? Because the words a detector meets are exactly the ones a dictionary lacks: names (*Rungkut*, *Johor Bahru*), brand names, slang (*gan*, *mantul*), misspellings, and words shared by several languages (*bank*, *hotel*, *data*). A four-word message may contain no dictionary word at all. Character n-grams avoid the problem because they look below the level of words: an unknown Malay word such as *basikal* still ends in `al_` and contains `sik`, pieces that carry some evidence about its language even though the whole word has never been seen. A dictionary is still useful, as the marker words of Section 26.7 show, but as a second opinion rather than as the main method.

26.3 The Mathematics, Gently

26.3.1 Character n-grams

We lowercase the text, keep only its words, and join them with the boundary mark "_", also placed at both ends:"Ke toko" becomes `_ke_toko_`. The boundary mark lets n-grams record where words begin and end, so `_th` means "a word starting with *th*" and `an_` means "a word ending with *an*". A string of length L contains

$$L - n + 1 \tag{26.1}$$

n-grams of length n (one starting at each position that leaves room for n characters). `_ke_toko_` has $L = 9$, hence 9 unigrams, 8 bigrams and 7 trigrams. We use all n-grams with $n = 1,2,3$ together.

26.3.2 The rank-profile method

Cavnar and Trenkle's detector [1] builds, for each language ℓ, a **profile** P_ℓ: the $K = 300$ most frequent n-grams of its training text, numbered by rank $r_\ell(g) = 0,1,2,\ldots$ from the most frequent. The new document gets a profile P_d in the same way. The **out-of-place distance** adds up how far each n-gram of the document has moved in the ranking:

$$D(d,\ell) = \sum_{g \in P_d} \begin{cases} |r_d(g) - r_\ell(g)| & \text{if } g \in P_\ell \\ K & \text{otherwise} \end{cases} \tag{26.2}$$

An n-gram that the language does not have among its top 300 costs the maximum penalty K. The detector chooses the language with the smallest distance. The method is simple, needs no probabilities, and works well for texts of a few hundred characters.

26.3.3 Naive Bayes over n-grams

The second method treats a text as a bag of n-grams $g_1, \ldots, g_m$ and chooses the language that makes them most probable, exactly as Chapter 25 did with words [2]. With equal priors for the four languages, the prior drops out, and

$$\hat{\ell} = \operatorname*{argmax}_{\ell} \sum_{i=1}^{m} \log P(g_i \mid \ell) \tag{26.3}$$

Let $c_\ell(g)$ be the count of n-gram g in the training text of language ℓ, N_ℓ the total number of n-grams in that text, and V the set of all n-grams seen in any language. Add-one smoothing gives

$$P(g \mid \ell) = \frac{c_\ell(g) + 1}{N_\ell + |V|} \tag{26.4}$$

Smoothing is essential here: a Dutch text contains the trigram `ij_` or `aa_`, which may never occur in the Indonesian sample, and without the "+1" a single such n-gram would give Indonesian probability zero and end the discussion. With smoothing, it only lowers Indonesian's score, which is exactly the right amount of evidence.

26.3.4 How sure is the decision?

The scores of Equation (26.3) are sums over all m n-grams, so they grow with the length of the text. To compare decisions on texts of different lengths, we divide the gap between the best score s_1 and the second-best s_2 by the number of n-grams:

$$\text{margin} = \frac{s_1 - s_2}{m} \tag{26.5}$$

It measures, on average per n-gram, how much more the winning language explains the text than its closest rival. A margin near zero means the text could just as well be in the second language; Section 26.7 uses it to decide when to answer "not sure".

26.3.5 A worked example

Take two tiny "training texts", Indonesian `_karena_` and Malay `_kerana_`, and look only at trigrams. Indonesian has `_ka kar are ren ena na_` and Malay has `_ke ker era ran ana na_`: six trigrams each, with only `na_` in common. The shared vocabulary V has 11 distinct trigrams, so by Equation (26.4) every trigram seen once in a language gets $(1+1)/(6+11) = 2/17$, and every unseen trigram gets $1/17$.

Now classify the word *kerana*. Its six trigrams are exactly the Malay ones. Under Malay, each has probability $2/17$, so the log-score of Equation (26.3) is $6\log(2/17)$. Under Indonesian, only `na_` was seen, so the score is $\log(2/17) + 5\log(1/17)$. The difference is $5 \log 2 \approx 3.47$ in favor of Malay, and the margin of Equation (26.5) is $3.47/6 \approx 0.58$ per trigram, a very clear decision. Real sentences are less clear-cut: most of their n-grams occur in both languages, and only a few carry the difference, which is why the margins in Section 26.7.3 are around 0.1 rather than 0.5.

26.4 The Data

Four languages, and the same amount of training text for each:

- **Indonesian** and **English**: the bodies of the news items of Chapter 21.
- **Malay**: `data/train_ms.txt`, seven short paragraphs of news-style Malay, written for this book in Malaysian spelling and vocabulary (*kerajaan*, *percuma*, *kerana*, *doktor*, *polis*).
- **Dutch**: `data/train_nl.txt`, seven paragraphs on the same everyday topics.

`load_training` cuts every language to the first 1,700 characters, the size of the shortest sample. Unequal amounts would bias the detectors toward the language with more text, a trap that Exercise 26.4 examines. For testing, `data/test.tsv` holds 48 short sentences, 12 per language, in the style of customer messages and everyday speech, none of them taken from the training text.

26.5 Building the Detectors

Listing 26.1 contains everything: the n-gram function, both detectors, and the marker-word improvement of Section 26.7.

Listing 26.1 `langid.py`: character n-grams, the rank-profile detector, the naive Bayes detector, and the marker-word rule.

```
"""langid.py - detect the language of a text from its character n-grams."""
import csv
import math
import re
from collections import Counter

LANGS = ["id", "ms", "en", "nl"]

def char_ngrams(text, n_max=3):
    """Character n-grams (n = 1..n_max) of the lowercased words, with _ marking
    the word boundaries: 'Ke toko' -> _ke_toko_ -> _, k, e, _k, ke, e_, ..."""
    words = re.findall(r"[^\W\d_]+", text.lower())
    padded = "_" + "_".join(words) + "_"
    return [padded[i:i + n] for n in range(1, n_max + 1)
            for i in range(len(padded) - n + 1)]

def load_training(cap=1700):
    """The same amount of text, cap characters, for every language."""
    texts = {}
    with open("data/news.tsv", encoding="utf-8", newline="") as f:
        for row in csv.DictReader(f, delimiter="\t"):
            texts[row["lang"]] = texts.get(row["lang"], "") + row["text"] + " "
    for lang in ("ms", "nl"):
        with open(f"data/train_{lang}.txt", encoding="utf-8") as f:
            texts[lang] = f.read()
    return {lang: texts[lang][:cap] for lang in LANGS}

class RankProfile:
    """Cavnar and Trenkle (1994): compare the rank orders of frequent n-grams."""

    def __init__(self, size=300):
        self.size = size

    def profile(self, text):
        counts = Counter(char_ngrams(text))
        top = sorted(counts, key=lambda g: (-counts[g], g))[:self.size]
        return {g: r for r, g in enumerate(top)}

    def fit(self, texts):
        self.profiles = {lang: self.profile(t) for lang, t in texts.items()}
        return self
```

Listing 26.1 (Continued) *langid.py: character n-grams, the rank-profile detector, the naive Bayes detector, and the marker-word rule.*

```
    def distances(self, text):
        doc = self.profile(text)
        return {lang: sum(abs(r - p[g]) if g in p else self.size
                          for g, r in doc.items())
                for lang, p in self.profiles.items()}

    def predict(self, text):
        d = self.distances(text)
        return min(d, key=lambda lang: (d[lang], lang))

class NaiveBayesLID:
    """Naive Bayes over character n-grams with add-one smoothing."""

    def fit(self, texts):
        self.counts = {lang: Counter(char_ngrams(t)) for lang, t in texts.items()}
        vocab = set().union(*self.counts.values())
        self.v = len(vocab)
        self.total = {lang: sum(c.values()) for lang, c in self.counts.items()}
        return self

    def log_scores(self, text):
        grams = char_ngrams(text)
        return {lang: sum(math.log((self.counts[lang][g] + 1)
                                   / (self.total[lang] + self.v))
                          for g in grams)
                for lang in self.counts}

    def predict(self, text):
        s = self.log_scores(text)
        return max(s, key=lambda lang: (s[lang], lang))

    def margin(self, text):
        """Log-score gap between the best and the second-best language,
        per n-gram: small values mean the decision was close."""
        s = sorted(self.log_scores(text).values(), reverse=True)
        return (s[0] - s[1]) / max(len(char_ngrams(text)), 1)
```

Listing 26.1 (Continued) *langid.py: character n-grams, the rank-profile detector, the naive Bayes detector, and the marker-word rule.*

```
# Well-known spelling and vocabulary differences, Indonesian versus Malaysian.
MARKERS = {
    "id": set("""karena mau uang rusak toko sepatu dokter baru gratis pemerintah
                 apakah kantor akun nomor polisi bus taksi sebentar kirim silakan
                 saja bilang mobil rekening universitas sandi""".split()),
    "ms": set("""kerana mahu wang rosak kedai kasut doktor baharu percuma kerajaan
                 adakah pejabat akaun nombor polis bas teksi sekejap hantar sila
                 sahaja cakap budak laluan universiti hadapan""".split()),
}

class WithMarkers(NaiveBayesLID):
    """Naive Bayes, but when Indonesian and Malay are the two best guesses,
    let a list of marker words decide if it can."""

    def predict(self, text):
        s = self.log_scores(text)
        best = sorted(s, key=lambda lang: (-s[lang], lang))[:2]
        if set(best) == {"id", "ms"}:
            words = set(re.findall(r"[^\W\d_]+", text.lower()))
            n_id = len(words & MARKERS["id"])
            n_ms = len(words & MARKERS["ms"])
            if n_id != n_ms:
                return "id" if n_id > n_ms else "ms"
        return best[0]
```

- `char_ngrams` implements Section 26.3.1. `re.findall(r"[^\W\d_]+", ...)` keeps runs of letters only, so digits and punctuation disappear.
- `RankProfile.profile` sorts the n-grams by count, with ties broken alphabetically, keeps the top `size`, and maps each to its rank. `distances` is Equation (26.2); `predict` takes the smallest.
- `NaiveBayesLID.fit` counts n-grams per language and the size of the shared vocabulary; `log_scores` is the sum of Equation (26.3) with the probabilities of Equation (26.4); `margin` is Equation (26.5).

26.6 Running It

Listing 26.2 computes the accuracy and confusion counts of each detector on the test sentences, and then repeats the test giving the detectors only the first L characters of each sentence.

Listing 26.2 `evaluate.py`: accuracy, confusion counts, and accuracy against text length.

```
"""evaluate.py - accuracy of the detectors, and how it depends on length.

    python evaluate.py                     on data/test.tsv
    python evaluate.py data/test_new.tsv   on another test file
"""

   all          0.750          0.812          0.958
```

Look at the first two tables. Both detectors are perfect on English and Dutch: 24 of 24. All their mistakes are between Indonesian and Malay, in both directions. The rank-profile method calls 8 of the 12 Indonesian sentences Malay; naive Bayes does better, 7 of 12 right, but it is still barely better than a coin toss on this pair. Overall accuracy is 0.750 and 0.812.

Figure 26.1 shows why. The most frequent trigrams of Indonesian and Malay are nearly the same list: `an_`, `_me`, `_pe`, `ang`, `men`, `ng_`, `_be`. The two languages share their grammar, their affixes and most of their vocabulary; the differences lie in a few spellings (*kerana*, *wang*, *baharu*) and word choices (*kedai*, *kasut*, *percuma*), which may not occur in a short sentence at all. English (`_th`, `the`, `ing`) and Dutch (`en_`, `_de`, `een`) look nothing like them, or like each other.

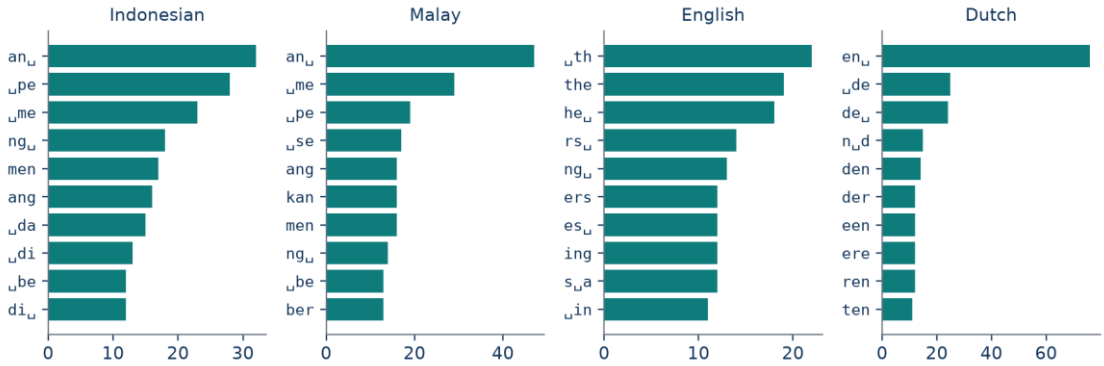

Figure 26.1 The ten most frequent character trigrams in the training text of each language; the open box marks a word boundary. Indonesian and Malay share almost the same list.

The bottom table of the output and **Figure 26.2** answer the question of length. With only 5 characters, about one short word, the detectors are right about two times in three; accuracy rises with length and levels off after about 40 characters. Short texts are hard for every detector, which is why a one-word message such as “ok” should not be trusted to any of them.

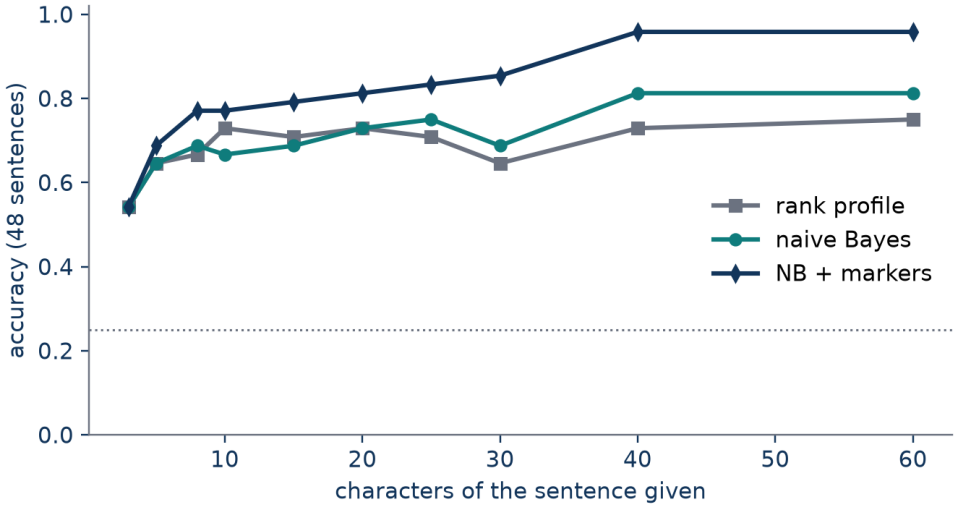

Figure 26.2 Accuracy of the three detectors on the 48 test sentences when only the first characters of each sentence are given. The dotted line is the accuracy of guessing among four languages.

26.7 Improving It

26.7.1 Marker words for close languages

Statistics over letters cannot separate Indonesian from Malay when the letters are the same. Linguistic knowledge can help. The dictionary `MARKERS` in **Listing 26.1** lists well-known pairs of differences: *karena* / *kerana*, *uang* / *wang*, *rusak* / *rosak*, *toko* / *kedai*, *sepatu* / *kasut*, *gratis* / *percuma*, *pemerintah* / *kerajaan*, *kantor* / *pejabat*, and so on. The class `WithMarkers` lets naive Bayes decide as before, but when its two best guesses are Indonesian and Malay, it counts the marker words of each language in the text; if one side has more, that side wins. This is a common pattern in practice: a statistical model does the bulk of the work, and a small, explainable rule handles a known weakness.

In the output of Section 26.6, the third detector reaches 0.958, and all 12 Malay sentences are now right. Only two Indonesian sentences remain wrong: “Anak-anak bermain bola di lapangan dekat rumah” and “Kereta api dari Surabaya ke Malang berangkat pukul tujuh”, neither of which contains a marker word.

26.7.2 An honest second test

That result should not be believed yet. The marker list was written by someone who had seen the test sentences, and several of those sentences contain marker words. To check, `data/test_new.tsv` has 16 new Indonesian and Malay sentences written only after the code was final, in everyday language:

```
python evaluate.py data/test_new.tsv
```

```
rank profile: accuracy 0.438 on 16 sentences
   true\pred   id   ms   en   nl
   id           3    5    0    0
   ms           4    4    0    0
naive Bayes: accuracy 0.500 on 16 sentences
   true\pred   id   ms   en   nl
   id           4    4    0    0
   ms           4    4    0    0
NB + markers: accuracy 0.500 on 16 sentences
   true\pred   id   ms   en   nl
   id           4    4    0    0
   ms           4    4    0    0

accuracy when only the first L characters are given
     L   rank profile    naive Bayes   NB + markers
     5          0.438          0.438          0.438
    10          0.375          0.438          0.438
    15          0.438          0.500          0.500
    20          0.625          0.438          0.438
    30          0.438          0.500          0.500
   all          0.438          0.500          0.500
```

The truth is sobering: all three detectors are at 0.44 to 0.50, the accuracy of tossing a coin between two languages. The new Malay sentences are full of words that are neither in the 1,700 characters of Malay training text nor in the marker list: *petang*, *perkhidmatan*, *menunggang*, *basikal*, *hujung*, *lorong*, *pinggan*, *Ahad*, *kapal terbang*, *cuti*. The marker rule never fires, and the letter statistics are too similar to help.

This is the most important lesson of the chapter. Telling closely related languages apart from short texts is a hard research problem in its own right; shared tasks on “discriminating between similar languages” have included exactly the Indonesian–Malay pair [3]. What it needs is not a

cleverer formula but **much more training text of the right kind**: thousands of sentences of informal Indonesian and Malay, so that words like *petang* and *basikal* are learned as Malay from data. The marker list can then grow from that data instead of from memory.

26.7.3 Knowing when not to answer

A detector that is unsure should say so. **Listing 26.3** prints, for each text, the score of every language relative to the best one, per n-gram, and answers "not sure" when the margin of Equation (26.5) is below 0.05.

Listing 26.3 `detect.py`: language scores for your own texts, with a "not sure" answer for close calls.

```
"""detect.py - print the most likely language of each argument."""
import sys

from langid import NaiveBayesLID, WithMarkers, char_ngrams, load_training

NAMES = {"id": "Indonesian", "ms": "Malay", "en": "English", "nl": "Dutch"}
texts = load_training()
nb, marked = NaiveBayesLID().fit(texts), WithMarkers().fit(texts)

for text in sys.argv[1:] or ["Cucian saya sudah selesai belum?",
                             "Kasut saya rosak, boleh dibaiki?",
                             "Waar is het station?", "ok"]:
    scores = nb.log_scores(text)
    n = len(char_ngrams(text))
    ranked = sorted(scores, key=lambda lang: -scores[lang])
    gaps = "  ".join(f"{lang} {(scores[lang] - scores[ranked[0]]) / n:+.2f}"
                     for lang in ranked)
    margin = nb.margin(text)
    verdict = NAMES[marked.predict(text)] if margin > 0.05 else "not sure"
    print(f"{text!r}\n   {gaps}   -> {verdict}")
```

```
python detect.py
```

```
'Cucian saya sudah selesai belum?'
   id +0.00  ms -0.06  en -0.41  nl -0.70   -> Indonesian
'Kasut saya rosak, boleh dibaiki?'
   ms +0.00  id -0.19  en -0.47  nl -0.72   -> Malay
'Waar is het station?'
   en +0.00  nl -0.07  ms -0.36  id -0.43   -> English
'ok'
   ms +0.00  en -0.01  nl -0.02  id -0.11   -> not sure
```

The first two examples are decided correctly, Indonesian by a margin of 0.06 over Malay and Malay by 0.19 over Indonesian (*kasut* and *rosak* help). "ok" is too short for any decision, and the program says so. "Waar is het station?" is Dutch but is called English by a small margin, 0.07: *is* and *station* are English words too, and four words are not enough to overcome them. A higher threshold would have caught it, at the price of saying "not sure" more often; Exercise 26.5 measures that trade-off.

26.7.4 Inside one decision

It is worth looking once at the numbers behind a single answer. "Kasut saya rosak" is lowercased and padded to `_kasut_saya_rosak_`, which by Equation (26.1) gives $18 + 17 + 16 = 51$ n-grams. Summing the smoothed log-probabilities of Equation (26.3) gives about -312.3 for Malay, -321.7 for Indonesian, -327.5 for English and -360.0 for Dutch. Malay wins by 9.4 in log-score, and the margin of Equation (26.5) is \$9.4 / 51 pprox 0.18\$ per n-gram, which is why `detect.py` printed

−0.19 for Indonesian in the second example (the small difference is only the rounding of the displayed numbers).

Where do those 9.4 points come from? Not from any single n-gram. The trigram `ros` does not occur in the Malay or the Indonesian training text at all; `_ka` occurs twice in Malay and once in Indonesian. Most of the 51 n-grams, such as `_sa`, `saya` pieces and `ya_`, are common in both languages and nearly cancel. The decision is the sum of many small differences, each worth a fraction of a point, which is both the strength of naive Bayes (no single rule needs to be right) and its weakness for Indonesian and Malay (when the small differences are absent, nothing is left).

The model is also small and fast. The four languages together store 4,031 (n-gram, language) counts, a few tens of kilobytes, and classifying one test sentence takes about a tenth of a millisecond on the machine used for this book. That is why language detection can run on every message a business receives, and why production systems can afford to run it on every sentence rather than on whole documents.

26.8 Testing

Listing 26.4 checks the n-grams of “Ke toko” against Equation (26.1), that the training texts have equal length, that both detectors get clear English and Dutch sentences right, and that the marker rule decides a sentence that differs only in *karena* / *kerana*.

Listing 26.4 `tests/test_langid.py`: tests for n-grams, balanced training, clear cases and marker words.

```
"""Run with:  python -m pytest -q"""
import os
import sys

HERE = os.path.dirname(os.path.dirname(os.path.abspath(__file__)))
sys.path.insert(0, HERE)
os.chdir(HERE)
from langid import (NaiveBayesLID, RankProfile, WithMarkers,  # noqa: E402
                    char_ngrams, load_training)

def test_char_ngrams_by_hand():
    grams = char_ngrams("Ke toko", 2)
    assert grams[:3] == ["_", "k", "e"]
    assert "_t" in grams and "o_" in grams and len(grams) == 9 + 8

def test_training_is_balanced():
    texts = load_training(cap=1000)
    assert {len(t) for t in texts.values()} == {1000}

def test_clear_cases():
    texts = load_training()
    for model in (RankProfile().fit(texts), NaiveBayesLID().fit(texts)):
        assert model.predict("The weather is very nice today") == "en"
        assert model.predict("Het weer is vandaag erg mooi") == "nl"

    m = WithMarkers().fit(load_training())
    assert m.predict("Saya tidak datang kerana hujan") == "ms"
    assert m.predict("Saya tidak datang karena hujan") == "id"
```

```
python -m pytest -q
```

```
....                                                                     [100%]
4 passed in 0.04s
```

26.9 Detectors in the Real World

Production detectors work on the same principles at a much larger scale. The fastText project published a language identification model trained on Wikipedia and other sources that recognizes 176 languages from character n-gram features [4], and GlotLID, built for low-resource languages, covered more than 1,600 languages in its 2023 paper, with more than 2,000 labels in its current release [5]. A survey of the field lists the same recurring difficulties this chapter met: short texts, closely related languages, and texts that mix languages [6]. Mixing is common in Indonesia, where a single message can say “Kak, laundry-nya sudah done belum?”; a detector that must give one answer per message will be wrong about part of such a text whatever it says, and a system that routes messages should work sentence by sentence or word by word when it matters.

26.10 Language Detection at Profitina Laundry

How would Profitina Laundry use this chapter? Three places in its software benefit, each with a different tolerance for mistakes.

Choosing the reply language. The FAQ bot of Chapter 29 answers in Indonesian or English. Here the cost of a mistake is small, since the customer can always ask again, and a strong clue is available that no detector uses: the language of the customer’s earlier messages. A good rule combines both: detect the language of each new message, but switch away from the customer’s usual language only when the margin of Equation (26.5) is large.

Guarding the spell checker. The corrector of Chapter 22 must not turn *done* into an Indonesian word. Running the detector on each word would be unreliable, because single words are the shortest texts of all, as **Figure 26.2** warns. A better guard is a list of English words commonly mixed into Indonesian messages (*laundry*, *pickup*, *express*, *done*, *thanks*), which the corrector accepts as they are.

Counting customers by language. For a monthly report, individual mistakes matter less than the totals. Averaging over hundreds of messages washes out random errors, but not systematic ones: if Malay messages are regularly called Indonesian, the report will undercount Malaysian customers. That is why the per-language confusion counts of **Listing 26.2** matter more for this use than the overall accuracy.

In all three cases the program suggests and a person can override: a staff member who sees a reply in the wrong language simply switches it, and that correction is a labeled example for the next version of the detector.

26.11 Common Mistakes, and How to Avoid Them

Unequal training data. A language with twice as much training text gets more accurate counts and, in rank methods, a different profile. *Avoid it:* use the same amount of text per language, as `load_training` does, or correct for the difference.

Forgetting smoothing. One unseen n-gram gives a language probability zero. *Avoid it:* use Equation (26.4).

Trusting short texts. Below about ten characters, every detector guesses. *Avoid it:* report "not sure" using the margin of Equation (26.5), or use context such as the language of the customer's previous messages.

Training on a different register. News-style training text does not prepare a detector for chat. *Avoid it:* train on text like the text you will classify.

Evaluating on sentences you designed the rules with. Marker words chosen while looking at the test set will score perfectly on it. *Avoid it:* keep a test set written afterward, as `data/test_new.tsv` was, and report both results.

Assuming one language per message. Code-mixed messages are normal in Indonesia. *Avoid it:* detect per sentence or per word when the application needs it.

26.12 Chapter Summary

- A text is cut into **character n-grams** with word-boundary marks (Equation (26.1)); even short texts provide many of them (**Listing 26.1**).
- The **rank-profile** detector compares the rank orders of the 300 most frequent n-grams with the out-of-place distance (Equation (26.2)). The **naive Bayes** detector sums smoothed log-probabilities of n-grams (Equation (26.3), Equation (26.4)).
- On 48 test sentences, both are perfect on English and Dutch and weak on Indonesian versus Malay, whose n-gram statistics are almost identical (**Listing 26.2**, **Figure 26.1**). Accuracy grows with text length (**Figure 26.2**).
- A small list of **marker words** fixes many Indonesian–Malay errors on the original test set, but a second, honest test shows that without more and better-matched training text, the pair remains close to a coin toss.
- The **margin** (Equation (26.5)) tells when a decision is close; answering "not sure" is better than a confident mistake (**Listing 26.3**).

26.13 Exercises

Exercise 26.1. List all unigrams, bigrams and trigrams of "Di pasar" after padding, and check the counts against Equation (26.1).

Exercise 26.2. With $K = 300$, a document profile of 40 n-grams, 30 of which occur in a language's profile with an average absolute rank difference of 50, has what out-of-place distance by Equation (26.2)? What is the largest possible distance for this document?

Exercise 26.3. The Indonesian training text contains 4,995 n-grams and the shared vocabulary has 2,313 n-grams. By Equation (26.4), what is the probability of an n-gram never seen in Indonesian? And of one seen 20 times?

Exercise 26.4. Explain what would happen to the Indonesian–Malay decisions if Indonesian were given 5,000 characters of training text and Malay only 1,700, for each of the two detectors.

Exercise 26.5. Write a program that computes, for the naive Bayes detector on `data/test.tsv`, how many sentences are answered and how accurate those answers are, for margin thresholds 0, 0.05, 0.10, 0.15 and 0.20.

Exercise 26.6. A customer writes "Kak, laundry-nya sudah done belum?". What would you want a detector to answer, and how would you change the program to provide it?

26.14 Solutions to the Exercises

Solution 26.1. Lowercased and padded: `_di_pasar_`, with $L = 10$. Unigrams (10): `_ d i _ p a s a r _`. Bigrams (9): `_d di i_ _p pa as sa ar r_`. Trigrams (8): `_di di_ i_p _pa pas asa sar ar_`. The counts 10,9,8 are $L - n + 1$ for $n = 1,2,3$, as Equation (26.1) says, 27 n-grams in all.

Solution 26.2. The 30 shared n-grams contribute $30 \times 50 = 1500$; the 10 missing ones contribute $10 \times 300 = 3000$; the distance is 4500. The largest possible distance, when none of the 40 n-grams is in the language's profile, is $40 \times 300 = 12000$.

Solution 26.3. The denominator is $4995 + 2313 = 7308$. An unseen n-gram gets $1/7308 \approx 1.37 \times 10^{-4}$; one seen 20 times gets $21/7308 \approx 2.87 \times 10^{-3}$, about 21 times more.

Solution 26.4. For **naive Bayes**, a larger Indonesian sample would contain more of the words and n-grams that occur in informal sentences, so fewer n-grams of a test sentence would be "unseen" for Indonesian; the Malay model, with less text, would more often pay the smoothing penalty. Ambiguous sentences would therefore drift toward Indonesian, raising Indonesian recall and lowering Malay recall. For the **rank profile**, the top 300 n-grams of a larger sample are estimated more reliably, but the profile size is fixed, so the effect is weaker; the ranks of rare n-grams change more than those of common ones. In both cases the lesson is to balance the training data, or to evaluate per language so that the bias is visible.

Solution 26.5. **Listing 26.5** keeps only the answers whose margin exceeds each threshold.

Listing 26.5 `solutions/margin_curve.py`: accuracy of the answers that pass a margin threshold.

```
"""margin_curve.py - Exercise 26.5: accuracy of the confident answers only."""
import csv
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from langid import NaiveBayesLID, load_training  # noqa: E402

with open("data/test.tsv", encoding="utf-8", newline="") as f:
    tests = [(r["lang"], r["text"]) for r in csv.DictReader(f, delimiter="\t")]
model = NaiveBayesLID().fit(load_training())
results = [(model.margin(t), model.predict(t) == lang) for lang, t in tests]

print(f"{'threshold':>9}{'answered':>10}{'accuracy':>10}")
for threshold in (0.0, 0.05, 0.10, 0.15, 0.20):
    kept = [ok for m, ok in results if m > threshold]
    acc = sum(kept) / len(kept) if kept else 0.0
    print(f"{threshold:>9.2f}{len(kept):>10}{acc:>10.3f}")
```

```
python solutions/margin_curve.py
```

```
threshold  answered  accuracy
     0.00        48     0.812
     0.05        35     0.857
     0.10        28     0.964
     0.15        22     0.955
     0.20        18     1.000
```

Raising the threshold from 0 to 0.10 reduces the answered sentences from 48 to 28 but raises their accuracy from 0.812 to 0.964; at 0.20, the 18 answers are all correct. The sentences left unanswered are mostly the Indonesian and Malay ones. Which threshold is right depends on the cost of a mistake compared with the cost of asking: for routing a message, "not sure" can simply mean "use the customer's usual language".

Solution 26.6. The honest answer is “Indonesian, with English words mixed in”. A single-label detector cannot say that. One change is to detect the language of each word (or of each window of three or four words) with the same n-gram model, and report the share of each language, here mostly Indonesian with *laundry* and *done* in English. For routing, the majority language decides the reply; for spelling correction, each word is checked in its own language, so that *done* is not “corrected” into *dune* or *dene*.

Chapter 27

Smart-Reply Suggestions for Business Chats

A customer writes “kak bed cover saya udah jadi belum?” and, above the keyboard, three buttons appear: *Sudah selesai kak, bisa diambil ya*, *Masih proses setrika kak, sore ini selesai*, *Baik kak, kami cek dulu ya*. The cashier taps one and moves on to the next chat. This chapter builds that feature for small shops that sell through chat. By the end of it you will be able to write a corpus of shop–customer chats in Indonesian and English; turn a shop’s past replies into a list of candidate replies; score every candidate for a new message with an n-gram model and Bayes’ rule; personalize the ranking so that each shop hears its own voice; measure the result with hit@k on messages the model never saw; and improve it by letting replies with the same meaning share what they have learned.

27.1 Who Uses Smart Replies Today

Indonesia sells through chat. A laundry, a home bakery, a phone-repair stall and a catering kitchen all take orders, quote prices and answer “is it ready yet?” in WhatsApp, and most of those questions are the same ten questions asked a thousand ways. Meta reported in July 2025 that the WhatsApp Business app has more than 200 million monthly users [1], and in April 2026 that more than 10 million conversations a week were already being handled by business AIs on WhatsApp and Messenger, up from one million at the start of the year, with the rollout reaching small and medium businesses in Indonesia [2]. Behind every one of those numbers sits a person who types “Siap kak, ditunggu ya” many times a day.

Suggested replies are the gentlest form of that automation. The program does not answer on its own; it proposes, and the person decides with one tap. Google introduced the idea for e-mail as *Smart Reply* in 2016, and within months it was used for 10% of all replies written on mobile in its Inbox app [3]. The later production system became faster and smaller, but kept the same shape: a fixed list of good replies, a model that scores each of them for the incoming message, and a rule that picks three to show [4].

For a small shop the benefit is easy to count. The replies in the corpus of this chapter are 37 characters long on average; a cashier who answers 150 chats a day and taps a suggestion for most of them saves several thousand keystrokes a day, and, more importantly, answers faster, in a consistent tone, with the right price and the right opening hours. This chapter builds such a suggester for four shops, measures how often the right reply is among its three suggestions, and ends with how to run it on a shop’s own chat history. Chapter 29 will answer questions from an FAQ; here we only suggest, which is safer and needs far less data.

27.2 The Idea in Plain Words

Think of a new assistant at Profitina Laundry in Rungkut. On the first day she knows nothing. After a week at the counter she has noticed that when customers write *harga*, *brp* or *berapa*, the owner answers “Cuci kiloan Rp8.000/kg kak, …”; when they write *udah jadi* or *bisa diambil*, he

answers “Sudah selesai kak, …” or “Masih proses setrika kak, …”. She does not understand the messages in any deep sense. She remembers which words came before which reply, and she knows which replies this shop sends most often. That is the whole model.

Figure 27.1 shows it as a machine. The owner’s past replies form a **whitelist**: only replies that were really sent, at least twice, may ever be suggested, so the program can never write something embarrassing. For a new message, the program gives every whitelisted reply a score with two parts. The first asks: *if this were the reply, how likely is a message like this one?* It is computed by a small n-gram language model trained only on the messages that received that reply. The second asks: *how often does this shop send this reply at all?* The three replies with the highest total are shown.

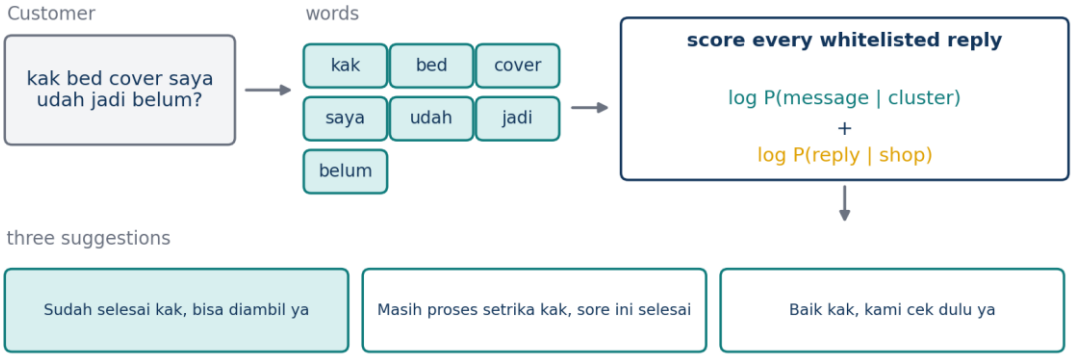

Figure 27.1 How a message becomes three suggestions: the message is split into words, every whitelisted reply of the shop is scored by how well it explains the message and how often the shop sends it, and the best three are shown.

Two refinements turn this into something a real shop can use. **Personalization**: a bakery and a laundry both get “berapa harganya?”, but they answer differently, so each shop’s own habits must weigh more than everybody’s. **Sharing**: a small catering business has only a few hundred chats, too few to learn every way of asking about prices; but the laundry and the bakery have seen hundreds of such messages. If we notice that “Nasi box mulai Rp20.000 bu” and “Cuci kiloan Rp8.000/kg kak” are answers to the same kind of message, the small shop can borrow the big shop’s knowledge of *messages* while keeping its own *replies*.

27.3 The Mathematics, Gently

27.3.1 Choosing a reply with Bayes’ rule

Write the incoming message as m, the shop as s and a candidate reply as r. We want the reply that is most probable given the message and the shop, $P(r \mid m, s)$. Bayes’ rule, which Chapter 15 used for sentiment, turns this around: the probability of the reply given the message is proportional to the probability of the message given the reply, times the probability of the reply before we read anything. Assuming that the words of a message depend on the reply and not on which shop received it,

$$\hat{r} = \operatorname*{argmax}_r P(r \mid m, s) = \operatorname*{argmax}_r \; P(m \mid r)\, P(r \mid s) \tag{27.1}$$

The symbol argmax_r means “the r that makes the expression largest”. The denominator of Bayes’ rule, $P(m \mid s)$, is the same for every candidate, so it can be dropped when we only compare

candidates. Probabilities of whole messages are tiny numbers, so the program adds logarithms instead of multiplying probabilities; because the logarithm grows whenever its argument grows, the best reply is the same.

27.3.2 The message as a chain of words

Write the message as words $w_1, w_2, \ldots, w_T$, and put a start symbol $w_0 = <s>$ in front. The chain rule of probability writes $P(m \mid r)$ exactly as a product of one-word predictions, each given all words before it. An **n-gram model** keeps only the last $n-1$ words of that history; with $n = 2$, a **bigram model**,

$$P(m \mid r) \approx \prod_{i=1}^{T} P\left(w_i \mid w_{i-1}, r\right) \tag{27.2}$$

This is the **Markov assumption**: each word is predicted from the one before it and from the reply. With $n = 1$, a **unigram model**, the order of the words is ignored and each word is predicted from the reply alone. Chapter 26 used exactly this construction with characters to tell languages apart; here the "classes" are replies and the pieces are words.

27.3.3 Estimating by counting, with interpolation

Let $c_r(v, w)$ be the number of times word w followed word v in the training messages that got reply r, $c_r(v)$ the number of times v was followed by anything there, $c_r(w)$ the number of times w occurred there, and N_r the total number of words in those messages. The counts give a bigram estimate $c_r(v,w)/c_r(v)$ and a unigram estimate $c_r(w)/N_r$. Neither is safe alone. A bigram that never occurred gets probability zero, and by Equation (27.2) one zero wipes out the whole message; a unigram ignores that *udah jadi* (already done) and *jadi berapa* (so how much) mean different things. **Linear interpolation** mixes three estimates [5], [6]:

$$P(w \mid v, r) = \lambda_2 \frac{c_r(v,w)}{c_r(v)} + \lambda_1 \frac{c_r(w)}{N_r} + \lambda_0 P_{\text{bg}}(w), \qquad \lambda_0 + \lambda_1 + \lambda_2 = 1 \tag{27.3}$$

The last term is a **background** model of all messages of all shops, with add-one smoothing so that even a word never seen anywhere keeps a small probability:

$$P_{\text{bg}}(w) = \frac{c(w) + 1}{N + |V| + 1} \tag{27.4}$$

Here $c(w)$ counts w over all training messages, N is the total number of words in them and $|V|$ the number of different words; the extra $+1$ reserves one slot for all unknown words together. When the previous word v never occurred in the messages of reply r, the bigram fraction is undefined, and its weight λ_2 moves to the unigram term, so the probabilities still add up to one. The weights λ are not learned by counting; they are chosen by trying a few settings on **development data**, a part of the data set aside for tuning, and never on the test data.

Table 27.1 works one example with the real counts of our training data and the weights $\lambda = (0.1, 0.7, 0.2)$ for $(\lambda_2, \lambda_1, \lambda_0)$. The message is "udah jadi belum" (done yet?), and two replies of the laundry compete: the status reply "Sudah selesai kak, bisa diambil ya", sent 44 times, and the price reply "Cuci kiloan Rp8.000/kg kak, …", sent 92 times.

Table 27.1 The bigram probabilities of Equation (27.3) for the message "udah jadi belum" under two laundry replies, with the real training counts.

Pair (v,w)	Status: $c_r(v,w)/c_r(v)$	Status: P	Price: $c_r(v,w)/c_r(v)$	Price: P
(<s>, udah)	6/44	0.0634	0/92	0.00167
(udah, jadi)	7/18	0.0648	unseen context	0.0206
(jadi, belum)	9/9	0.1473	0/10	0.0019
$\log P(m \mid r)$		−7.41		−16.54

Check the first row by hand. For the status reply, <s> was followed 44 times by some word, 6 times by *udah*; *udah* occurs 18 times among 262 words of those messages; and the background gives it 0.00835. So $P = 0.1 \cdot 6/44 + 0.7 \cdot 18/262 + 0.2 \cdot 0.00835 = 0.0136 + 0.0481 + 0.0017 = 0.0634$. The most telling row is the last one. The word *jadi* did occur in messages that got the price reply, ten times, in "kalau 5 kemeja jadi berapa" (then how much for 5 shirts); but there it was never followed by *belum*. The bigram term notices this and gives the price reply almost nothing, while a unigram model would only see that *jadi* is common in both.

27.3.4 The shop's own habits

The second factor of Equation (27.1), $P(r \mid s)$, is the **prior**: how often shop s sends reply r, before reading the message. Let $c_s(r)$ be the number of times shop s sent r, n_s the number of replies the shop sent in total, $c(r)$ and n the same over all shops, and $|R|$ the number of whitelisted replies. The prior mixes the shop's own habits with everybody's:

$$P(r \mid s) = \gamma \, \frac{c_s(r) + 0.1}{n_s + 0.1\,|R|} + (1 - \gamma)\, \frac{c(r)}{n} \tag{27.5}$$

With $\gamma = 0$ every shop gets the same, global prior; with $\gamma = 1$ each shop uses only its own counts, with a pseudo-count of 0.1 so that no reply has probability exactly zero. The **personalization weight** γ is chosen on development data, like the λs. In the example of **Table 27.1**, the laundry sent 864 replies in the training data, so with $\gamma = 1$ the status reply gets $\ln((44 + 0.1)/(864 + 10.4)) = -2.99$ and the price reply -2.25. The price reply is more common, but the totals are $-7.41 - 2.99 = -10.40$ against $-16.54 - 2.25 = -18.79$: the message outweighs the habit by a factor of $e^{8.4} \approx 4{,}400$.

27.3.5 Measuring with hit@k

A suggester shows k replies, usually three. It has done its job if the reply the person really sent is among them. For a test set of $|T|$ messages m_j from shops s_j with real replies r_j, the **hit rate at** k is

$$\text{hit@}k = \frac{1}{|T|} \sum_{j=1}^{|T|} \mathbb{1}\left[\, r_j \in \text{top}_k(m_j, s_j) \,\right] \tag{27.6}$$

where $\mathbb{1}[\cdot]$ is 1 when the condition holds and 0 otherwise. Hit@1 asks whether the first suggestion was right; hit@3 whether any of the three buttons was. The measure is strict: if the owner wrote a slightly different sentence from any whitelisted reply, it counts as a miss even when a suggestion would have done the job. Real products therefore also measure how often people *tap* a suggestion; Exercise 27.4 adds a gentler offline measure, the mean reciprocal rank.

27.3.6 Replies that mean the same thing

To let shops share, we need to know which replies answer the same kind of message. Describe each reply r by the word counts $a_r(w) = c_r(w)$ of its messages, and compare two replies with the **cosine similarity** of these count vectors [7]:

$$\cos(a, b) = \frac{\sum_w a\,(w)\, b(w)}{\sqrt{\sum_w a\,(w)^2}\,\sqrt{\sum_w b\,(w)^2}} \tag{27.7}$$

It is 1 when the two replies received messages with exactly the same word proportions and 0 when they share no word at all. Replies whose similarity reaches a threshold θ are put in one **cluster**. Then $P(m \mid r)$ in Equation (27.1) is replaced by $P(m \mid \text{cluster of } r)$, estimated from the pooled messages of every reply in the cluster, from every shop; the prior $P(r \mid s)$ still decides which reply of the cluster this particular shop would send. The Smart Reply system does the same with semantic clusters of replies, for the same reason: the data of many replies together teaches the model far more than each reply alone [3].

27.4 Building It Step by Step

The code of this chapter uses only the Python standard library. It lives in `Chapter027/`: `data/shops.json` (the templates we wrote), `make_corpus.py`, `smartreply.py` (the model), `clusters.py` (the improvement of Section 27.7), `suggest.py` (the application), `evaluate.py`, the tests and the solutions.

27.4.1 Writing the corpus

Real shops will not hand us their customers' chats, and they should not, as Section 27.9 explains. So we write our own. `data/shops.json` holds, for each of four shops, the ways customers ask about ten kinds of things (opening hours, prices, "is it ready?", pick-up and delivery, payment, location, ordering, cancelling, thanks and complaints), in Indonesian and English, with slots for items, days, times and quantities, and the replies that shop really gives, each with a weight for how often. A few lines of it:

```
"price": ["{hi}{hon} {item} berapa harganya?", "harga {item} berapa {hon}",
          "{hon} brp ya untuk {item}", "{hi}mau tanya harga {item} {hon}",
          "kalau {qty} {item} jadi berapa {hon}?", ...
"price": [["Cuci kiloan Rp8.000/kg kak, daftar harga lengkap kami kirim ya", 4],
          ["Bed cover mulai Rp35.000 kak", 1]],
```

Listing 27.1 expands the templates into 3,200 message–reply pairs. Two details make the chats realistic. `chatty` rewrites words the way customers type them (*udah*, *brp*, *gak*, *yg*) and sometimes drops the question mark. And one reply in ten is a "let me check" reply, such as "Baik kak, kami cek dulu ya", whatever the question: shop owners really do answer that way when they are busy, and no model can predict it from the message.

Listing 27.1 `make_corpus.py`: expanding the chat templates into a corpus of message–reply pairs.

```
"""make_corpus.py - expand the chat templates of data/shops.json into chats.tsv."""
import csv
import json
import random
import re

SHORT = {"sudah": ["udah", "sdh"], "berapa": ["brp"], "bisa": ["bs"],
         "tidak": ["gak", "ga"], "terima kasih": ["trims", "makasih"],
         "yang": ["yg"], "saya": ["aku", "sy"], "mau": ["mo"]}

def pick(rng, weighted):
    """weighted is a list of [text, weight] pairs."""
    return rng.choices([t for t, _ in weighted], [w for _, w in weighted])[0]

def chatty(rng, text):
    """Informal spelling, as customers really type: short forms, no '?'."""
    for long, shorts in SHORT.items():
        if long in text and rng.random() < 0.3:
            text = text.replace(long, rng.choice(shorts))
    if rng.random() < 0.3:
        text = text.replace("?", "")
    return re.sub(r"\s+", " ", text).strip()

def fill(rng, template, slots, items):
    values = {k: rng.choice(v) for k, v in slots.items()}
    values["item"] = rng.choice(items)
    return template.format(**values)

def main(seed=27):
    spec = json.load(open("data/shops.json", encoding="utf-8"))
    rng = random.Random(seed)
    intents = list(spec["intent_weights"])
    weights = list(spec["intent_weights"].values())
    rows = []
    for shop, s in spec["shops"].items():
        for _ in range(s["pairs"]):
            lang = "en" if rng.random() < s["en_share"] else "id"
            intent = rng.choices(intents, weights)[0]
            if intent == "complaint":
                template = rng.choice(s["complaint"][lang])
            else:
                template = rng.choice(spec["messages"][lang][intent])
```

Listing 27.1 (Continued) *make_corpus.py: expanding the chat templates into a corpus of message–reply pairs.*

```
            message = chatty(rng, fill(rng, template, spec["slots"],
                                       s["items"][lang]))
            if rng.random() < spec["hold_share"]:
                reply = pick(rng, s["hold"][lang])     # "let me check" replies
            else:
                reply = pick(rng, s["replies"][lang][intent])
            rows.append([shop, lang, message, reply])
    rng.shuffle(rows)                                  # interleave the shops
    with open("data/chats.tsv", "w", encoding="utf-8", newline="") as f:
        out = csv.writer(f, delimiter="\t", lineterminator="\n")
        out.writerow(["id", "shop", "lang", "message", "reply"])
        for i, row in enumerate(rows, 1):
            out.writerow([i] + row)
    print(f"wrote data/chats.tsv: {len(rows)} message-reply pairs")

if __name__ == "__main__":
    main()
```

```
python make_corpus.py
```

```
wrote data/chats.tsv: 3200 message-reply pairs
```

Table 27.2 summarizes the result. The shops differ in size on purpose: the laundry has more than twice as many chats as the catering kitchen, which lets Section 27.7 ask what a small shop gains from a large one.

Table 27.2 The four shops of the corpus: message–reply pairs, how many are in English, how many different replies each shop sends, and its most frequent reply.

Shop	Pairs	In English	Different replies	Most frequent reply
laundry	1,200	323	33	Cuci kiloan Rp8.000/kg kak, … (124)
bakery	800	177	27	Sama-sama kak, selamat menikmati (80)
phone	700	105	25	Boleh info tipe hp-nya kak? (69)
catering	500	50	23	Nasi box mulai Rp20.000 bu, … (71)

The 3,200 pairs contain 2,119 different customer messages, 5.2 words long on average.

27.4.2 The model

Listing 27.2 is the whole suggester.

        for k in ks:
            hits[k] += row["reply"] in top[:k]
    return {k: hits[k] / len(rows) for k in ks}
```

- `tokens` lowercases and keeps runs of letters and digits, so “BRP harganya?!” becomes `brp`, `harganya`. `split` shuffles once with a fixed seed and cuts 70% for training, 15% for development and 15% for testing.
- `fit` walks through every training pair and fills five tables of counts: `bi`, `ctx` and `uni` per reply for Equation (27.3), `bg` for Equation (27.4), and `count` and `shop_count` for Equation (27.5). The whitelist `replies` keeps replies sent at least `min_count` times.
- `prob` is Equation (27.3), including the rule that an unseen context hands its weight to the unigram term. `prior` is Equation (27.5). `logp_message` sums the log-probabilities of Equation (27.2), and `score` adds the log prior, as Equation (27.1) prescribes; with `use_words=False` only the prior is left, which gives the “most frequent replies” baseline.
- `rank` scores every whitelisted reply that starts with `prefix` and returns the best `k`, breaking ties alphabetically so that the result never depends on dictionary order. `hit_at_k` is Equation (27.6).

27.4.3 The application

Listing 27.3 is the program a shop would call. It trains on all 3,200 pairs, because once the settings have been chosen, every pair we have should help, and it prints the suggestions for one message. With `--explain` it also prints the two parts of each score.

Listing 27.3 `suggest.py`: the suggestion app, with an optional explanation of every score.

```
"""suggest.py - reply suggestions for one customer message."""
import argparse
import math

from clusters import ClusteredModel
from smartreply import load, tokens

SHOPS = ["laundry", "bakery", "phone", "catering"]

def main():
    ap = argparse.ArgumentParser(description=__doc__)
    ap.add_argument("message", help="the customer's message")
    ap.add_argument("--shop", default="laundry", choices=SHOPS)
    ap.add_argument("--prefix", default="", help="what the seller has typed")
    ap.add_argument("-k", type=int, default=3, help="number of suggestions")
    ap.add_argument("--explain", action="store_true", help="show the scores")
    args = ap.parse_args()
    # the settings chosen on development data by evaluate.py; for use, the
    # model learns from every pair we have
    model = ClusteredModel((0.1, 0.7, 0.2), gamma=1.0, theta=0.7).fit(load())
    words = tokens(args.message)
    top = model.rank(args.message, args.shop, args.k, args.prefix)
    for i, r in enumerate(top, 1):
        print(f"[{i}] {r}")
        if args.explain:
            lm = model.logp_message(words, r)
            lp = math.log(model.prior(r, args.shop))
            print(f"    log P(m|cluster {model.cluster[r]}) = {lm:7.2f}"
                  f"   log P(r|shop) = {lp:6.2f}   total = {lm + lp:7.2f}")
    if not top:
        print("(no suggestion starts with that prefix)")

if __name__ == "__main__":
    main()
```

It uses `ClusteredModel`, the improved model of Section 27.7, with the settings that `evaluate.py` chose on the development data. Training takes less than a tenth of a second, so the program simply trains every time it starts; a server would train once and keep the model in memory.

27.4.4 Tests

Listing 27.4 checks the pieces on a six-pair toy corpus where every number can be verified by hand: a bigram probability, that the probabilities of Equation (27.3) add up to one for a seen and an unseen context, that the shop prior prefers the shop's own replies, and that two replies answering the same messages land in one cluster.

Listing 27.4 `tests/test_smartreply.py`: unit tests for the tokenizer, the probabilities, the prior, hit@k and the clusters.

```
"""Run with:  python -m unittest discover -s tests"""
import math

```

27.5 Running It

The laundry receives the message of the chapter's opening:

```
python suggest.py "kak bed cover saya udah jadi belum?" --explain
```

```
[1] Sudah selesai kak, bisa diambil ya
    log P(m|cluster 4) =  -20.33   log P(r|shop) =  -3.00   total =  -23.33
[2] Masih proses setrika kak, sore ini selesai
    log P(m|cluster 4) =  -20.33   log P(r|shop) =  -3.49   total =  -23.82
[3] Baik kak, kami cek dulu ya
    log P(m|cluster 1) =  -25.24   log P(r|shop) =  -2.55   total =  -27.79
```

The two status replies share one cluster, so their message scores are identical, -20.33; the prior decides their order, and "Sudah selesai" is sent more often than "Masih proses setrika". The third suggestion, "Baik kak, kami cek dulu ya", explains the message worse (-25.24) but is the laundry's most frequent reply of all, which is exactly what a sensible third button should be. The same message sent to the bakery gets the bakery's own words:

```
python suggest.py "kak bed cover saya udah jadi belum?" --shop bakery
```

```
[1] Sudah jadi kak, siap diambil
[2] Masih dipanggang kak, satu jam lagi
[3] Sebentar ya kak, saya cek
```

A bakery does not wash bed covers, but the question is still a status question, and the answers are the bakery's status answers. A phone-repair stall asked about a price with a model name the program has never seen:

```
python suggest.py "min brp harga ganti lcd samsung a14" --shop phone
```

```
[1] Tergantung tipe hp kak, boleh info tipenya?
[2] Ganti LCD mulai Rp350.000 kak
[3] Boleh info tipe hp-nya kak?
```

The words *samsung* and *a14* are unknown, and the background term of Equation (27.4) gives them the same tiny probability under every reply, so they do not disturb the ranking; *brp*, *harga*, *ganti* and *lcd* do the work. All three suggestions are sensible, and the first and third ask for the phone type, which is what the owner needs to know before quoting. An English message to the catering kitchen:

```
python suggest.py "is my order ready?" --shop catering
```

```
[1] Your order is being cooked and will arrive on time
[2] For which date?
[3] Still being ironed, ready this afternoon
```

The first two suggestions are right, but the third, "Still being ironed, ready this afternoon", belongs to the laundry. The catering kitchen has only 50 English chats, fewer than ten of them about status, so when its own English replies run out, a reply of another shop in the same cluster fills the third place: with the pseudo-count of Equation (27.5), other shops' replies are improbable but not impossible. Exercise 27.6 discusses why a real product would forbid this.

27.6 Measuring It

Listing 27.5 compares six suggesters on the 480 test pairs. For each one, it first chooses the settings (λ, γ and later θ) that give the best hit@3, with hit@1 as the tie-breaker, on the 480 development pairs; only then does it look at the test pairs, once.

Listing 27.5 `evaluate.py`: choosing every setting on the development data, then measuring hit@1 and hit@3 on the test data.

```
"""evaluate.py - hit@1 and hit@3 of every model; settings chosen on dev data."""
import time

from clusters import ClusteredModel
from smartreply import ReplyModel, hit_at_k, load, split

UNIGRAM = [(0.0, 0.9, 0.1), (0.0, 0.8, 0.2), (0.0, 0.6, 0.4)]
BIGRAM = [(0.1, 0.7, 0.2), (0.2, 0.6, 0.2), (0.3, 0.5, 0.2), (0.5, 0.3, 0.2)]
GAMMAS = [0.0, 0.5, 0.9, 1.0]
THETAS = [0.6, 0.7, 0.8, 0.9]

def tune(make, grid, dev, train):

```

The run takes about 16 seconds, almost all of it the tuning. **Figure 27.2** draws the first table. Read it from left to right.

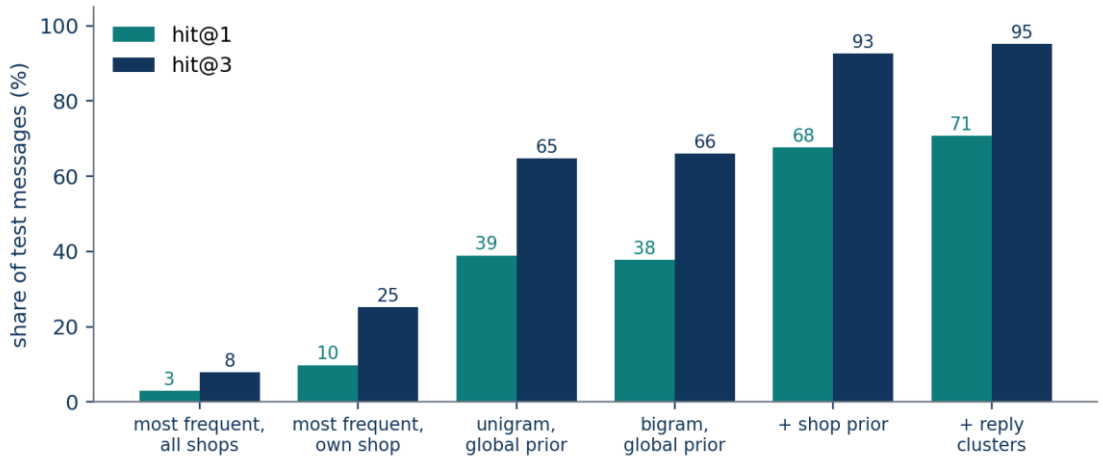

Figure 27.2 Hit@1 and hit@3 on 480 test messages for six suggesters, from always showing the most frequent replies to the per-reply bigram models with a shop prior and reply clusters.

- **The most frequent replies**, without reading the message, are nearly useless: 8% hit@3 when every shop gets the same three buttons, 25% when each shop gets its own three favorites. Any benefit below comes from reading the message.
- **Reading the message** with a unigram model lifts hit@3 to 65%. The bigram model is slightly better at hit@3 (66%) and slightly worse at hit@1 (37.7% against 39.0%). With about 20 training messages behind a typical reply, most word pairs have been seen once or not at all, and the extra detail of the bigram costs about as much as it gains.
- **The shop prior** is the biggest single step: 93% hit@3. Without it, a laundry customer's "berapa harganya?" is as likely to get the bakery's price reply as the laundry's, because the messages are the same. With $\gamma = 1$, chosen on the development data, each shop effectively suggests only its own replies. Notice that the tuning chose the unigram model here, $\lambda = (0.0, 0.6, 0.4)$: with the data split by reply, bigrams still do not pay.
- **Reply clusters** add the last two to three points: 70.8% hit@1 and 95.2% hit@3. The 104 whitelisted replies form 34 clusters, so a typical cluster pools the messages of three replies from several shops, and with that much more data per model, the tuning now *does* choose a bigram weight, $\lambda_2 = 0.1$.

The last lesson is the central one of n-gram models, and it is worth saying plainly: a longer context helps only when there is enough data to estimate it. Section 27.7 shows where the extra data came from.

Why not 100%? Remember that one reply in ten is a "let me check" reply that ignores the message, and that many questions have two equally good answers ("Sudah selesai" or "Masih proses", depending on the actual state of the order, which is not in the message). No model can predict those from the text; for hit@1 they set a ceiling well below 100%. Hit@3 is the number to watch for a three-button interface, and 95% means that about 19 customers in 20 can be answered with one tap. The time per suggestion, under a millisecond on a laptop, is no obstacle either.

27.7 Improving It

27.7.1 Letting replies share: clusters

Listing 27.6 is the improvement of Section 27.3.6. `ClusteredModel` inherits everything from `ReplyModel` and changes two things: `fit` builds the clusters, and `logp_message` asks the cluster's model instead of the reply's.

Listing 27.6 `clusters.py`: grouping replies whose messages look alike, and one message model per cluster.

```
"""clusters.py - replies with the same meaning share one message model."""
import math
from collections import Counter

from smartreply import ReplyModel

def cosine(a, b):
    """Cosine similarity of two word-count vectors (Counters)."""
    dot = sum(a[w] * b[w] for w in a)
    return dot / math.sqrt(sum(v * v for v in a.values())
                           * sum(v * v for v in b.values()))

class ClusteredModel(ReplyModel):
    """Replies whose messages look alike, in any shop, form one cluster.
    P(m | cluster) is learned from the pooled messages of the cluster;
    P(r | shop) still decides which reply of the cluster a shop would send."""

    def __init__(self, lambdas=(0.3, 0.5, 0.2), gamma=1.0, theta=0.8):
        super().__init__(lambdas, gamma)
        self.theta = theta                          # minimum cosine to join

    def fit(self, rows):
        super().fit(rows)                           # counts, priors, whitelist
        lang = {row["reply"]: row["lang"] for row in rows}
        self.cluster, profiles = {}, []             # profiles: (lang, counts)
        for r in sorted(self.replies, key=lambda r: (-self.count[r], r)):
            best, best_sim = None, self.theta
            for i, (lg, words) in enumerate(profiles):
                sim = cosine(self.uni[r], words) if lg == lang[r] else 0.0
                if sim >= best_sim:
                    best, best_sim = i, sim
            if best is None:                        # nothing similar: new cluster
                best = len(profiles)
                profiles.append((lang[r], Counter()))
            profiles[best][1].update(self.uni[r])
            self.cluster[r] = best
        pooled = [dict(row, reply=self.cluster.get(row["reply"], -1))
                  for row in rows]
        self.msg = ReplyModel((self.l2, self.l1, self.l0)).fit(pooled)
        self.n_clusters = len(profiles)
        return self

    def logp_message(self, words, r):
        return self.msg.logp_message(words, self.cluster[r])
```

The clustering is deliberately simple. Replies are visited from the most to the least frequent. Each joins the existing cluster of the same language whose pooled word counts are most similar to its own by Equation (27.7), provided the similarity is at least θ; otherwise it starts a new cluster. Then every training pair is relabeled with its reply's cluster number, and an ordinary `ReplyModel` is trained on the relabeled pairs: the "reply" of that inner model is the cluster. Replies used only once are not whitelisted and get the label -1, a cluster of their own that is never suggested.

With $\theta = 0.7$, chosen on the development data, the clusters are recognizably the kinds of questions of Section 27.4.1: all five Indonesian "where are you?" replies of the four shops form one cluster, all five Indonesian opening-hours replies another, and the seven Indonesian status replies, "Sudah selesai" and "Masih proses" alike, a third. The four Indonesian "let me check" replies form a cluster of their own, whose messages are a mixture of everything. The complaint replies mostly stay alone, because each shop's customers complain about different things: musty shirts, hard bread, a flickering screen. Nobody labeled these groups; the messages alone revealed them.

The second table of the output of `evaluate.py` shows who profits. The laundry, with 864 training pairs, gains less than a point of hit@3; the bakery gains five (from 90.8% to 95.8%) and the catering kitchen, the smallest shop, gains five as well (from 81.8% to 87.0%). **Figure 27.3** repeats the experiment for the catering kitchen with less and less of its own data, keeping the other shops' data complete; it is computed by the program of Exercise 27.5.

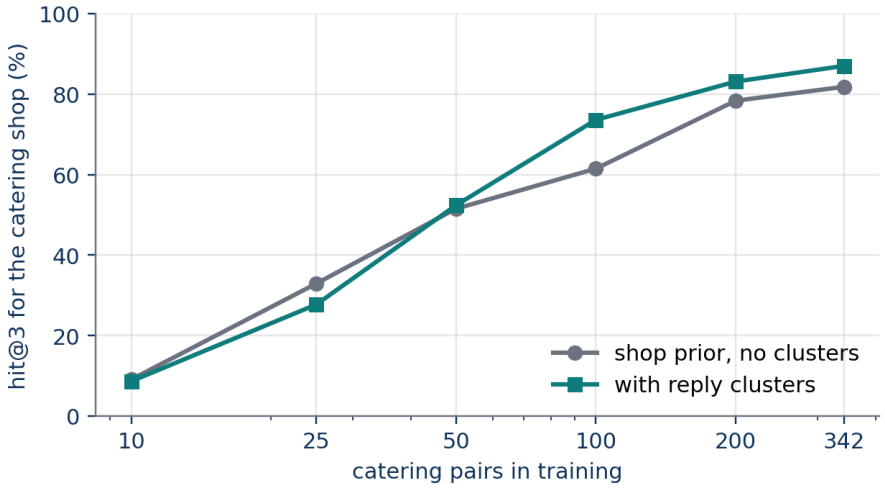

Figure 27.3 Hit@3 for the catering shop's test messages as the number of its own training pairs grows (averages of three random subsets), without and with reply clusters. The other shops' data is always complete.

From about 100 of its own chats onward, clusters are clearly better: at 100 pairs they reach 74% against 61%. Below 50 pairs neither method works, and clusters cannot help, for a simple reason: with so few chats, most of the shop's replies have not been sent twice and are not on the whitelist. Borrowing knowledge of *messages* from other shops does not give a shop *replies* it has never written. A new shop must start by writing its ten or twenty standard replies by hand, which is exactly what the "quick replies" feature of WhatsApp Business asks its users to do.

27.7.2 Following the seller's fingers

A suggestion bar should keep helping when none of the three buttons fits and the seller starts typing. `rank` already accepts a `prefix`: only replies that begin with what has been typed remain candidates, and they are ranked by the same score.

```
python suggest.py "kak bisa antar besok?" --prefix "Bisa kak, m"
```

```
[1] Bisa kak, mohon kirim alamat lengkapnya ya
```

After eleven characters, one reply is left, and one tap completes the remaining 31. This is the simplest form of "smart compose"; Chapter 60 builds a full autocomplete with a trie, and Chapter 36 predicts the next word of free text.

27.7.3 What else would help

- **Diversity.** When the top three replies are all variants of "yes", the person has no real choice. Smart Reply deliberately shows replies from different clusters, for instance one positive and one negative [3]. With `ClusteredModel` this is a small change: take the best reply of each of the three best clusters.
- **More context.** Our model reads only the last customer message. The previous turn often decides the answer: after "bisa antar besok?", a short "jam 10 ya" means a time for the delivery.

Adding the previous message's words as extra features, or the words of the shop's last reply, is the next step.

- **Neural scoring.** The production Smart Reply of 2017 replaced the n-gram likelihood by a small neural network that maps messages and replies into vectors and scores them by their dot product [4]. Chapter 37 trains such vectors for words, and Chapter 54 for whole texts.

27.8 Common Mistakes, and How to Avoid Them

Tuning on the test data. Choosing λ, γ or θ by their test hit@3 makes the reported number optimistic, because the test data has then been used for training. *Avoid it:* choose on a development split and look at the test split once, as `evaluate.py` does.

Suggesting free text. A generator that writes new replies can write a wrong price or a rude sentence. *Avoid it:* suggest only from a whitelist of replies the shop really sent, and let a person tap.

Forgetting the prior. Without $P(r \mid s)$, every shop gets every shop's replies (65% hit@3 instead of 93%). *Avoid it:* personalize, and tune how much.

Multiplying probabilities. A product of twenty probabilities around 0.01 is 10^{-40}, and with longer messages it underflows to zero in floating point. *Avoid it:* add logarithms.

Assigning zero to unseen words. One unknown word such as a new phone model would make every reply impossible. *Avoid it:* keep a background model with a slot for unknown words, Equation (27.4).

Using a bigger n than the data supports. With 20 messages per reply, bigram counts are mostly zeros and ones. *Avoid it:* let development data decide the weights, and pool data (clusters) before asking for longer contexts.

Splitting by message instead of by conversation in real data. When the same customer asks the same question twice, once in training and once in testing, the test becomes easy. *Avoid it:* in real data, split by customer or by date.

27.9 Using It for Real

Getting the data. WhatsApp lets a user export a chat as a text file (*More → Export chat*), and the WhatsApp Business Platform delivers messages to a business's own server through its API. Either way, pair each customer message with the next reply the shop sent within, say, ten minutes, and write the pairs in the format of `data/chats.tsv` (`shop`, `lang`, `message`, `reply`). A shop that has answered a few hundred chats has enough for the laundry-sized results of this chapter; a new shop should first write its standard replies, as Section 27.7.1 found.

Cleaning the replies. Real replies contain names, prices and order numbers ("Siap kak Nabila, total Rp56.000"). Replace them with placeholders ("Siap kak {name}, total {total}") before counting, so that the same reply is recognized as the same, and fill the placeholders from the order system when the suggestion is shown.

Personal data. Customer chats are personal data. Under Indonesia's Personal Data Protection Law (UU No. 27 Tahun 2022) [8], a shop may process them for a clear purpose that customers can know about, must keep them secure, and must not keep them longer than needed. Train on the shop's own chats, on the shop's own computer or server; strip phone numbers and addresses

from the messages before counting (the model does not need them); and never pool one shop's raw chats with another's. Clusters of Section 27.7 need only word counts per reply, which is what shops could share, if they wished, without sharing any chat.

Serving it. Train once, keep the `ClusteredModel` in memory, and answer a request in about a millisecond. Chapter 91 wraps such a model in a web service with FastAPI; a WhatsApp integration then calls it for every incoming message and shows the three replies in the shop's inbox tool. Retrain weekly so that new replies join the whitelist.

Watching it. Log which suggestion was tapped, if any. The share of messages answered with a tap is the real hit rate, and a drop is the first sign that customers have started asking new things; Chapter 98 turns that into monitoring.

27.10 Chapter Summary

- A smart-reply suggester scores a **whitelist** of the shop's past replies for each incoming message and shows the best three (**Figure 27.1**). Bayes' rule splits the score into how well a reply explains the message and how often the shop sends it (Equation (27.1)).
- $P(m \mid r)$ is an **n-gram model** of the messages that received reply r (Equation (27.2)), estimated by counting and **interpolated** with a unigram and a smoothed background model (Equation (27.3), Equation (27.4), **Table 27.1**).
- The **shop prior** (Equation (27.5)) personalizes the suggestions; it is the largest single improvement (65% to 93% hit@3).
- **Hit@k** (Equation (27.6)) measures whether the real reply is among k suggestions; every setting is chosen on development data and the test data is used once (**Listing 27.5**, **Figure 27.2**).
- **Reply clusters** built with cosine similarity (Equation (27.7), **Listing 27.6**) pool the messages of replies that mean the same, from all shops. The pooled data makes bigrams worthwhile and helps small shops most (**Figure 27.3**): 95.2% hit@3 overall.
- The corpus (**Listing 27.1**, **Table 27.2**), the model (**Listing 27.2**), the app (**Listing 27.3**) and the tests (**Listing 27.4**) use only the standard library, and a suggestion takes under a millisecond.

27.11 Exercises

Exercise 27.1. Using **Table 27.1**, verify the second and third probabilities of the status reply with Equation (27.3). The needed counts: *udah* is followed 18 times in the messages of the status reply, 7 times by *jadi*; *jadi* occurs 9 times among 262 words; the background gives *jadi* 0.00918 and *belum* 0.00951; *jadi* is followed 9 times, always by *belum*; *belum* occurs 17 times.

Exercise 27.2. A shop has sent 200 replies: "Siap kak" 120 times, "Sudah selesai" 60 times and "Maaf kak" 20 times, and these are the only three whitelisted replies. Over all shops, "Siap kak" has been sent 300 times out of 1,000 replies. Compute $P(\text{Siap kak} \mid s)$ with Equation (27.5) for $\gamma = 0$, $\gamma = 1$ and $\gamma = 0.5$.

Exercise 27.3. Before clustering, the tuning chose a unigram model; after clustering, it chose a bigram weight $\lambda_2 = 0.1$. Explain why, in terms of the number of messages behind each model.

Exercise 27.4. Hit@k gives no credit for a real reply ranked fourth. The **mean reciprocal rank** (MRR) averages 1/rank of the real reply over the test messages, with 0 when it is not ranked at all. Write a program that computes the MRR of the clustered model on the test data.

Exercise 27.5. Write a program that trains the model with all other shops' data and only 10, 25, 50, 100 and 200 of the catering shop's training pairs (plus all 342), averaged over three random subsets, and reports the catering hit@3 with and without clusters. Explain the result for 10 pairs.

Exercise 27.6. In Section 27.5, the catering kitchen was offered a laundry reply. Give two ways to prevent this and name one situation in which a reply of another shop might nevertheless be useful.

27.12 Solutions to the Exercises

Solution 27.1. Second row, the pair (*udah*, *jadi*): the context *udah* was seen 18 times, so the bigram term is $0.1 \cdot 7/18 = 0.0389$; the unigram term is $0.7 \cdot 9/262 = 0.0240$; the background term is $0.2 \cdot 0.00918 = 0.0018$. The sum is 0.0648. Third row, (*jadi*, *belum*): $0.1 \cdot 9/9 + 0.7 \cdot 17/262 + 0.2 \cdot 0.00951 = 0.1 + 0.0454 + 0.0019 = 0.1473$. With the first row, $\ln 0.0634 + \ln 0.0648 + \ln 0.1473 = -2.758 - 2.736 - 1.915 = -7.41$, as in the table.

Solution 27.2. With $\gamma = 0$ the prior is global: $300/1000 = 0.30$. With $\gamma = 1$: $(120 + 0.1)/(200 + 0.1 \cdot 3) = 120.1/200.3 = 0.5996$. With $\gamma = 0.5$: $0.5 \cdot 0.5996 + 0.5 \cdot 0.30 = 0.4498$. The shop sends "Siap kak" twice as often as shops in general, and the personalized prior says so.

Solution 27.3. A bigram estimate $c_r(v, w)/c_r(v)$ needs each context word v to have been seen several times with its different continuations. Without clusters, a typical whitelisted reply has about 20 training messages, roughly 100 words, spread over about 360 different words: most pairs occur once or never, the bigram fraction is mostly 0 or 1, and giving it weight adds noise. With 34 clusters instead of 104 replies, each model sees about three times as many messages, from several shops; pairs such as (*udah*, *jadi*) or (*jadi*, *berapa*) are then seen often enough to be trusted, and a small bigram weight pays. More data per model supports a longer context, the same trade-off as for every n-gram model.

Solution 27.4. **Listing 27.7** ranks all whitelisted replies for every test message and averages the reciprocal ranks.

Listing 27.7 `solutions/mrr.py`: the mean reciprocal rank of the clustered model.

```
"""mrr.py - Exercise 27.4: mean reciprocal rank of the final model."""
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from clusters import ClusteredModel  # noqa: E402
from smartreply import load, split  # noqa: E402

train, dev, test = split(load())
model = ClusteredModel((0.1, 0.7, 0.2), gamma=1.0, theta=0.7).fit(train)
total, missing = 0.0, 0
for row in test:
    ranking = model.rank(row["message"], row["shop"], k=len(model.replies))
    if row["reply"] in ranking:
        total += 1 / (ranking.index(row["reply"]) + 1)
    else:
        missing += 1                        # not whitelisted: reciprocal rank 0
print(f"MRR = {total / len(test):.3f}   ({missing} test replies not whitelisted)")
```

```
python solutions/mrr.py
```

```
MRR = 0.828   (5 test replies not whitelisted)
```

An MRR of 0.828 means that, on average, the real reply sits a little lower than first place: consistent with 70.8% at rank one and 95.2% within the first three. Five test replies were sent only once in the training data, so they are not on the whitelist and can never be suggested; they score 0.

Solution 27.5. Listing 27.8 runs the experiment; its numbers are those of **Figure 27.3**.

Listing 27.8 `solutions/learning_curve.py`: the catering shop's hit@3 with less and less of its own data.

```

```

```
python solutions/learning_curve.py
```

```
catering pairs  no clusters  clusters
            10        0.091     0.087
            25        0.329     0.277
            50        0.515     0.524
           100        0.615     0.736
           200        0.784     0.831
           342        0.818     0.870
```

With 10 pairs, both models reach only 9%. The catering replies are either missing from the whitelist (sent fewer than twice) or so rare that the prior of Equation (27.5) ranks them below the few that are there; the model knows perfectly well what the customer is asking, thanks to the other shops, but has almost no catering reply to offer. The cure is not more modeling but a handful of hand-written standard replies.

Solution 27.6. First, set $\gamma = 1$ and remove the pseudo-count, so that a shop's prior is exactly zero for replies it never sent; `rank` then must skip replies with prior zero instead of taking log0. Second, and simpler, filter the candidates in `rank` to the shop's own whitelist. A reply of another shop may still be useful as a *template* for a new shop: showing the catering kitchen "Your order is ready for pick up" as an idea, clearly marked as coming from elsewhere, helps it write its own standard reply, which is exactly what Solution 27.5 found a new shop needs.

Chapter 28
Named-Entity Finder

"Bu Ratna Dewi membayar Rp45.000 di Profitina Laundry Keputih kemarin." A person reading this sentence sees at once *who* paid, *how much*, and *where*. A program sees fourteen tokens. This chapter teaches a program to find the **named entities** in a sentence: persons, locations, organizations, dates and amounts of money, in Indonesian and in English. By the end of it you will be able to represent entities with BIO tags; write a rule-based finder with patterns and gazetteers; train an averaged-perceptron tagger that learns from annotated sentences, without the heavier machinery of conditional random fields; combine the two by feeding rule decisions to the learner as features; add a gazetteer of names built from Profitina Laundry's own sample records; evaluate at the level of whole entities with precision, recall and F1; and see, on a harder test set written afterward, how brittle both approaches are when sentences stop looking like the training data.

28.1 Why Find Entities?

Profitina Laundry receives hundreds of messages a week. "Pak Rudi Hartono membayar Rp72.000 untuk layanan kilat." "Tolong antar ke Jalan Kenari hari Kamis." "Mrs. Anna Smith from Australia asked whether shoes can be cleaned." Hidden in each message are the facts the business needs: a customer name to look up the order, an amount to check the payment, a street for the courier, a day for the schedule. Finding them automatically turns free text into fields of a form.

The same task appears everywhere. News archives are indexed by the people and places they mention. Search engines answer "who is the coach of the basketball team" by finding person names near the word *coach*. Privacy tools find names, addresses and numbers in documents so that they can be removed before a document is shared, which is exactly what Indonesia's personal data protection law expects of anyone who handles such documents [1]. This task is called **named-entity recognition** (NER); it was defined as a shared task in the 1990s, and the CoNLL-2003 evaluation fixed the classic types (person, location, organization, miscellaneous) and the way results are measured [2].

The plan of this chapter follows the history of the field: first rules written by hand, then a statistical tagger that learns from examples, then a combination of both.

28.2 The Idea in Plain Words

How does a becak driver know that "Pak Hendra" is a person and "Keputih" a place? Partly from **clues in the words themselves**: *Pak* and *Bu* are always followed by a name; *Jalan* and *Pasar* by a place; *PT*, *Bank* and *Universitas* start the name of an organization; *Rp* starts an amount. Partly from **lists he knows by heart**: the districts of Surabaya, the cities of East Java, the months of the year. And partly from **experience of how sentences go**: after "dari" (from) there is often a place, after "menurut" (according to) a person.

A rule-based finder writes the first two kinds of knowledge down as patterns and lists, called **gazetteers**. A statistical finder learns the third kind from sentences in which a person has marked

every entity. Both work token by token, deciding for every token whether it begins an entity, continues one, or is outside all entities.

Why is this hard at all? Because the same word can be different things. *Bunga* is a flower, the interest on a loan, and a woman's name. *Malang* is a city and an adjective meaning unlucky. *Kota Baru* is a place, but *kota baru* is simply "a new town". *Jumat* is a day, but *Masjid Jumat* could be part of a name. A person resolves these from context without noticing; a program has to be told which clues to use, or has to learn them from examples. Capital letters help in edited text, but customer messages are often written in lowercase, and then even *surabaya* looks like any other word. Every method in this chapter is, in the end, a way of weighing such clues against each other.

28.3 The Mathematics, Gently

28.3.1 BIO tags

Entities can be several tokens long ("Profitina Laundry Keputih", "1 Februari 2022"), so we cannot simply label each token with a type: two different people standing next to each other would merge into one. The **BIO** scheme gives each token one tag: `B-TYPE` for the first token of an entity, `I-TYPE` for every following token of the same entity, and `O` for tokens outside all entities [3], [4]. **Figure 28.1** shows an annotated training sentence. With five types there are $2 \times 5 + 1 = 11$ possible tags.

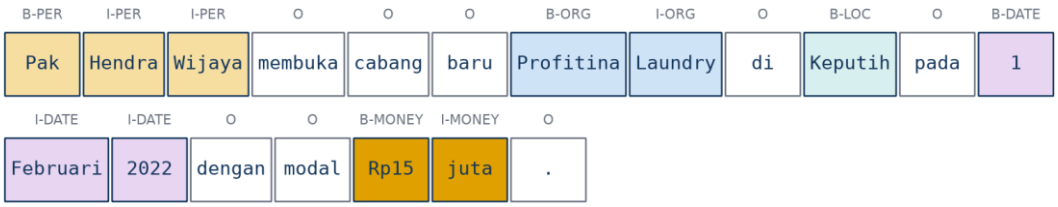

Figure 28.1 A training sentence with its BIO tags. Every entity starts with a B- tag and continues with I- tags of the same type; all other tokens are O.

Our training data is written in an easy-to-type bracket format, `[PER Pak Hendra Wijaya] membuka cabang baru [ORG Profitina Laundry] ...`, and the program converts it to tokens and BIO tags. We include titles such as *Pak*, *Bu*, *dr.* and *Mr.* in the person entity; that is a convention, and any convention is fine as long as the annotation follows it consistently.

28.3.2 The perceptron tagger

The statistical tagger describes the situation at token i by a list of **features**: the word itself, its shape (*Xx* for "Surabaya", *d* for "2026"), its last three letters, the words to its left and right, whether it is capitalized, and the tag chosen for the previous token. Write $\phi(x, i, t_{i-1})$ for this list. Every pair of a feature f and a tag t has a **weight** $w_{f,t}$, and the score of tag t is the sum of the weights of the active features:

$$\text{score}(t) = \sum_{f \in \phi(x,i,t_{i-1})} w_{f,t} \tag{28.1}$$

The tagger walks through the sentence from left to right and gives each token its highest-scoring tag; the chosen tag becomes the "previous tag" feature of the next token. This **greedy decoding** is the simplest way to let tags depend on each other:

$$\hat{t}_i = \operatorname*{argmax}_t \text{score}(t \mid \phi(x, i, \hat{t}_{i-1})) \tag{28.2}$$

28.3.3 Learning the weights

The **perceptron** learns by making mistakes. It starts with all weights at zero and goes through the training sentences token by token. When its guess $\hat{t}$ differs from the true tag t^*, it adds 1 to the weights of the active features for the true tag and subtracts 1 for the wrong one:

$$w_{f,t^*} \leftarrow w_{f,t^*} + 1, \qquad w_{f,\hat{t}} \leftarrow w_{f,\hat{t}} - 1 \qquad \text{for every } f \in \phi \tag{28.3}$$

After the update, the same situation scores the true tag higher than before. When the guess is right, nothing changes. Passing over the data several times (**epochs**), in a shuffled order, lets the weights settle.

The plain perceptron's final weights depend too much on the last few examples it saw. The **averaged perceptron** returns instead the average of the weights over all S training steps,

$$\bar{w}_{f,t} = \frac{1}{S} \sum_{s=1}^{S} w_{f,t}^{(s)} \tag{28.4}$$

which is much more stable and generalizes better [5], [6]. The code computes this average without storing every intermediate weight: it remembers, for each weight, when it last changed, and adds "value × time unchanged" to a running total.

Why not a conditional random field (CRF), the standard statistical model for NER for many years [7]? A CRF scores whole tag sequences and needs dynamic programming both to train and to decode. The averaged perceptron with greedy decoding is a few dozen lines, trains in a fraction of a second, and on small data performs almost as well. It is the right first model; Chapter 39 and Part 9 show the neural models that replaced both.

28.3.4 Measuring entities, not tokens

A tagger that labels every token `O` is right on most tokens, because most tokens are not entities, so token accuracy is misleading. NER is evaluated on **whole entities**: a predicted entity counts as correct only if its start, its end and its type all match a gold entity exactly [2]. With G the set of gold entities and P the set of predicted ones,

$$\text{precision} = \frac{|G \cap P|}{|P|}, \qquad \text{recall} = \frac{|G \cap P|}{|G|}, \qquad F_1 = \frac{2 \cdot \text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}} \tag{28.5}$$

Finding "Hendra Wijaya" when the gold entity is "Pak Hendra Wijaya" is therefore both a false positive and a false negative: exact boundaries matter.

28.4 The Data

`data/train.txt` has 58 annotated sentences, 30 in Indonesian and 28 in English, with 132 entities: 27 persons, 40 locations, 28 organizations, 23 dates and 14 amounts of money. `data/test.txt` has 20 sentences with 50 entities in the same style. The organizations are invented for the book, the places are real districts and cities, and the person names are the kind that appear in Profitina Laundry's sample customer list. **Listing 28.1** reads the bracket format

and converts it to BIO tags using the tokenizer of Chapter 21; `spans` turns a tag sequence back into a set of (start, end, type) entities, which is what we compare.

Listing 28.1 `corpus.py`: reading annotations as tokens with BIO tags, and turning tags into entity spans.

```
"""corpus.py - read "[TYPE words]" annotations as tokens with BIO tags."""
import re

from tokenizer import tokenize

SPAN_RE = re.compile(r"\[(PER|LOC|ORG|DATE|MONEY) ([^\]]+)\]")

def parse(line):
    """'[PER Bu Siti] membayar ...' -> (['Bu', 'Siti', 'membayar', ...],
                                        ['B-PER', 'I-PER', 'O', ...])"""
    tokens, tags, pos = [], [], 0
    for m in SPAN_RE.finditer(line):
        outside = [t.text for t in tokenize(line[pos:m.start()])]
        tokens += outside
        tags += ["O"] * len(outside)
        inside = [t.text for t in tokenize(m.group(2))]
        tokens += inside
        tags += ["B-" + m.group(1)] + ["I-" + m.group(1)] * (len(inside) - 1)
        pos = m.end()
    rest = [t.text for t in tokenize(line[pos:])]
    return tokens + rest, tags + ["O"] * len(rest)

def load(path):
    with open(path, encoding="utf-8") as f:
        return [parse(line.strip()) for line in f if line.strip()]

def spans(tags):
    """The entities of a tag sequence as a set of (start, end, type)."""
    out, start, kind = set(), None, None
    for i, tag in enumerate(tags + ["O"]):
        if start is not None and not tag.startswith("I-"):
            out.add((start, i, kind))
            start = None
        if tag.startswith("B-") or (tag.startswith("I-") and start is None):
            start, kind = i, tag[2:]
    return out
```

28.5 Building the Rule-Based Finder

Listing 28.2 is the hand-written finder. It works in passes, one per kind of clue, and a later pass never overwrites a token that an earlier pass has already labeled (`tag_span` checks that all tokens are still `O`). The order of the passes is part of the design: amounts and dates are the most reliable patterns, persons introduced by a title come before organizations so that "Dr. Andi Pratama of Harapan Sehat Hospital" is not swallowed whole by the organization pass, and places come last.

Listing 28.2 `rules.py`: patterns and gazetteers for persons, places, organizations, dates and money.

```
"""rules.py - a hand-written named-entity finder for Indonesian and English."""

        self.weights = {f: dict(t) for f, t in self.weights.items()}
        return self
```

- `shape` compresses a token into its character classes, merging repeats: “Surabaya” becomes *Xx*, “Rp80.000” becomes *Xxd.d*. Shapes let the model generalize from names it has seen to names it has not.
- `features` builds ϕ of Equation (28.1): about fifteen strings such as `w=surabaya`, `shape=Xx`, `left=di` and `prev=O`. With `rules`, it adds the rule finder’s tag for the token as a feature; with `names`, whether the token and its neighbors are in the name list of Section 28.8.
- `score` adds up the weights of Equation (28.1); `tag` performs the greedy decoding of Equation (28.2).
- `fit` is the training loop of Equation (28.3). During training the “previous tag” feature uses the *true* previous tag (**teacher forcing**), so that one early mistake does not spoil a whole sentence’s updates. The final loop computes the averages of Equation (28.4).

Training all four variants on 58 sentences takes well under a second.

28.7 Measuring It

Listing 28.4 trains the taggers and computes the entity-level scores of Equation (28.5) on both test files, overall and per type.

data/test_hard.txt: 16 sentences, 30 entities
                        P     R    F1   F1 per type: PER LOC ORG DATE MONEY
rules                0.78  0.23  0.36   0.00 0.33 0.33 1.00 0.00
perceptron           0.37  0.43  0.40   0.00 0.61 0.24 0.73 0.00
perceptron + rules   0.44  0.27  0.33   0.00 0.33 0.40 0.73 0.00
+ rules + names      0.85  0.37  0.51   0.57 0.33 0.33 1.00 0.00
```

Start with the ordinary test set. The rules reach an F1 of 0.98, the perceptron alone 0.89, and the perceptron with rule features 0.96. On data that looks like what they were written for, hand-made rules are excellent: every organization, place, date and amount is found; only two persons are missed. The perceptron learned from just 58 sentences, and its weakest type is persons (0.67), because a person's name is the kind of token it has usually never seen.

Now the second table. `data/test_hard.txt` was written *after* the rules were frozen, on purpose unlike the training data: names without titles ("Kemarin Fajar Nugraha datang"), places outside the gazetteer (*Kediri*, *Banyuwangi*, *Pontianak*, *Rotterdam*), shop names without trigger words (*Sumber Rejeki*), and amounts without *Rp* ("50 ribu", "120 thousand rupiah"). The rules collapse to an F1 of 0.36: their precision stays high (0.78, what they find is usually right) but their recall falls to 0.23. The perceptron is slightly better (0.40), because features such as capitalization and the word after *dari* generalize a little beyond its training sentences. **Figure 28.2** shows both tables.

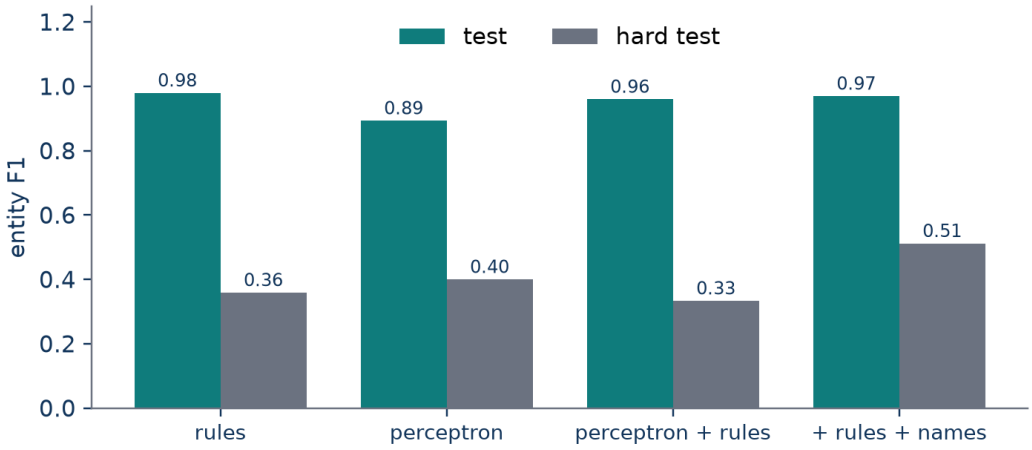

Figure 28.2 Entity-level F1 of the four taggers on the ordinary test set and on the hard test set written after the rules were fixed.

The drop is the most important result of the chapter. A score measured on test sentences that resemble the training sentences says little about sentences that do not. Customer messages are much more like the hard set than like the tidy training sentences, so 0.36 to 0.51, not 0.98, is the honest estimate for this business.

28.8 Improving It: A Name List from the Laundry's Own Records

The biggest gap on the hard set is persons: without a title or a cue word, neither approach recognizes "Fajar Nugraha" as a name. A person would, simply because *Fajar* is a common

Indonesian given name. The model can be given the same knowledge with a **name gazetteer**, and Profitina Laundry already has one: the names in its customer and employee records. **Listing 28.5** extracts the name parts from the `name` column of the sample records into `data/names.txt`.

Listing 28.5 `make_names.py`: a list of name parts built from the laundry's sample records.

```
"""make_names.py - build a list of name parts from the laundry's sample records."""
import csv

SOURCES = ["data/Customer.csv", "data/Employee.csv"]
names = set()
for path in SOURCES:
    with open(path, encoding="utf-8", newline="") as f:
        for row in csv.DictReader(f):
            names.update(part for part in row["name"].split() if part.isalpha())
with open("data/names.txt", "w", encoding="utf-8") as f:
    f.write("\n".join(sorted(names)) + "\n")
print(f"{len(names)} name parts written to data/names.txt")
```

```
python make_names.py
```

```
153 name parts written to data/names.txt
```

The perceptron receives three extra features, whether the token and each of its neighbors is in the list, and *learns* how much to trust them; a name list used as a feature can be outweighed by other evidence, while a name list used as a rule cannot. This matters because name lists are ambiguous: *Tanjung* is both a family name in the records and the first word of *Tanjung Perak*, a port. In the last row of the evaluation, the person F1 on the hard set rises from 0 to 0.57, and the overall F1 to 0.51, with precision 0.85. On the ordinary test set the combination scores 0.97.

Using customer records this way is itself processing of personal data. Only the name parts are needed, not addresses, phone numbers or orders, and `make_names.py` reads only the `id` and `name` columns; the list stays inside the business's own system. That is the principle of data minimization that UU PDP asks for [1].

The remaining mistakes are listed by the `--errors` option:

```
python evaluate.py --errors
```

```
data/test.txt: 20 sentences, 50 entities
                        P     R    F1   F1 per type: PER LOC ORG DATE MONEY

```

They fall into clear groups. Unknown places (*Kediri*, *Banyuwangi*, *Pontianak*, *Rotterdam*) need a larger gazetteer or more training sentences with places after *dari* and *from*. Organizations without trigger words (*Sumber Rejeki*) need training examples. Amounts without *Rp* need a rule, which Exercise 28.4 adds. And *Malang* inside "Politeknik Negeri Malang" was tagged as a place, while the whole phrase is an organization; nested names like this are a classic difficulty of NER.

Finally, **Listing 28.6** tags any sentence with the best combination:

Listing 28.6 `find.py`: marking the entities in new sentences.

```

28.9 What Is Special About Indonesian Names

Most NER research has been done on English news, and several of its habits need adjusting for Indonesian text.

Single names. Many Indonesians have one name only, and a one-word name without a title looks exactly like any capitalized word at the start of a sentence. Features that look beyond the word itself, the word before it and the name gazetteer of Section 28.8, carry most of the weight here.

Titles and forms of address. Indonesian messages are full of forms of address: *Pak*, *Bu*, *Mas*, *Mbak*, *Kak*, *Dik*, often without a name ("Kak, cucian saya sudah selesai?"). A rule that treats every *Kak* as the start of a person entity will produce false alarms; the rule in **Listing 28.2** requires a capitalized word after the title, and the learner can weigh the title against the context.

Capitalization in chat. News capitalizes names reliably; customer messages often do not ("bu dewi", "di rungkut"). Our features lean heavily on capitalization, so for chat text they should be complemented by lowercase gazetteer matches and, above all, by training sentences written in lowercase.

Organization names with legal forms. Indonesian company names begin with *PT* or *CV* and may end with *Tbk* (a listed company), while government bodies follow patterns such as *Dinas ... Kota ...* and *Kementerian ...*. These regular forms make rules effective for organizations, as the ordinary test set showed.

Place names that are also other things. *Malang* is a city and an adjective (unlucky); *Padang* is a city and a word for a field; *Tanjung* is a cape, a family name and part of *Tanjung Perak*. Context decides, which is again an argument for a learned model over fixed lists.

Public Indonesian NER datasets exist for training larger models, and benchmarks such as IndoNLU collect them together with standard splits and evaluation scripts [8]. With a few thousand annotated sentences instead of our 58, the perceptron of this chapter, or a neural tagger, would learn most of these patterns from data.

28.9.1 Annotating your own data

Every number in this chapter rests on annotation, and annotation is harder than it looks. Is "Profitina Laundry Keputih" one organization, or an organization followed by a place? Is "Lebaran" a date? Is "Pak" part of the name? Before annotating, write the answers down as **guidelines** with examples, as the bracket conventions of Section 28.3.1 do, and settle new doubtful cases by adding them to the guidelines rather than by deciding them silently.

Then check that the guidelines work by letting two people annotate the same sample independently. The share of tokens on which they agree, p_o, is misleading on its own, because two people who both label almost everything `O` agree most of the time by chance. **Cohen's kappa** corrects for that [9]:

$$\kappa = racp_o - p_e1 - p_e \tag{28.6}$$

where p_e is the agreement expected by chance from how often each person uses each label. For a simplified example with only two labels, suppose each of two annotators marks 30% of the tokens as part of an entity and 70% as `O`. Chance agreement is then $p_e = 0.7times0.7 + 0.3times0.3 = 0.58$. If they actually agree on 90% of the tokens, $p_o = 0.9$ and Equation (28.6) gives $\kappa = (0.9 - 0.58)/(1 - 0.58) = 0.32/0.42 pprox 0.76$. A kappa of 1 means perfect agreement; values around 0.8 are usually taken as good for NER; values below about 0.6 mean that the guidelines, not the annotators, need work.

How much data is enough? The learning curve of Chapter 25 answers that for any task: annotate in batches of, say, fifty sentences, retrain after each batch, and stop when the entity F1 on a fixed development set stops improving. For a laundry's messages, a few hundred sentences drawn from real messages, not the tidy sentences of our training file, would teach the tagger far more than our 58, and would make the hard test set of this chapter look much less hard.

28.10 Testing

Listing 28.7 checks the conversion from brackets to BIO tags, the conversion from tags back to spans, the rule finder on a sentence with one entity of each of four types, and word shapes.

Listing 28.7 `tests/test_ner.py`: tests for the corpus reader, the rules and the features.

```

28.11 Common Mistakes, and How to Avoid Them

Evaluating tokens instead of entities. Token accuracy is high even for a tagger that finds nothing. *Avoid it:* use entity-level precision, recall and F1 (Equation (28.5)).

Inconsistent annotation. If some sentences include *Pak* in the person and others do not, every system is punished for the annotators' disagreement. *Avoid it:* write the conventions down before annotating, and check a sample twice.

Rules that fire in the wrong order. An organization pattern run before the title pattern swallowed "Andi Pratama of Harapan Sehat Hospital" whole in an early version of **Listing 28.2**. *Avoid it:* run the most reliable patterns first and never overwrite a decision.

Testing only on sentences like the training data. The rules scored 0.98 on such sentences and 0.36 on others. *Avoid it:* build a test set from real input, or written independently after the system, as `data/test_hard.txt` was.

Using a gazetteer as a hard rule. *Tanjung* is a name and a place. *Avoid it:* give gazetteer membership to a learner as a feature, so that context can override it.

Collecting more personal data than needed. A name list needs names, not phone numbers. *Avoid it:* read only the columns you need, as `make_names.py` does.

28.12 Chapter Summary

- **Named-entity recognition** finds persons, locations, organizations, dates and amounts. Entities are encoded with **BIO** tags (**Figure 28.1**, **Listing 28.1**).
- A **rule-based finder** uses patterns and gazetteers, applied in passes that never overwrite each other (**Listing 28.2**).
- An **averaged perceptron** scores tags by summing feature weights (Equation (28.1)), decodes greedily (Equation (28.2)), learns by correcting mistakes (Equation (28.3)) and averages its weights for stability (Equation (28.4)); rule decisions and a **name gazetteer** can be added as features (**Listing 28.3**, **Listing 28.5**).
- Evaluation is at the level of **whole entities** (Equation (28.5), **Listing 28.4**). On the ordinary test set the rules reach 0.98 F1; on a harder set written afterward, every approach falls, and the combination of perceptron, rules and names does best with 0.51 (**Figure 28.2**).
- Honest test data, consistent annotation and minimal use of personal data matter as much as the algorithm.

28.13 Exercises

Exercise 28.1. Write the BIO tags for "Bu Siti dari Rungkut membayar Rp35.000 pada hari Senin." following the conventions of this chapter.

Exercise 28.2. A gold standard contains 30 entities. A tagger predicts 20 entities, of which 12 exactly match gold entities. Compute precision, recall and F1 by Equation (28.5). How many of the 20 predictions were wrong, and how many gold entities were missed?

Exercise 28.3. The perceptron guesses `B-LOC` for the token "Malang" in "Politeknik Negeri Malang", whose true tag is `I-ORG`. Its active features include `w=malang`, `shape=Xx` and `prev=I-ORG`. Write the updates of Equation (28.3) for these three features. Why does `prev=I-ORG` help the model avoid this mistake in the future?

Exercise 28.4. Extend the rules so that amounts written without *Rp* or *$* are found: a number followed by *ribu*, *juta*, *thousand*, *million* and similar words, optionally followed by *rupiah*. Measure the effect on the MONEY entities of the hard test set.

Exercise 28.5. Explain why greedy decoding (Equation (28.2)) can produce the tag sequence `O I-PER`, which is invalid in the BIO scheme, and describe two ways to prevent it.

Exercise 28.6. Profitina Laundry wants to remove all names, phone numbers and addresses from customer messages before using them to train the classifier of Chapter 25. Which parts of this chapter would you reuse, what would you add, and what error rate would you accept?

28.14 Solutions to the Exercises

Solution 28.1. Tokens and tags: *Bu* B-PER, *Siti* I-PER, *dari* O, *Rungkut* B-LOC, *membayar* O, *Rp35.000* B-MONEY, *pada* O, *hari* B-DATE, *Senin* I-DATE, *.* O. The title *Bu* belongs to the person and *hari* to the date, following the conventions of the training data.

Solution 28.2. Precision $= 12/20 = 0.60$; recall $= 12/30 = 0.40$; $F_1 = 2 \times 0.60 \times 0.40/(0.60 + 0.40) = 0.48$. Eight predictions were wrong (false positives) and eighteen gold entities were missed (false negatives). A prediction with the right type but a wrong boundary counts in both groups.

Solution 28.3. For each of the three features, the weight for the true tag rises and the weight for the wrong guess falls: $w_{\text{w=malang, I-ORG}} += 1$, $w_{\text{w=malang, B-LOC}} -= 1$, and the same for `shape=Xx` and `prev=I-ORG`. The feature `prev=I-ORG` is the useful one: in training data, a token after `I-ORG` is almost always `I-ORG` or `O`, never `B-LOC` inside the same name, so strengthening that link teaches the model that an organization in progress tends to continue. The other two updates are less helpful, since *Malang* is usually a place; that is exactly the ambiguity that makes nested names hard.

Solution 28.4. **Listing 28.8** wraps `rule_tags` with one more pass: a number followed by a scale word, and optionally *rupiah*, *dollars* or *dolar*, is an amount.

Listing 28.8 `solutions/money_rule.py`: amounts written as words, such as “50 ribu” and “120 thousand rupiah”.

```
"""money_rule.py - Exercise 28.4: amounts written without Rp or $."""
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from corpus import load, spans  # noqa: E402
from rules import SCALES, rule_tags, tag_span  # noqa: E402

CURRENCY = {"rupiah", "dollars", "dolar"}

def rule_tags_plus(toks):
    tags = rule_tags(toks)
    low = [t.lower() for t in toks]
    for i in range(len(toks) - 1):
        if toks[i].isdigit() and low[i + 1] in SCALES:     # "50 ribu"
            end = i + 2
            if end < len(toks) and low[end] in CURRENCY:   # "... rupiah"
                end += 1
            tag_span(tags, i, end, "MONEY")
    return tags

data = load("data/test_hard.txt")
for name, tagger in (("rules", rule_tags), ("rules + amounts", rule_tags_plus)):
    found = [(spans(g), spans(tagger(t))) for t, g in data]
    money = [({x for x in g if x[2] == "MONEY"}, {x for x in p if x[2] == "MONEY"})
             for g, p in found]
    tp = sum(len(g & p) for g, p in money)
    print(f"{name:<16} MONEY found {tp} of {sum(len(g) for g, _ in money)}, "
          f"false alarms {sum(len(p - g) for g, p in money)}")
```

```
python solutions/money_rule.py
```

```
rules            MONEY found 0 of 3, false alarms 0
rules + amounts  MONEY found 3 of 3, false alarms 0
```

All three amounts of the hard set are found, with no false alarm. The rule would also fire on “50 ribu orang” (fifty thousand people), which is not money; a safer version requires a money word nearby (*bayar*, *harga*, *biaya*, *transfer*, *costs*) or the word *rupiah*. Every rule trades recall against precision, and the trade should be decided by looking at real messages.

Solution 28.5. Greedy decoding chooses each tag using only the previous *predicted* tag as a feature; nothing forbids choosing `I-PER` after `O` if the other features point strongly to a name. Two remedies: (1) **constrained decoding**, which simply excludes tags that cannot follow the previous one (an `I-X` may only follow `B-X` or `I-X`), or repairs an invalid `I-X` into `B-X` afterward, as `spans` in

Listing 28.1 effectively does; (2) **sequence decoding** with the Viterbi algorithm, as in CRFs, which finds the best *valid* sequence for the whole sentence instead of deciding token by token.

Solution 28.6. Reuse the tokenizer, the BIO machinery and the tagger with rules and names. Add rules for phone numbers (Exercise 21.3 wrote one), e-mail addresses (already a token kind in Chapter 21) and street addresses (*Jl.*, *Jalan*, *No.*, *Blok*), and replace every found entity by its type (`[PER]`, `[PHONE]`). For anonymization, recall matters much more than precision: a missed name is a privacy leak, while a wrongly removed word only makes a training sentence slightly worse. So the acceptable error rate is very low for missed entities, and a person should review a sample of the cleaned messages before the data is used.

Chapter 29

FAQ Answer Bot (BM25)

Every business answers the same questions again and again: what does it cost, when are you open, where are you, can you pick it up? This chapter builds a bot that answers such questions for Profitina Laundry by finding the best entry in a list of frequently asked questions. By the end of it you will be able to explain and implement Okapi BM25, the ranking formula used by the default configuration of search engines such as Elasticsearch; see why it saturates term frequency and normalizes document length; compare it with the TF-IDF cosine of Chapter 23; measure a retrieval system with top-1 accuracy and mean reciprocal rank; improve it with chat-specific stop words and light stemming; decide with a threshold when the bot should hand a question to a person; and serve the bot as a small web page and JSON API with Flask. The same retrieval step is the "R" of the retrieval-augmented generation of Chapter 84 [1].

29.1 Why an FAQ Bot?

At Profitina Laundry's three outlets the phone and the chat inbox ring all day with questions that already have answers: the price per kilogram, the express service, the opening hours, the addresses, pickup and delivery, payment by QRIS. Staff answer them between weighing laundry and handing out orders, and each answer takes a minute that could have gone to a customer at the counter. A bot that answers the routine questions instantly, and passes everything else to a person, saves those minutes and answers at night too.

There are two ways to build such a bot. One is to *generate* an answer with a language model, which Part 9 does. The other, older and much safer for a business, is to *retrieve*: keep a list of approved question–answer pairs, find the pair whose question best matches what the customer wrote, and return its answer word for word. A retrieving bot can only say what the business has written and approved; it never invents a price. Its whole quality depends on one thing, the ranking function that decides which entry matches best. This chapter builds the most successful classical ranking function, BM25.

29.2 The Idea in Plain Words

Imagine that the laundry's answers are written on sixteen cards, each with a question on top and the answer below. A customer asks "buka jam berapa kak?". A helpful becak driver waiting outside, who can read but does not know the business, could still find the right card: he would look for cards that contain the customer's important words, *buka* and *jam*, and prefer a card that contains the rarer of them, since *jam* appears on few cards while a word like *harga* appears on many.

That is TF-IDF again, from Chapter 23. BM25 adds two pieces of common sense.

- **Repetition helps, but less and less.** A card that says *jam* twice is a slightly better match than a card that says it once, but a card that says it ten times is not ten times better. BM25 lets the benefit of repetition **saturate**.

- **Long cards should not win just by being long.** A long card contains more words and therefore matches more queries by chance. BM25 **normalizes** by the length of each card compared with the average card.

Finally, the bot must know when *no* card fits. “Siapa pemenang piala dunia?” (who won the World Cup?) should not be answered with the opening hours just because *siapa* and *dunia* share nothing and some card has to be “best”. A **threshold** on the score decides when to say “I don’t know, I’ll pass this to our staff”.

Retrieval also makes the bot easy to maintain. When prices change, someone edits one card, and the bot answers with the new price at once; there is no model to retrain. When customers keep asking something the cards do not cover, the handover log shows it, and a new card is written. The bot is only as good as its cards, and that is a strength: the business stays in control of every word the bot says.

Writing good cards is part of the work. Each card should answer one question, in the words customers use rather than in internal jargon; it should state prices and times exactly; and it should exist in every language the bot serves. A card that tries to answer three questions at once becomes long, and length normalization then makes it lose against shorter cards for all three. When two cards keep competing for the same questions, they should usually be merged or rewritten.

29.3 The Mathematics, Gently

29.3.1 The BM25 score

Let d be a document (an FAQ card), q a query with terms $t_1, \dots, t_m$, $f(t, d)$ the number of times term t occurs in d, $|d|$ the length of d in terms, and $\overline{|d|}$ the average length of all N documents. Let n_t be the number of documents that contain t. The **Okapi BM25** score is [2], [3]

$$\mathrm{BM25}(q, d) = \sum_{t \in q} \mathrm{idf}(t) \cdot \frac{f(t, d)\,(k_1 + 1)}{f(t, d) + k_1 \left(1 - b + b\,\dfrac{|d|}{\overline{|d|}}\right)} \tag{29.1}$$

with the inverse document frequency

$$\mathrm{idf}(t) = \ln\left(1 + \frac{N - n_t + 0.5}{n_t + 0.5}\right) \tag{29.2}$$

Two parameters shape it: k_1 controls saturation and b controls length normalization. Lucene and Elasticsearch use $k_1 = 1.2$ and $b = 0.75$ by default [4], and so do we.

Equation (29.2) plays the same role as the idf of Chapter 23: a term in few documents weighs a lot, a term in most documents weighs little. The “+1” inside the logarithm keeps the idf positive even for a term that occurs in more than half of the documents, which older versions of the formula allowed to go negative.

29.3.2 Saturation

Set $b = 0$ for a moment, so that length plays no part. The fraction in Equation (29.1) becomes $\frac{f(k_1+1)}{f+k_1}$. For $f = 1$ it equals exactly 1; as f grows it rises, but more and more slowly, because

$$\lim_{f \to \infty} \frac{f\,(k_1 + 1)}{f + k_1} = k_1 + 1 \tag{29.3}$$

With $k_1 = 1.2$, no amount of repetition can give a term more than 2.2 times the weight of a single occurrence. Plain TF-IDF has no such ceiling. The left panel of **Figure 29.1** draws the curve for three values of k_1: small k_1 saturates almost at once, large k_1 behaves more like raw counting.

29.3.3 Length normalization

The factor $1 - b + b\,|d|/\overline{|d|}$ equals 1 for a document of average length. For a document twice as long as average it equals $1 - b + 2b = 1 + b$, which enlarges the denominator and lowers the score; for a short document it is below 1 and raises the score. With $b = 0$ length is ignored; with $b = 1$ it is fully normalized. The right panel of **Figure 29.1** shows the weight of a term that occurs twice, as a function of relative document length.

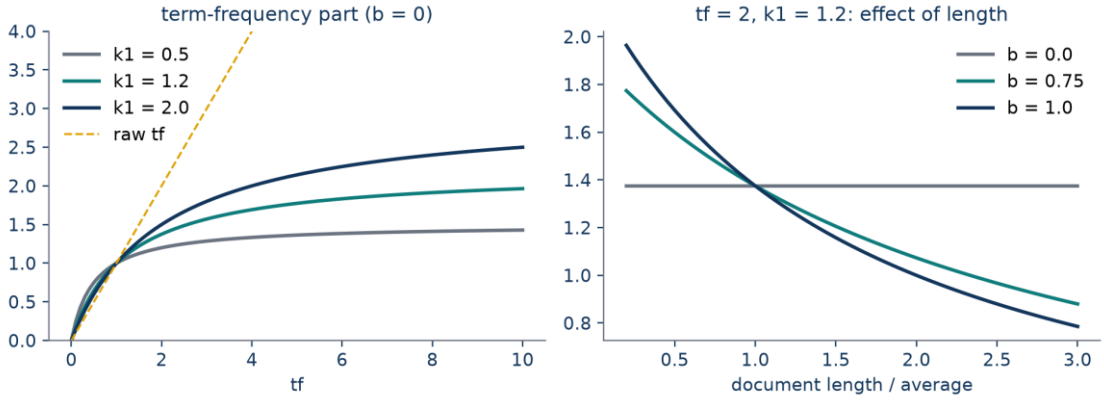

Figure 29.1 Left: the term-frequency part of BM25 saturates at $k_1 + 1$, unlike raw term frequency. Right: for a term that occurs twice, longer documents get less credit, and more so for larger b.

29.3.4 A worked example

Take three cards: d_1 = "harga cuci kiloan", d_2 = "harga setrika", d_3 = "jam buka outlet", so $N = 3$, the lengths are 3,2,3 and $\overline{|d|} = 8/3 \approx 2.67$. For the query "harga", $n_{\text{harga}} = 2$ and Equation (29.2) gives $\ln(1 + 1.5/2.5) = \ln 1.6 \approx 0.470$. In d_2, $f = 1$ and $|d|/\overline{|d|} = 0.75$, so the denominator is $1 + 1.2 \times (0.25 + 0.75 \times 0.75) = 1 + 1.2 \times 0.8125 = 1.975$, and the score is $0.470 \times 2.2/1.975 \approx 0.523$. In d_1, the relative length is 1.125, the denominator is $1 + 1.2 \times 1.094 = 2.313$, and the score is $0.470 \times 2.2/2.313 \approx 0.447$. Both cards mention *harga* once, and the shorter card wins, as length normalization intends. For the query "jam", $n = 1$ and the idf is $\ln(1 + 2.5/1.5) = \ln 2.667 \approx 0.981$: a rarer word, twice the weight.

29.3.5 Measuring a retrieval system

For each test question we know which card is correct. **Top-1 accuracy** is the fraction of questions whose best-ranked card is the correct one. It ignores near misses, so we also compute the **mean reciprocal rank**: if the correct card is at position r_q in the ranking for question q, its reciprocal rank is $1/r_q$ (1 for first place, 0.5 for second, 0.33 for third), and

$$\text{MRR} = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{r_q} \tag{29.4}$$

averaged over the set Q of test questions. MRR rewards a system that puts the right card near the top even when it is not first [5].

29.3.6 When not to answer

The bot answers with the best card d^* only if its score reaches a threshold θ:

$$\text{answer}(q) = \begin{cases} d^* & \text{if } \text{BM25}(q, d^*) \geq \theta \\ \text{hand over to staff} & \text{otherwise} \end{cases} \tag{29.5}$$

A low θ answers almost everything, including questions the FAQ does not cover; a high θ hands over many questions the bot could have answered. Choosing θ is a business decision about which mistake is worse, informed by data.

29.4 The Data

`data/faq.tsv` holds 16 FAQ entries, each in Indonesian and in English, 32 cards in all, based on Profitina Laundry's services and prices: wash, dry and fold at Rp8,000 per kilogram, express service in one day, dry cleaning, bed covers, shoes and helmets, three outlets in Rungkut, Keputih and Wiyung, opening hours, pickup and delivery, payment methods, stains, compensation, and order status. `data/queries.tsv` has 40 test questions phrased the way customers write, in both languages, each labeled with the id of the card that answers it; four of them ("do you sell washing machines", "siapa pemenang piala dunia") are outside the FAQ and should be handed over. `data/dev.tsv` has 12 more questions, used only to choose the threshold.

29.5 Building the Ranker and the Bot

Listing 29.1 implements Equation (29.1) and Equation (29.2) from scratch. The `Analyzer` turns a text into index terms with the tokenizer and stop words of Chapter 21; its two options, chat stop words and light stemming, are the improvement of Section 29.7.

Listing 29.1 `bm25.py`: an analyzer and the Okapi BM25 ranker.

```
"""bm25.py - Okapi BM25 ranking, written from scratch."""
import math
from collections import Counter

from stopwords import STOPWORDS
from tokenizer import words

# Words that fill chat messages but say nothing about the question.
CHAT_STOPWORDS = set("""saya aku kak mas mbak bu pak ya dong sih nih bisa apakah
ada mau tolong boleh my me i you your we our there get what how where when
which much many""".split())

def light_stem(word, vocabulary):
    """Strip one common suffix or prefix, but only if what remains is a word
    of the vocabulary (the idea of Chapter 21's clitic splitter)."""
    for suffix in ("ing", "ed", "es", "s", "kan", "nya", "an"):
        stem = word[:-len(suffix)]
        if word.endswith(suffix) and len(stem) > 2 and stem in vocabulary:
            return stem
    for prefix in ("di", "me", "ber", "ter", "se"):
        stem = word[len(prefix):]
        if word.startswith(prefix) and len(stem) > 2 and stem in vocabulary:
            return stem
    return word

class Analyzer:
    """Text -> list of index terms."""

    def __init__(self, chat_stopwords=False, vocabulary=None):
        self.stop = STOPWORDS | (CHAT_STOPWORDS if chat_stopwords else set())
        self.vocabulary = vocabulary

    def __call__(self, text):
        out = [w for w in words(text) if w not in self.stop]
        if self.vocabulary is not None:
            out = [light_stem(w, self.vocabulary) for w in out]
        return out

class BM25:
    def __init__(self, k1=1.2, b=0.75, analyzer=None):
        self.k1, self.b = k1, b
        self.terms = analyzer or Analyzer()
```

Listing 29.1 (Continued) *bm25.py: an analyzer and the Okapi BM25 ranker.*

```
    def fit(self, docs):
        """docs: list of texts. Stores term frequencies and document lengths."""
        self.tf = [Counter(self.terms(d)) for d in docs]
        self.length = [sum(tf.values()) for tf in self.tf]
        self.avg_length = sum(self.length) / len(docs)
        self.n_docs = len(docs)
        self.df = Counter(t for tf in self.tf for t in tf)
        return self

    def idf(self, t):
        n = self.df[t]
        return math.log(1 + (self.n_docs - n + 0.5) / (n + 0.5))

    def score(self, query_terms, i):
        tf, norm = self.tf[i], self.length[i] / self.avg_length
        s = 0.0
        for t in query_terms:
            f = tf[t]
            if f:
                s += self.idf(t) * f * (self.k1 + 1) / (
                    f + self.k1 * (1 - self.b + self.b * norm))
        return s

    def rank(self, query):
        """All documents as (score, index), best first."""
        q = self.terms(query)
        return sorted(((self.score(q, i), i) for i in range(self.n_docs)),
                      key=lambda x: (-x[0], x[1]))
```

- `fit` stores, for every document, a `Counter` of its terms (the $f(t, d)$ of Equation (29.1)), its length, the average length, and the document frequency n_t of every term.
- `score` computes the sum of Equation (29.1) for one document. Terms of the query that do not occur in the document contribute nothing, so only the matching terms are visited.
- `rank` returns every document with its score, best first, breaking ties by position so that results are reproducible.

Listing 29.2 is the bot. Each card is indexed as its question written twice followed by its answer: the question is what customers' wording resembles most, so it counts double, but the answer adds useful words such as *QRIS* or *kilogram*.

Listing 29.2 `faqbot.py`: the FAQ bot, with a threshold and a polite handover.

                                 "do you deliver to my house",
                                 "boleh bayar pakai qris",
                                 "apakah menerima cuci mobil"]
    for q in questions:
        row, score = bot.ask(q)
        if row is None:                             # a crude language guess
            lang = "en" if set(words(q)) & {"do", "you", "the", "can"} else "id"
            answer = f"{FALLBACK[lang]} (best score {score:.2f})"
        else:
            answer = f"[{row['id']}] {row['answer']} (score {score:.2f})"
        print(f"Q: {q}")
        print(textwrap.fill(answer, 78, initial_indent="A: ",
                            subsequent_indent="   "))

if __name__ == "__main__":
    main()
```

```
python faqbot.py
```

```
Q: cucian saya bisa selesai sehari?
A: [f07] Cucian reguler selesai dalam dua sampai tiga hari kerja. Kami
   mengirim pesan saat cucian siap diambil. (score 7.98)
Q: do you deliver to my house
A: Sorry, I cannot answer that yet. Your question has been passed to our
   staff. (best score 0.00)
Q: boleh bayar pakai qris
A: [f06] Kami menerima tunai, transfer bank, dan QRIS dari semua dompet
   digital. (score 5.90)
Q: apakah menerima cuci mobil
A: Maaf, saya belum bisa menjawab. Pertanyaan Anda kami teruskan ke petugas
   outlet. (best score 3.25)
```

Two answers are right (QRIS payment) or rightly declined (car washing, which the laundry does not offer). One is declined although the FAQ covers it: “do you deliver to my house” shares no index term with the pickup card, because the card says *delivery*, not *deliver*, and the light stemmer of Section 29.7 only strips endings to reach a word that exists in the FAQ. And one is wrong: “cucian saya bisa selesai sehari?” (can my laundry be done in a day?) returns the regular-service card, because it shares *cucian* and *selesai* with it, while the express card says *satu hari* and *kilat*, not *sehari*. These are **vocabulary mismatches**, the central weakness of word-matching retrieval, and Exercise 29.4 attacks them.

29.5.1 One query, traced

Follow one query through Equation (29.1): “buka jam berapa kak”. The analyzer removes *kak* as a chat stop word, and the light stemmer turns *berapa* into *apa*, because *ber-* is a prefix and *apa* occurs in the FAQ. That is a false stem, since *berapa* (how much) is not *apa* (what) with a prefix, and it is a reminder that even a timid stemmer makes mistakes; here it happens to do no harm. The query terms are therefore *buka*, *jam* and *apa*.

The best card is the Indonesian opening-hours card f03. It is 18 terms long, almost exactly the average of 18.16, so the length factor is about 1 and each term’s fraction in Equation (29.1) is close to $rac{f(k_1 + 1)}{f + k_1}$:

- *buka* occurs in 1 of the 32 cards, so by Equation (29.2) its idf is $\ln(1 + 31.5/1.5) = \ln 22 pprox 3.091$; it occurs 3 times in the card (the question counts twice), and contributes 4.866, about 1.57 times its idf rather than 3 times, because of saturation;
- *jam* also has idf 3.091, occurs twice, and contributes 4.260;
- *apa* occurs in 7 cards, so its idf is only 1.482; it occurs twice and contributes 2.042.

The total is 11.17, which is the score `client.py` reported for the same question in Section 29.8. The next-best cards score only 2.23 and 2.11, so the decision is clear and far above the threshold of 5. A trace like this is the best way to understand a surprising answer: it shows which words carried the score, and whether a stop word, a false stem or a missing synonym was responsible.

29.6 Measuring It

Listing 29.3 compares four rankers on the 40 test questions: TF-IDF cosine as in Chapter 23, BM25 on the questions alone, BM25 on questions and answers, and BM25 with the improvements of Section 29.7. It then shows how the threshold of Equation (29.5) trades right answers against wrong ones and handovers, on the development and the test questions.

Listing 29.3 `evaluate.py`: top-1 accuracy and MRR of four rankers, and the threshold trade-off.

        5                   11     1      0          23     4     13
        6                   11     0      1          20     1     19
```

Read the first table with Equation (29.4) in mind.

- **Indexing the answers matters.** BM25 on questions alone reaches only 0.472 top-1; adding the answers raises it to 0.667, because answers contain words customers use (*QRIS*, *kilogram*, *Minggu*) that the short questions lack.
- **BM25 and TF-IDF tie on top-1** here (0.667), with BM25 slightly ahead on MRR (0.768 against 0.759). With cards this short, saturation and length normalization have little to work on; on collections of long, uneven documents the difference is usually larger, which is why BM25 became the standard [2].
- **Cleaning the query helps most.** Removing chat filler (*saya*, *kak*, *bisa*, *ya*, *my*, *you*) and light stemming raise top-1 to 0.750 and MRR to 0.830. Filler words do not only fail to help: they actively pull queries toward cards that happen to contain *bisa* or *my*.

29.6.1 Choosing the threshold

The second table and **Figure 29.2** show the trade-off of Equation (29.5) for the improved ranker. With $\theta = 0$ the bot answers everything: 27 of 40 test questions right and 13 wrong, including all four questions outside the FAQ. Raising the threshold converts wrong answers into handovers, but also converts some right answers into handovers. On the development questions, $\theta = 5$ and $\theta = 6$ both make the most right decisions (11 of 12); we take the lower one, which hands over fewer questions, and that is the value `faqbot.py` uses. On the test questions it gives 23 right, only 4 wrong, and 13 handed to staff.

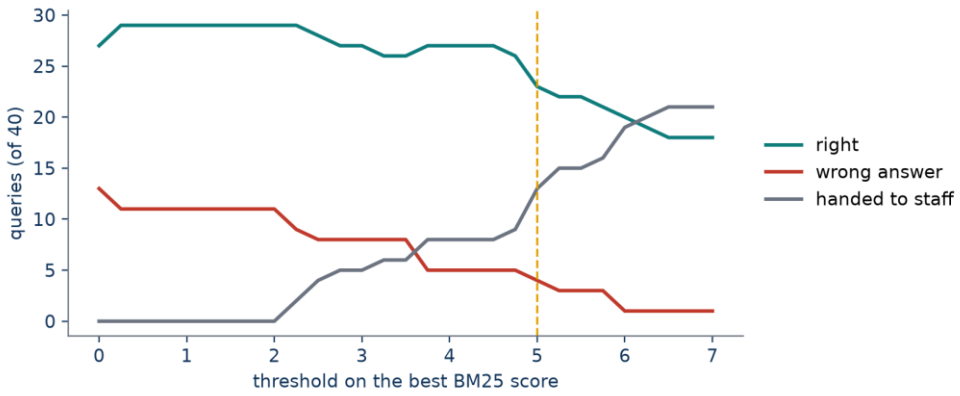

Figure 29.2 Right answers, wrong answers and handovers to staff on the 40 test questions as the threshold on the best BM25 score rises. The dashed line is the threshold chosen on the development questions.

Is that a good trade? For a laundry, a wrong answer about a price or a compensation rule can cause a real dispute, while a handover only costs a staff member a minute. Four wrong answers in

forty is still too many for comfort, which is one more reason to fix the vocabulary mismatches rather than to rely on the threshold alone. The threshold is chosen on development data, not on the test data, for the reason explained in Chapter 27: a parameter tuned on the test set makes the test result optimistic. With only 12 development questions the choice is rough; collecting a few hundred real questions would make it reliable.

29.7 Improving It

The improved analyzer in **Listing 29.1** does two things.

Chat stop words. The general stop list of Chapter 21 was built for news. Customer chat has its own filler: forms of address (*kak*, *mas*, *bu*), particles (*ya*, *dong*, *sih*), and words that appear in almost every question (*bisa*, *apakah*, *ada*, *my*, *you*, *how*, *what*). `CHAT_STOPWORDS` removes them from queries and cards alike.

Light stemming against the FAQ vocabulary. `light_stem` removes one common suffix (*-ing*, *-ed*, *-s*, *-kan*, *-nya*, *-an*) or prefix (*di-*, *me-*, *ber-*, *ter-*, *se-*), but only when the remainder is a word that occurs in the FAQ. This is the vocabulary check of Chapter 21's clitic splitter reused: *dijemput* becomes *jemput* because *jemput* appears in the FAQ, while *dian* stays *dian*. The stemmer is deliberately timid; an aggressive Indonesian stemmer would conflate more forms but also create false matches.

Both changes are general, written from knowledge of how customers write rather than from the test questions, and together they gained 3 more correct top answers out of 36.

What they cannot fix is a missing word: *sehari* is not a form of *satu hari*, and *sneakers* is not a form of *sepatu*. For that, a retrieval system needs either a **synonym list** maintained by the business (Exercise 29.4) or a representation of meaning rather than spelling, such as the embeddings of Chapter 54, which match "can I get it back in one day" to "express service" without sharing a word.

29.8 Serving the Bot on the Web

A bot is only useful where customers can reach it. **Listing 29.4** wraps it in a small Flask application [6]: a page with a form for people, and a JSON endpoint, `/api/ask?q=...`, for other programs such as a chat integration. The page template is `templates/index.html` in the chapter folder.

Listing 29.4 `app.py`: the FAQ bot as a web page and a JSON API.

```
"""app.py - the FAQ bot as a small web page and JSON API (Flask).

    python app.py        then open http://127.0.0.1:5029
"""
from flask import Flask, jsonify, render_template, request

from faqbot import FALLBACK, FaqBot, load_faq

app = Flask(__name__)
bot = FaqBot(load_faq())

def answer(question):
    row, score = bot.ask(question)
    if row is None:
        return {"id": None, "answer": FALLBACK["id"], "score": round(score, 2)}
    return {"id": row["id"], "answer": row["answer"], "score": round(score, 2)}

@app.get("/")
def page():
    q = request.args.get("q", "")
    return render_template("index.html", q=q, result=answer(q) if q else None)

@app.get("/api/ask")
def api():
    return jsonify(answer(request.args.get("q", "")))

if __name__ == "__main__":
    app.run(host="127.0.0.1", port=5029)
```

Start it with `python app.py` and open `http://127.0.0.1:5029` in a browser. From a second terminal, **Listing 29.5** asks the API two questions with Python's standard library alone:

Listing 29.5 `client.py`: asking the running API.

```
"""client.py - ask the running web API a question (start app.py first)."""
import json
import sys
import textwrap
import urllib.parse
import urllib.request

URL = "http://127.0.0.1:5029/api/ask?q="

for question in sys.argv[1:] or ["jam berapa buka", "do you sell washing machines"]:
    with urllib.request.urlopen(URL + urllib.parse.quote(question)) as reply:
        data = json.load(reply)
    print(f"Q: {question}   ->  id {data['id']}, score {data['score']}")
    print(textwrap.fill(data["answer"], 78, initial_indent="   ",
                        subsequent_indent="   "))
```

```
  python app.py            (first terminal; stop it with Ctrl+C)
  python client.py         (second terminal)
```

```
Q: jam berapa buka   ->  id f03, score 11.17
   Semua outlet buka setiap hari dari pukul 07.00 sampai 21.00, termasuk hari
   Minggu dan hari libur.
Q: do you sell washing machines   ->  id None, score 3.53
   Maaf, saya belum bisa menjawab. Pertanyaan Anda kami teruskan ke petugas
   outlet.
```

The server listens only on `127.0.0.1`, the local machine, which is right for development. Putting it on the internet safely, behind a real web server, with logging and rate limits, is the subject of

Chapters 91 and 92. Notice also that the handover message is always Indonesian, even for an English question: the language detector of Chapter 26 would fix that.

29.9 Testing

Listing 29.6 checks the idf of Equation (29.2) by hand, that repeated terms saturate below $(k_1 + 1)$ times a single occurrence as Equation (29.3) says, that the stemmer only stems to known words, that the bot answers a known question and declines an unrelated one, and that the web API returns the right card, using Flask's test client so that no server needs to run.

Listing 29.6 `tests/test_faqbot.py`: tests for BM25, the stemmer, the bot and the web API.

```
"""Run with:  python -m pytest -q"""
import math
import os
import sys

HERE = os.path.dirname(os.path.dirname(os.path.abspath(__file__)))
sys.path.insert(0, HERE)
os.chdir(HERE)
from bm25 import BM25, light_stem  # noqa: E402
from faqbot import FaqBot, load_faq  # noqa: E402

DOCS = ["harga cuci kiloan", "harga setrika", "jam buka outlet"]

def test_idf_by_hand():
    m = BM25().fit(DOCS)
    assert math.isclose(m.idf("harga"), math.log(1 + (3 - 2 + 0.5) / (2 + 0.5)))
    assert m.idf("jam") > m.idf("harga")          # rarer means heavier

def test_term_frequency_saturates():
    m = BM25(b=0).fit(["cuci", "cuci cuci", "cuci " * 50])
    s1, s2, s50 = (m.score(["cuci"], i) for i in range(3))
    assert s1 < s2 < s50 < s1 * (1.2 + 1)          # never more than (k1+1)x

def test_light_stem_needs_a_known_stem():
    assert light_stem("dicuci", {"cuci"}) == "cuci"
    assert light_stem("dian", {"cuci"}) == "dian"

def test_bot_answers_and_declines():
    bot = FaqBot(load_faq())
    assert bot.ask("jam berapa buka?")[0]["id"] == "f03"
    assert bot.ask("siapa pemenang piala dunia")[0] is None

def test_web_api():
    from app import app
    reply = app.test_client().get("/api/ask?q=bisa bayar pakai qris").get_json()
    assert reply["id"] == "f06"
```

```
python -m pytest -q
```

```
.....                                                                    [100%]
5 passed in 0.08s
```

29.10 Common Mistakes, and How to Avoid Them

Indexing questions only. Short questions miss many words customers use. *Avoid it:* index the answers as well, with the question weighted more, as `faqbot.py` does.

Answering everything. Without a threshold, the bot answers "who won the World Cup" with a laundry price. *Avoid it:* decline below a threshold chosen on development data, and hand over politely.

Tuning the threshold on the test set. *Avoid it:* keep development and test questions separate.

Ignoring vocabulary mismatch. *sehari* and *satu hari*, *deliver* and *delivery* never meet in a word-matching index. *Avoid it:* maintain a synonym list for the domain, stem carefully, or use embeddings.

Aggressive stemming. Cutting every *-an* turns *layanan* into *layan* and *jalan* into *jal*. *Avoid it:* only stem to words that exist in the collection.

Letting the bot improvise. A retrieving bot must only return approved answers. *Avoid it:* never edit or combine answers automatically; when the answer is not in the FAQ, a person replies, and the question is a candidate for a new FAQ entry.

Letting the cards go stale. Prices, hours and addresses change, and a bot that still quotes last year's price does more harm than no bot at all. *Avoid it:* give every card an owner and a review date, and read the handover log every week for questions that show a card is missing or out of date.

Exposing a development server. Flask's built-in server is for development. *Avoid it:* deploy behind a production server (Chapter 91).

29.11 Chapter Summary

- A **retrieval** FAQ bot returns the approved answer of the best-matching card; it never invents facts (**Listing 29.2**).
- **Okapi BM25** (Equation (29.1)) combines an idf (Equation (29.2)), a **saturating** term frequency (Equation (29.3)) and **length normalization**, with $k_1 = 1.2$ and $b = 0.75$ as common defaults (**Figure 29.1**, **Listing 29.1**).
- **Top-1 accuracy** and **mean reciprocal rank** (Equation (29.4)) measure ranking (**Listing 29.3**). Indexing answers, removing chat filler and light stemming raise top-1 from 0.472 to 0.750 on our 40 questions.
- A **threshold** (Equation (29.5)) decides when to hand a question to staff; it trades wrong answers against handovers and must be chosen on development data (**Figure 29.2**).
- **Vocabulary mismatch** remains the main weakness of word matching; synonym lists and embeddings address it.
- A few lines of Flask serve the bot as a web page and a JSON API (**Listing 29.4**, **Listing 29.5**).

29.12 Exercises

Exercise 29.1. Using the three cards of Section 29.3.4, compute the BM25 score of the query "harga setrika" for d_2 = "harga setrika".

Exercise 29.2. With $k_1 = 1.2$ and $b = 0$, a term occurs 1, 2, 5 and 100 times in a document. Compute the term-frequency part $\frac{f(k_1+1)}{f+k_1}$ for each and compare with Equation (29.3).

Exercise 29.3. For five test questions, the correct card is ranked 1, 1, 2, 4 and 10. Compute top-1 accuracy and MRR by Equation (29.4).

Exercise 29.4. Write a synonym list for the laundry domain and expand every query with the synonyms of its words before ranking. Measure top-1 and MRR with and without the list. What is the danger of judging the list on the same 40 test questions?

Exercise 29.5. Explain, using the second table of Section 29.6, why no threshold gives more than 29 right decisions out of 40, and what would have to change to do better.

Exercise 29.6. A customer writes "Kak, cucian saya yang kemarin sudah selesai belum? Atas nama Bu Dewi." The FAQ answers how to check an order, but the customer wants the status of *her* order. What should the bot do, and which chapters of this part would help?

29.13 Solutions to the Exercises

Solution 29.1. For *harga*: idf $=0.470$ (Section 29.3.4); for *setrika*: $n = 1$, idf $=\ln(1 + 2.5/1.5) \approx 0.981$. In d_2 both terms occur once and the relative length is 0.75, so each term's fraction is $2.2/1.975 \approx 1.114$. The score is $(0.470 + 0.981) \times 1.114 \approx 1.616$. The rare word *setrika* contributes about twice as much as *harga*.

Solution 29.2. $f = 1$: $2.2/2.2 = 1.000$. $f = 2$: $4.4/3.2 = 1.375$. $f = 5$: $11/6.2 \approx 1.774$. $f = 100$: $220/101.2 \approx 2.174$. The values approach $k_1 + 1 = 2.2$, as Equation (29.3) says; a hundred occurrences are worth barely more than twice one occurrence.

Solution 29.3. Top-1 accuracy is $2/5 = 0.4$. The reciprocal ranks are 1,1,0.5,0.25,0.1, summing to 2.85, so MRR $=2.85/5 = 0.57$. MRR gives partial credit for the question ranked second and very little for the one ranked tenth.

Solution 29.4. **Listing 29.7** expands each query by appending the synonyms of any listed word or phrase it contains, and wraps the index so that both the bot and the evaluation see the expanded query.

Listing 29.7 `solutions/synonyms.py`: query expansion with a synonym list.

```python
"""synonyms.py - Exercise 29.4: expand queries with a small synonym list."""
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from evaluate import load_queries, ranking_quality  # noqa: E402
from faqbot import FaqBot, load_faq  # noqa: E402

SYNONYMS = {"sehari": "satu hari kilat", "cepat": "kilat", "kilo": "kilogram",
            "kg": "kilogram", "dijemput": "jemput antar", "ambil": "jemput",
            "deliver": "delivery", "collect": "pickup", "sneakers": "sepatu",
            "bedcover": "bed cover", "alamat": "lokasi", "cabang": "outlet",
            "sobek": "rusak", "alergi": "sensitif", "track": "status",
            "sudah selesai": "status"}

def expand(query):
    q = query.lower()
    return q + " " + " ".join(v for k, v in SYNONYMS.items() if k in q)

class Expanding:
    """Wrap an index so that every query is expanded before ranking."""

    def __init__(self, index):
        self.inner = index

    def rank(self, query):
        return self.inner.rank(expand(query))

faq = load_faq()
test = load_queries("data/queries.tsv")
plain, synonyms = FaqBot(faq), FaqBot(faq)
synonyms.index = Expanding(synonyms.index)
for name, bot in (("without synonyms", plain), ("with synonyms", synonyms)):
    top, mrr = ranking_quality(bot, test)
    print(f"{name:<18} top-1 {top:.3f}   MRR {mrr:.3f}")
print(expand("cucian saya bisa selesai sehari?"))
```

```
python solutions/synonyms.py
```

```
without synonyms   top-1 0.750   MRR 0.830
with synonyms      top-1 0.861   MRR 0.931
cucian saya bisa selesai sehari? satu hari kilat
```

Top-1 rises from 0.750 to 0.861 and MRR from 0.830 to 0.931. But this list was written after reading the bot's mistakes on the test questions (*sehari*, *sneakers*, *bedcover*, *sobek*), so the gain is optimistic in exactly the way Chapter 22 warned about: the list is tuned to these 40 questions. The honest procedure is to build the list from past messages or from the development set, freeze it, and then measure on new questions. In daily use, the best source of synonyms is the handover log: every question the bot could not answer shows a word the list is missing.

Solution 29.5. Even with no threshold, the ranker puts the wrong card first for 9 of the 36 answerable questions and must answer the 4 outside the FAQ with some card; 27 right decisions are the starting point. A threshold can only turn answers into handovers; it cannot turn a wrong ranking into a right one. The best it achieves is 29, by declining two out-of-scope questions whose scores are near zero. To do better, the *ranking* must improve (synonyms, stemming, embeddings), so that the right card is first more often and the scores of right and wrong answers separate more clearly.

Solution 29.6. The bot should recognize that the question is about a specific order, not a general policy, and hand it to staff or to the order system, perhaps after replying with FAQ card f15 on how to check an order. The named-entity finder of Chapter 28 can extract “Bu Dewi” and “kemarin” to pre-fill the lookup, the topic classifier of Chapter 25 can route the message to the order-status desk, and the spell checker of Chapter 22 can clean the text first. The bot’s rule stays the same: it gives approved general answers, and anything about a person’s own order goes to a person or to a system that knows the order, never to a guess.

Chapter 30

Plagiarism Checker

Did someone copy this text? The question comes up for teachers reading essays, editors receiving articles, and businesses that find their product descriptions on a competitor's website. It also comes up inside computers, which must find duplicate web pages, repeated documents in a training corpus, and near-identical customer messages sent twice. This last chapter of Part 3 builds a checker that measures how much two texts share, shows the shared passages, and scales to large collections. By the end of it you will be able to cut a text into shingles; measure overlap with the Jaccard similarity and with containment; estimate Jaccard similarity from short MinHash signatures and know how accurate the estimate is; find similar pairs among many documents without comparing every pair, using locality-sensitive hashing; and state clearly what such a checker can and cannot detect, including paraphrase and translation.

30.1 Why Check for Copying?

Profitina Laundry publishes short care guides on its website: how to wash a kebaya, how to keep leather shoes new, how to remove a coffee stain. They take time to write well. A month later, a guide appears almost word for word on another laundry's blog. Was it copied? A person can see it by reading both side by side, but not across hundreds of pages. The same need, at a larger scale, faces every teacher who receives forty essays, every journal that receives manuscripts, and every search engine that must not show the same page ten times under ten addresses.

Copy detection is also a basic tool of data cleaning. The corpora used to train language models are full of duplicated pages, and duplicates make a model memorize text rather than learn from it, a danger that returns with the language models of Part 9. Finding near-duplicates among millions of documents is a standard step before training, and it uses exactly the techniques of this chapter: shingles, MinHash and locality-sensitive hashing, introduced by Andrei Broder and colleagues to find near-duplicate web pages for the AltaVista search engine [1], [2].

Detecting copying is not the same as judging it. Two texts can share phrases for innocent reasons: quotations, standard expressions, a common source. The checker measures and shows; a person reads the evidence and decides.

30.2 The Idea in Plain Words

Imagine cutting each text into overlapping strips of three words, like a becak driver noting every three-stop stretch of a route: "kebaya adalah pakaian", "adalah pakaian yang", "pakaian yang indah", and so on. Two routes that share many stretches probably follow the same road, even if they start at different places or take a detour in the middle. Two texts that share many three-word strips probably share wording, even if a few words were changed or the sentences were reordered.

The strips are called **shingles**, because they overlap like the shingles of a roof. The fraction of all strips that the two texts have in common is their **Jaccard similarity**. That is the whole checker for two documents.

For many documents a second idea is needed, because comparing every pair becomes impossible: a million documents make half a trillion pairs. **MinHash** summarizes each document's set of strips by a short list of numbers, its **signature**, such that two signatures agree in about the same fraction of positions as the two documents share strips. **Locality-sensitive hashing** then sorts the signatures into buckets so that similar documents tend to land in the same bucket, and only documents that share a bucket are compared.

Why not simply compare the texts character by character, or compute a fingerprint of each whole text and look for equal fingerprints? Because one changed word defeats both. A whole-text fingerprint of `kebaya_salin` shares nothing with that of `kebaya_asli`, although the two are almost the same; and an alignment of two long texts, as in the edit distance of Chapter 22, takes time proportional to the product of their lengths and still says nothing when sentences have been reordered. Shingles sit in between: small enough that a local change only affects the few shingles around it, large enough that two unrelated texts rarely share one by chance.

30.3 The Mathematics, Gently

30.3.1 Shingles and Jaccard similarity

A text of n words has at most

$$n - k + 1 \tag{30.1}$$

shingles of k words (one starting at each position that leaves room for k words); repeated shingles count once, because we keep a set. Let A and B be the shingle sets of two texts. Their **Jaccard similarity** is

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|} \tag{30.2}$$

the number of shared shingles divided by the number of distinct shingles in either text. It is 1 for identical sets, 0 for disjoint ones, and it does not depend on the order of the sentences, since a shingle is found wherever it occurs. When one text may be a part of another, a better question is "how much of A is found in B?", the **containment**

$$C(A, B) = \frac{|A \cap B|}{|A|} \tag{30.3}$$

which is 1 when all of A appears in B, however long B is [1].

A small example with $k = 3$: "kebaya dicuci dengan tangan" has the shingles *kebaya dicuci dengan* and *dicuci dengan tangan*; "kebaya dicuci dengan mesin" has *kebaya dicuci dengan* and *dicuci dengan mesin*. One shingle is shared and three are distinct, so $J = 1/3$. Changing a single word removed two of the four shingles from the intersection: every changed word breaks up to k shingles. That is why k controls sensitivity; larger k makes the measure stricter.

30.3.2 MinHash

Pick a hash function h that gives each shingle a pseudo-random number, and for a set A record $\min_{x \in A} h(x)$, the smallest value over its shingles. The remarkable fact is

$$P\left[\min_{x\in A} h(x) = \min_{x\in B} h(x)\right] = J(A,B) \tag{30.4}$$

Why? Consider the union $A \cup B$. Under a random hash function, each of its elements is equally likely to be the one with the smallest value. If that element lies in $A \cap B$, it is the minimum of both A and B, and the two minima are equal. If it lies in only one of the sets, it is the minimum of that set but not of the other, and (with no ties) the minima differ. So the probability that the minima agree is the fraction of the union that lies in the intersection, which is exactly Equation (30.2).

One hash function gives a single yes-or-no observation. With n independent hash functions $h_1, \ldots, h_n$, the **signature** of A is the list of its n minima, and the fraction of positions where two signatures agree estimates the Jaccard similarity:

$$\hat{J} = \frac{1}{n}\sum_{i=1}^{n} [\mathrm{sig}_A(i) = \mathrm{sig}_B(i)] \tag{30.5}$$

Each position agrees with probability J, so $\hat{J}$ is an average of n coin flips, and, as for the accuracy of Chapter 25, its standard error is

$$\mathrm{SE}(\hat{J}) = \sqrt{\frac{J(1-J)}{n}} \tag{30.6}$$

With $n = 128$ and $J = 0.5$, the error is about 0.044. Four times as many hash functions halve the error. A signature of 128 numbers replaces a set of hundreds or thousands of shingles, whatever the length of the text [3].

30.3.3 A family of hash functions

We need many different hash functions that behave randomly. A classic construction first turns each shingle into an integer x with an ordinary hash (we use CRC-32, which, unlike Python's built-in `hash`, gives the same number on every run), then applies

$$h_{a,b}(x) = (ax + b) \bmod p \tag{30.7}$$

with a large prime p and random integers $a \neq 0$ and b [4]. Every pair (a, b), drawn once from a seeded random generator, gives a new hash function. We use the Mersenne prime $p = 2^{61} - 1$, far larger than any CRC-32 value.

30.3.4 Locality-sensitive hashing

Comparing signatures is cheap, but comparing all pairs is still quadratic. **LSH** avoids it [3], [5]. Divide each signature into b **bands** of r rows each ($n = b \times r$). For each band, put every document into a bucket keyed by its r values in that band. Two documents become a **candidate pair** if they fall into the same bucket for at least one band. For two documents with Jaccard similarity s, one band agrees completely with probability s^r, so it fails with probability $1 - s^r$, all b bands fail with probability $(1 - s^r)^b$, and

$$P(\text{candidate}) = 1 - (1 - s^r)^b \tag{30.8}$$

As a function of s, this is an S-shaped curve: nearly 0 for dissimilar pairs, nearly 1 for similar ones, with the steep part near the **threshold**

$$t \approx \left(\frac{1}{b}\right)^{1/r} \tag{30.9}$$

With $b = 20$ bands of $r = 5$ rows, $t \approx (1/20)^{1/5} \approx 0.55$. Choosing b and r moves the threshold: more rows per band make it stricter, more bands make it more lenient. **Figure 30.2** (right) draws the curve for three choices.

30.4 The Data

`data/essays` holds eight short care guides written for this chapter:

- `kebaya_asli`, an original guide to caring for a kebaya, in Indonesian;
- `kebaya_salin`, a copy with a few words changed (*pakaian* to *busana*, *terbaik* to *paling baik*) and the last sentence dropped;
- `kebaya_campur`, which copies the first three sentences and continues with new text about batik;
- `kebaya_parafrasa`, the same advice rewritten in different words;
- `kebaya_english`, an English translation of the original;
- `sepatu_kulit` and `shoes_original`, guides to leather shoes in Indonesian and English;
- `shoes_rewritten`, the English shoe guide with its sentences reordered and two small edits.

For the scale experiment of Section 30.7, `lsh_demo.py` also uses the 96 news items of Chapter 21.

30.5 Building the Checker

Listing 30.1 implements Equation (30.2) and Equation (30.3), with shingles of words from the tokenizer of Chapter 21 and, for Exercise 30.4, of characters.

Listing 30.1 `shingles.py`: word and character shingles, Jaccard similarity and containment.

```
"""shingles.py - k-word shingles and Jaccard similarity."""
from tokenizer import words

def shingles(text, k=3):
    """The set of all runs of k consecutive (lowercased) words."""
    ws = words(text)
    return {" ".join(ws[i:i + k]) for i in range(len(ws) - k + 1)}

def char_shingles(text, k=5):
    """The set of all runs of k characters, spaces normalized."""
    s = " ".join(words(text))
    return {s[i:i + k] for i in range(len(s) - k + 1)}

def jaccard(a, b):
    """|A ∩ B| / |A ∪ B|; two empty sets count as identical."""
    if not a and not b:
        return 1.0
    return len(a & b) / len(a | b)

def containment(a, b):
    """|A ∩ B| / |A|: how much of A is found in B."""
    return len(a & b) / len(a) if a else 0.0
```

Listing 30.2 implements Sections 30.3.2 to 30.3.4.

Listing 30.2 `minhash.py`: MinHash signatures with a seeded hash family, the Jaccard estimate, and LSH banding.

```
"""minhash.py - MinHash signatures and locality-sensitive hashing (LSH)."""
import random
import zlib
from collections import defaultdict

PRIME = (1 << 61) - 1                    # a Mersenne prime, larger than any hash

def stable_hash(s):
    """Python's hash() changes between runs; crc32 does not."""
    return zlib.crc32(s.encode("utf-8"))

class MinHasher:
    def __init__(self, n_hashes=128, seed=30):
        rng = random.Random(seed)
        self.params = [(rng.randrange(1, PRIME), rng.randrange(0, PRIME))
                       for _ in range(n_hashes)]

    def signature(self, shingle_set):
        """For each hash function, the smallest hash value over the set."""
        xs = [stable_hash(s) for s in shingle_set]
        return [min((a * x + b) % PRIME for x in xs) for a, b in self.params]

def estimate(sig_a, sig_b):
    """Share of positions where two signatures agree: an estimate of Jaccard."""
    return sum(x == y for x, y in zip(sig_a, sig_b)) / len(sig_a)

def lsh_candidates(signatures, bands, rows):
    """Pairs of documents that agree completely on at least one band."""
    assert bands * rows <= len(next(iter(signatures.values())))
    candidates = set()
    for band in range(bands):
        buckets = defaultdict(list)
        for doc, sig in signatures.items():
            key = tuple(sig[band * rows:(band + 1) * rows])
            buckets[key].append(doc)
        for docs in buckets.values():
            for i in range(len(docs)):
                for j in range(i + 1, len(docs)):
                    candidates.add(tuple(sorted((docs[i], docs[j]))))
    return candidates
```

- `MinHasher.__init__` draws the (a, b) pairs of Equation (30.7) once, with a fixed seed, so that signatures computed on different days or machines can be compared.
- `signature` hashes every shingle with CRC-32 and, for each hash function, keeps the minimum.
- `estimate` is Equation (30.5).
- `lsh_candidates` cuts every signature into bands, uses each band's values as a dictionary key, and reports every pair that shares a bucket in some band.

Listing 30.3 compares every pair of essays in a folder. For each pair it prints the exact Jaccard similarity, the MinHash estimate, and the containment of the first text in the second, and it flags pairs above 0.30. For the most similar pair it prints the shared passages: stretches of text in which every consecutive shingle also occurs in the other text.

Listing 30.3 `check.py`: pairwise comparison of a folder of essays, with shared passages.

```
"""check.py - compare every pair of essays and show what they share."""
import glob
import os
import sys
import textwrap

from minhash import MinHasher, estimate
from shingles import containment, jaccard, shingles
from tokenizer import words

FLAG = 0.30

def shared_passages(text_a, text_b, k=3):
    """Runs of consecutive k-shingles of text_a that all occur in text_b,
    returned as the stretches of text they cover."""
    ws, other = words(text_a), shingles(text_b, k)
    shared = [" ".join(ws[i:i + k]) in other for i in range(len(ws) - k + 1)]
    runs, start = [], None
    for i, s in enumerate(shared + [False]):
        if s and start is None:
            start = i
        elif not s and start is not None:
            runs.append(" ".join(ws[start:i - 1 + k]))
            start = None
    return runs

def main():
    folder = sys.argv[1] if len(sys.argv) > 1 else "data/essays"
    texts = {}
    for path in sorted(glob.glob(os.path.join(folder, "*.txt"))):
        with open(path, encoding="utf-8") as f:
            texts[os.path.basename(path)[:-4]] = f.read()
    sets = {name: shingles(t) for name, t in texts.items()}
    hasher = MinHasher()
    sigs = {name: hasher.signature(s) for name, s in sets.items()}
```

Listing 30.3 (Continued) *check.py: pairwise comparison of a folder of essays, with shared passages.*

```
    names = sorted(texts)
    pairs = [(jaccard(sets[a], sets[b]), a, b)
             for i, a in enumerate(names) for b in names[i + 1:]]
    print(f"{'pair':<38}{'Jaccard':>8}{'MinHash':>9}{'A in B':>8}")
    for j, a, b in sorted(pairs, reverse=True)[:8]:
        flag = "  <--" if j >= FLAG else ""
        print(f"{a + ' / ' + b:<38}{j:>8.3f}{estimate(sigs[a], sigs[b]):>9.3f}"
              f"{containment(sets[a], sets[b]):>8.3f}{flag}")

    j, a, b = max(pairs)

                            subsequent_indent="   "))

if __name__ == "__main__":
    main()
```

30.6 Running It

```
python check.py
```

```
pair                                  Jaccard  MinHash  A in B
shoes_original / shoes_rewritten        0.766    0.781   0.864  <--
kebaya_asli / kebaya_salin              0.731    0.719   0.792  <--
kebaya_asli / kebaya_campur             0.228    0.234   0.342
kebaya_campur / kebaya_salin            0.205    0.188   0.347
kebaya_parafrasa / sepatu_kulit         0.005    0.008   0.010
kebaya_salin / sepatu_kulit             0.005    0.008   0.010
kebaya_parafrasa / kebaya_salin         0.005    0.008   0.010
kebaya_asli / sepatu_kulit              0.005    0.008   0.008

longest shared passages of shoes_original and shoes_rewritten:
  "for stubborn stains a professional shoe cleaning service can clean them
   without damaging the leather"
  "if the shoes get wet in the rain stuff them with newspaper and let them dry
   at room temperature never next to a fire or a heater"
```

The two flagged pairs are the two copies. `shoes_rewritten` reaches $J = 0.766$ although every sentence was moved: shingles do not care about order, only a few shingles at the new sentence boundaries are lost. `kebaya_salin` reaches 0.731: the original has 120 shingles and the copy 105, 95 of them shared, so by Equation (30.2) $J = 95/130 = 0.731$, and $95/120 = 0.792$ of the original is contained in the copy. The MinHash estimates with 128 hash functions are within 0.02 of the exact values, as Equation (30.6) predicts: for $J = 0.73$ the standard error is $\sqrt{0.73 \times 0.27/128} \approx 0.039$.

`kebaya_campur`, which copies three of its eight sentences, gets only $J = 0.228$, below the flag. Here Jaccard is the wrong question: the union includes all the new batik text, which dilutes the overlap. Containment asks the right question. The program prints the share of the *first* file found in the second, 0.342 of the original; the share of the mixed essay found in the original is $41/101 = 0.406$. A reviewer who wants to know "how much of this submission comes from elsewhere" should look at containment, not at Jaccard.

Figure 30.1 shows the whole picture. Everything else is near zero, including two pairs that *are* the same content: the paraphrase (`kebaya_parafrasa`) shares only one shingle in two hundred with the original, and the English translation shares none. Shingle-based checking finds copied *wording*; it is blind to copied *ideas*.

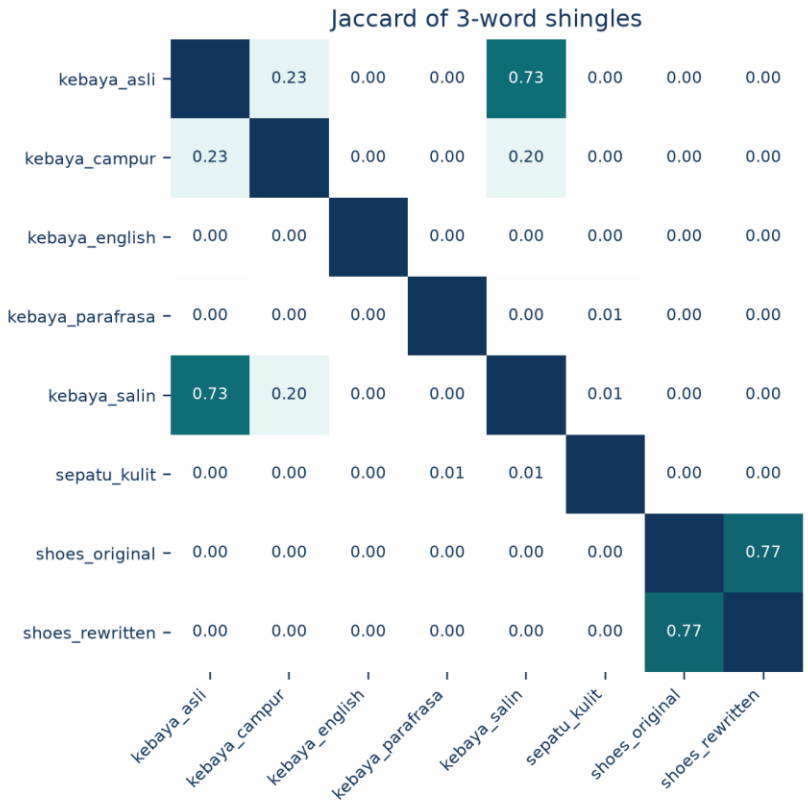

Figure 30.1 Jaccard similarity of 3-word shingles for every pair of the eight essays. Only the near-verbatim copies stand out; the paraphrase and the translation look unrelated.

The shared passages printed at the end are what a person needs in order to judge: two long runs, each a whole sentence of the shoe guide, found in the rewritten version. Showing the evidence, rather than only a percentage, is what makes a checker useful and fair.

30.7 Scaling Up with LSH

Eight essays make 28 pairs. **Listing 30.4** builds a larger test: the 96 news items plus 24 altered copies of randomly chosen items, in which 5%, 10%, 20% or 40% of the words are replaced by random words from the corpus. It computes the exact Jaccard similarity of all 7,140 pairs as the ground truth, then asks LSH with 20 bands of 5 rows which pairs are candidates.

Listing 30.4 `lsh_demo.py`: near-duplicate search with LSH among 120 texts.

```
"""lsh_demo.py - find near-duplicates among 120 texts without comparing all."""

```

```
120 texts, 7140 pairs; 7 pairs have Jaccard >= 0.5
LSH (20 bands x 5 rows) proposed 8 candidate pairs
  found 7 of the 7 similar pairs, 1 candidates below 0.5
changed words  mean Jaccard to source  found by LSH
           5%                   0.75         5 of 6
          10%                   0.51         3 of 6
          20%                   0.34         0 of 6
          40%                   0.09         0 of 6
time: all pairs 0.018 s, signatures + LSH 0.059 s
largest MinHash error on the candidates: 0.050
```

Of 7,140 pairs, LSH proposes only 8 candidates, and those 8 include all 7 pairs whose Jaccard similarity is at least 0.5. Only one candidate falls below 0.5. The table explains what "similar" means for 3-word shingles: replacing 5% of the words keeps a mean Jaccard of 0.75, 10% keeps 0.51, and 20% already drops it to 0.34, because every changed word destroys up to three shingles. The copies with 20% and 40% changes are therefore not found; with a threshold near 0.55 they are not supposed to be. To catch them, choose b and r with a lower threshold by Equation (30.9), at the price of more candidates to check.

The timing line needs an honest reading. For 120 texts, comparing all pairs directly is actually *faster* than computing signatures, because 7,140 small set operations take a fraction of a second. LSH pays off at scale: the number of pairs grows with the square of the number of documents, while signatures and buckets grow linearly. At a million documents there are about 5×10^{11} pairs, far too many to compare, while computing a million signatures and bucketing them is routine. The same design finds near-duplicates in web crawls and training corpora [3].

Figure 30.2 shows the two quantitative promises of this chapter checked against reality. On the left, the error of the MinHash estimate for the pair `kebaya_asli`–`kebaya_campur` ($J = 0.228$), measured over 40 random seeds for each signature length, follows the curve of Equation (30.6). On the right, the S-curves of Equation (30.8) for three band settings.

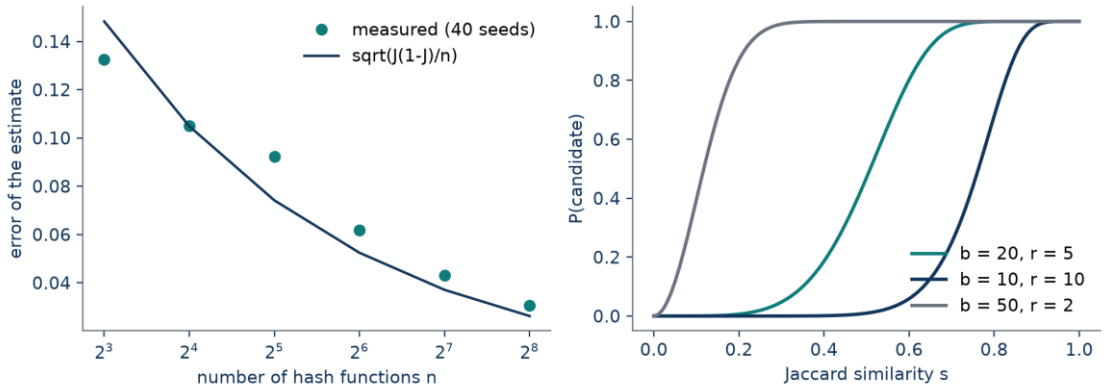

Figure 30.2 Left: the error of the MinHash estimate falls as the square root of the number of hash functions, as predicted. Right: the probability that a pair becomes an LSH candidate as a function of its Jaccard similarity, for three choices of bands and rows.

30.8 Improving It and Knowing Its Limits

Normalize before shingling. Lowercasing and dropping punctuation, as `words` does, already stops trivial evasions. Further steps help: removing stop words makes shingles out of content words only, and mapping digits and simple spelling variants to one form defeats changes such as *5.000* to *lima ribu*.

Choose k for the task. Large k (5 to 10 words) finds long copied passages with very few accidental matches; small k finds shorter overlaps but also shared idioms. Characters instead of words are more robust to small edits but raise every similarity, as Exercise 30.4 shows.

Report containment and passages. A single percentage invites misuse. Reporting where the shared text is, and how much of each document it covers, lets a person judge whether it is quotation, common phrasing or copying.

Know what it cannot see. Paraphrase and translation leave no shared shingles. Detecting them needs representations of meaning: the embeddings of Chapter 54 compare texts by content, and multilingual embeddings compare across languages. Research evaluations of plagiarism detection treat these "obfuscated" and cross-language cases as the hard ones [6].

Mind the people. A similarity score is evidence, not a verdict. In a school or a company, the person whose text is flagged should see the shared passages and have the chance to explain; common sources, quotations and templates are legitimate reasons for overlap.

30.8.1 Choosing k, measured

How much does the choice of k matter? **Table 30.1** compares the original kebaya guide with four other essays for shingle sizes from 1 to 7 words.

Table 30.1 Jaccard similarity of `kebaya_asli` with four other essays for shingles of k words.

k	Copy (`salin`)	Mixed (`campur`)	Paraphrase	Unrelated (`sepatu_kulit`)
1	0.839	0.381	0.178	0.143
2	0.773	0.235	0.037	0.010
3	0.731	0.228	0.005	0.005
4	0.702	0.223	0.000	0.000
5	0.674	0.219	0.000	0.000
7	0.619	0.210	0.000	0.000

Single words ($k = 1$) are too forgiving: an unrelated text about shoes already scores 0.143, because both texts use *dan*, *yang*, *dengan* and *agar*. From $k = 3$ on, unrelated texts drop to zero, while the copy stays high. Larger k lowers the copy's score slowly, since each of the few changed words now breaks more shingles, but the gap between copy and unrelated text remains wide. The mixed essay changes little with k, because its copied part is three whole sentences and its new part shares nothing. Values between 3 and 5 are the usual choice for word shingles, and the table shows why: they are the smallest values at which chance overlap disappears.

30.9 Testing

Listing 30.5 checks the shingles and Jaccard of the small example of Section 30.3.1, that MinHash gives exactly 1 for identical sets and a close estimate of 1/3 for two overlapping sets, and that LSH makes identical documents, and only those, a candidate pair.

Listing 30.5 `tests/test_plagiarism.py`: tests for shingles, MinHash and LSH.

```
"""Run with:  python -m pytest -q"""
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from minhash import MinHasher, estimate, lsh_candidates  # noqa: E402
from shingles import jaccard, shingles  # noqa: E402

def test_shingles_and_jaccard_by_hand():
    a = shingles("kebaya dicuci dengan tangan")
    b = shingles("kebaya dicuci dengan mesin")
    assert a == {"kebaya dicuci dengan", "dicuci dengan tangan"}
    assert jaccard(a, b) == 1 / 3

def test_minhash_estimates_jaccard():
    a = {f"s{i}" for i in range(100)}
    b = {f"s{i}" for i in range(50, 150)}             # true Jaccard 1/3
    h = MinHasher(n_hashes=400)
    assert estimate(h.signature(a), h.signature(a)) == 1.0
    assert abs(estimate(h.signature(a), h.signature(b)) - 1 / 3) < 0.08

def test_lsh_puts_identical_documents_together():
    h = MinHasher(n_hashes=20)
    sigs = {"x": h.signature({"a b c"}), "y": h.signature({"a b c"}),
            "z": h.signature({"p q r"})}
    assert lsh_candidates(sigs, bands=4, rows=5) == {("x", "y")}
```

```
python -m pytest -q
```

```
...                                                                      [100%]
3 passed in 0.06s
```

30.10 Common Mistakes, and How to Avoid Them

Using Python's `hash` for signatures. It is randomized per process, so signatures computed in different runs do not match. *Avoid it:* use a stable hash such as CRC-32 and a seeded hash family.

Judging partial copies by Jaccard. New text around a copied passage dilutes Jaccard. *Avoid it:* report containment (Equation (30.3)) as well.

Too few hash functions. With 16 hash functions, the error of Equation (30.6) is about 0.12, enough to misjudge a borderline pair. *Avoid it:* use at least 100 to 200, and compute the exact Jaccard for the candidates that matter.

Setting LSH bands without looking at the threshold. *Avoid it:* compute t with Equation (30.9) and draw the curve of Equation (30.8) for your choice.

Believing a low score proves originality. Paraphrases and translations score near zero. *Avoid it:* say what the method measures, which is shared wording.

Reporting a number without evidence. *Avoid it:* show the shared passages, as `check.py` does, and let a person decide.

30.11 Chapter Summary

- A text becomes a set of **shingles** (Equation (30.1)); **Jaccard similarity** (Equation (30.2)) measures shared wording regardless of order, and **containment** (Equation (30.3)) measures how much of one text is inside another (**Listing 30.1**).
- **MinHash**: the minima of a random hash agree with probability equal to the Jaccard similarity (Equation (30.4)); a signature of n minima estimates it (Equation (30.5)) with error $\sqrt{J(1-J)/n}$ (Equation (30.6)), using a seeded family $(ax + b) \bmod p$ (Equation (30.7), **Listing 30.2**).
- **LSH** with b bands of r rows makes a pair a candidate with probability $1-(1-s^r)^b$ (Equation (30.8)), an S-curve with threshold near $(1/b)^{1/r}$ (Equation (30.9), **Figure 30.2**); it finds similar pairs without comparing all pairs (**Listing 30.4**).
- On our essays, copies and reordered copies score above 0.7, a partial copy is revealed by containment, and paraphrase and translation are invisible (**Listing 30.3**, **Figure 30.1**).
- A checker measures and shows evidence; people judge.

This chapter closes Part 3. Over ten chapters we cut text into tokens, corrected it, weighed its words, summarized it, classified it, recognized its language, generated it, found names in it, retrieved answers from it and compared it. Every method worked on the surface of words and characters, and every chapter met the same boundary: words that differ but mean the same. Part 4 crosses that boundary with neural networks, which learn representations of meaning from data.

30.12 Exercises

Exercise 30.1. Compute the 3-word shingles and the Jaccard similarity of "cuci kering jas dua potong" and "cuci kering jas satu potong". How would the answer change with $k = 2$?

Exercise 30.2. Two documents have Jaccard similarity 0.8. With 64 hash functions, what is the standard error of the MinHash estimate by Equation (30.6)? How many hash functions are needed to bring it below 0.02?

Exercise 30.3. With 100 hash functions, compare $b = 20, r = 5$ with $b = 10, r = 10$. Compute the threshold by Equation (30.9) and the candidate probability by Equation (30.8) for pairs with $s = 0.4$ and $s = 0.8$. Which setting would you choose to find copies with 20% of the words changed?

Exercise 30.4. Write a program that compares `kebaya_asli` with the copy, the mixed essay, the paraphrase, the translation and the unrelated shoe guide, using 3-word shingles, 5-character shingles and single words. Which measure separates the paraphrase from the unrelated text best, and at what cost?

Exercise 30.5. Prove that the Jaccard similarity of two texts does not change when the sentences of one of them are reordered, except for the shingles that cross sentence boundaries. How many shingles can a reordering of m sentences change at most?

Exercise 30.6. Profitina Laundry wants to detect customers who post the same review text on several accounts. Describe a system with the tools of this chapter, and say which parameters you would choose and why.

30.13 Solutions to the Exercises

Solution 30.1. The first text has the shingles *cuci kering jas*, *kering jas dua*, *jas dua potong*; the second *cuci kering jas*, *kering jas satu*, *jas satu potong*. One is shared, five are distinct, so $J = 1/5 =$

0.2. With $k = 2$ the shingles are *cuci kering*, *kering jas*, *jas dua*, *dua potong* against *cuci kering*, *kering jas*, *jas satu*, *satu potong*: two shared out of six distinct, $J = 1/3$. Smaller k is more forgiving of a changed word, because each word takes part in fewer shingles.

Solution 30.2. SE $= \sqrt{0.8 \times 0.2/64} = \sqrt{0.0025} = 0.05$. For SE < 0.02 we need $0.16/n < 0.0004$, so $n > 400$.

Solution 30.3. For $b = 20, r = 5$: $t \approx 0.05^{0.2} \approx 0.55$; at $s = 0.4$, $s^5 = 0.0102$ and $P = 1 - 0.9898^{20} \approx 0.19$; at $s = 0.8$, $s^5 = 0.328$ and $P = 1 - 0.672^{20} \approx 0.9996$. For $b = 10, r = 10$: $t \approx 0.1^{0.1} \approx 0.79$; at $s = 0.4$, $s^{10} \approx 0.0001$ and $P \approx 0.001$; at $s = 0.8$, $s^{10} = 0.107$ and $P = 1 - 0.893^{10} \approx 0.68$. Copies with 20% of the words changed have Jaccard around 0.34 (Section 30.7), below both thresholds; neither setting finds them reliably. A lower threshold, such as $b = 50, r = 2$ with $t \approx 0.14$, would find them, together with many more candidates, which then need exact checking.

Solution 30.4. **Listing 30.6** computes the three measures for each pair.

Listing 30.6 `solutions/char_vs_word.py`: 3-word shingles, 5-character shingles and single words compared.

```
"""char_vs_word.py - Exercise 30.4: word shingles against character shingles."""
import os
import sys

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from shingles import char_shingles, jaccard, shingles  # noqa: E402

def read(name):
    with open(f"data/essays/{name}.txt", encoding="utf-8") as f:
        return f.read()

base = read("kebaya_asli")
print(f"{'kebaya_asli compared with':<26}{'3 words':>9}{'5 chars':>9}"
      f"{'1 word':>8}")
for other in ("kebaya_salin", "kebaya_campur", "kebaya_parafrasa",
              "kebaya_english", "sepatu_kulit"):
    text = read(other)
    print(f"{other:<26}{jaccard(shingles(base), shingles(text)):>9.3f}"
          f"{jaccard(char_shingles(base), char_shingles(text)):>9.3f}"
          f"{jaccard(shingles(base, 1), shingles(text, 1)):>8.3f}")
```

```
python solutions/char_vs_word.py
```

```
kebaya_asli compared with   3 words  5 chars  1 word
kebaya_salin                  0.731    0.807   0.839
kebaya_campur                 0.228    0.346   0.381
kebaya_parafrasa              0.005    0.159   0.178
kebaya_english                0.000    0.009   0.006
sepatu_kulit                  0.005    0.111   0.143
```

With 3-word shingles, the paraphrase (0.005) and the unrelated shoe guide (0.005) are indistinguishable. Character shingles and single words raise the paraphrase to 0.159 and 0.178, but they also raise the unrelated text to 0.111 and 0.143, because any two Indonesian texts share common words and letter sequences. The gap between paraphrase and unrelated text grows only slightly, while the gap between copy and everything else shrinks. Smaller units trade precision for recall; none of them really detects paraphrase, and all of them miss the translation.

Solution 30.5. A shingle lies either entirely inside one sentence or across the boundary between two consecutive sentences (with $k = 3$, a boundary shingle contains the last one or two words of one sentence and the first words of the next). Reordering sentences keeps every sentence intact, so every inner shingle survives; only boundary shingles can change. Each of the $m - 1$ boundaries carries $k - 1$ shingles, so at most $(m - 1)(k - 1)$ shingles change, $2(m - 1)$ for $k = 3$. For the six-sentence shoe guide that is at most 10 of about 110 shingles, which is why `shoes_rewritten` still scores 0.766.

Solution 30.6. Treat each review as a document; normalize it (lowercase, remove punctuation and emoji); take 3-word shingles, since reviews are short; compute MinHash signatures with about 128 functions; and bucket them with LSH at a fairly high threshold, such as $b = 16, r = 8$ ($t \approx 0.71$), because identical or near-identical texts are what we are looking for and a high threshold keeps unrelated short reviews ("bersih dan cepat, recommended") from colliding. For each candidate pair, compute the exact Jaccard similarity and report pairs above, say, 0.8 whose accounts differ, together with the shared text. Short generic reviews will still collide, so a person should review the flagged accounts before any action is taken, and the reviews themselves, not personal details of the accounts, are what the system needs to store.

Chapter 31

Perceptron from Scratch

This chapter opens Part 4 of the book, *Neural Networks*, the ten chapters in which our programs stop following rules we wrote and start adjusting thousands of small numbers until they behave well on their own. We begin with the smallest possible neural network: one artificial neuron, the *perceptron*. By the end of the chapter you will be able to explain in plain words what a perceptron computes, write the weighted sum and the learning rule as equations and work them by hand, program a complete perceptron in about thirty lines of Python with NumPy, use it in a small application that sorts iris flowers from two measurements, see with your own eyes why a single perceptron can never learn the XOR function, and make the perceptron behave sensibly on data that no straight line can separate, with the *pocket* and *averaged* variants. Everything runs in under two seconds on an ordinary laptop.

31.1 Why Start with One Neuron?

Imagine a small flower stall at Pasar Bunga Kayoon in Surabaya. Every morning a wholesaler drops off crates of irises, and two varieties arrive mixed together: a small one with short, narrow petals and a larger one with long, broad petals. The stall keeper sorts them by eye. She does not measure anything; after years of practice she simply *knows*. If we asked her how she decides, she might say: “Long petals and wide petals, that is the big one. Short and narrow, the small one.” That sentence is already an algorithm. It says: look at two numbers, give each of them some importance, add them up, and compare the total with a threshold.

A perceptron is exactly that sentence written as arithmetic. It looks at a few numbers, multiplies each by a *weight* that says how much the number matters, adds the products, and answers “yes” if the total is big enough and “no” otherwise. What makes it interesting, and what made it front-page news in 1958, is that nobody has to choose the weights. The perceptron finds them itself, by looking at examples and nudging the weights a little every time it gets an example wrong [1].

Why spend a whole chapter on something so small, when later chapters build networks with millions of weights? Because every one of those large networks is made of units that do almost exactly what a perceptron does: a weighted sum followed by a simple function [2]. The ideas you meet here, *weights*, *bias*, *learning rate*, *epoch*, *training error*, *decision boundary*, *linear separability*, return in every chapter of Part 4. If you understand them with four data points that you can check with a pencil, the large networks will hold no mystery. And the one thing a single perceptron *cannot* do, which we will discover in Section 31.5, is precisely the reason the next chapter stacks neurons in layers.

31.2 The Idea in Plain Words

Let us describe the perceptron without any mathematics first, as if explaining it to a friend at a warung.

The perceptron receives a short list of numbers about one thing. For a flower these might be petal length and petal width in centimeters. For a laundry order they might be weight in kilograms and number of stained items. These numbers are called the *inputs* or *features*.

Next to every input the perceptron keeps one more number, its *weight*. A large positive weight means "when this input is large, lean toward yes". A negative weight means "when this input is large, lean toward no". A weight near zero means "I do not care much about this input".

The perceptron multiplies every input by its weight and adds everything up. It also adds one extra number that does not belong to any input, the *bias*. The bias is the perceptron's general mood: a large negative bias makes it hard to say yes, a positive one makes it easy.

Finally, the perceptron looks at the total. If the total is zero or more, it answers 1 ("yes", "fire", "big flower"). If the total is negative, it answers 0. This on-off decision is called the *step function*, because its graph looks like a single stair step.

That is how a perceptron *answers*. How does it *learn*? We show it an example whose correct answer we know. If its answer is right, we change nothing. If it said 0 but should have said 1, the total was too small, so we raise every weight a little in the direction of its input (and raise the bias). If it said 1 but should have said 0, we lower them. Then we move to the next example. One pass through all the examples is called an *epoch*. We keep going, epoch after epoch, until a whole epoch passes without a single mistake, or until we run out of patience.

Figure 31.1 draws the whole thing. The circles on the left are the inputs, including a constant input 1 that carries the bias; the arrows carry the weights; the dark circle adds; the box applies the step; and $\hat{y}$ (read "y hat") on the right is the perceptron's answer. The hat is the usual mark for "a prediction of y", as opposed to y itself, which is the true answer.

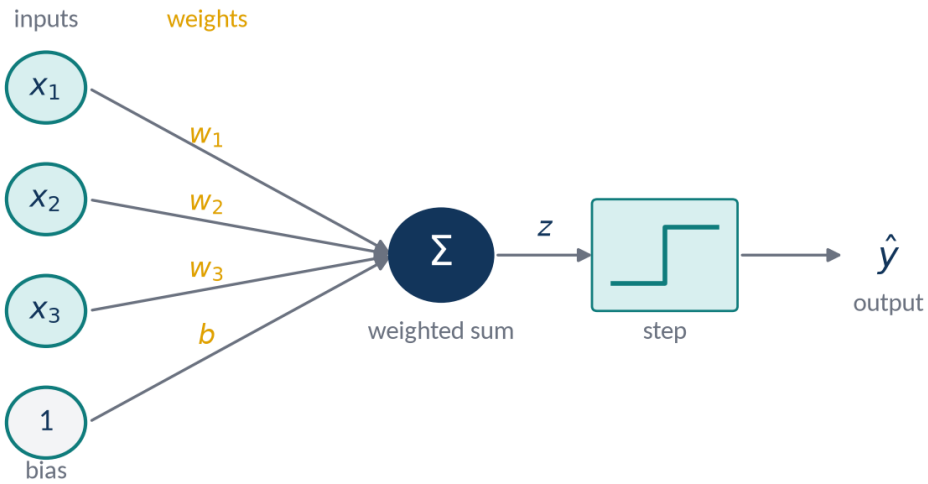

Figure 31.1 A perceptron with three inputs. Each input is multiplied by its weight, the products and the bias are added into z, and the step function turns z into the answer $\hat{y}$.

The name comes from Frank Rosenblatt, who described the perceptron in 1958 and built it as a machine, the Mark I Perceptron, whose weights were motor-driven potentiometers [1]. The neuron picture behind it is older: in 1943 Warren McCulloch and Walter Pitts showed that simple threshold units wired together can compute any logical function [3]. Rosenblatt's contribution was the *learning rule*, the recipe for finding the weights from examples.

> **KEY INSIGHT.** A perceptron does not store the examples it has seen. Everything it has learned is squeezed into a handful of numbers, the weights and the bias. Learning means changing those numbers; using the perceptron means doing one weighted sum.

31.3 The Mathematics, Gently

31.3.1 The weighted sum

Suppose an example has n features. We write them as $x_1, x_2, \ldots, x_n$, and collect them into a *vector* $\mathbf{x} = (x_1, x_2, \ldots, x_n)$. A vector here is nothing more than a list of numbers in a fixed order. In the same way the weights are $w_1, w_2, \ldots, w_n$, collected into $\mathbf{w}$, and the bias is a single number b. The perceptron first computes

$$z = w_1 x_1 + w_2 x_2 + \cdots + w_n x_n + b = \sum_{j=1}^{n} w_j x_j + b = \mathbf{w} \cdot \mathbf{x} + b \tag{31.1}$$

The symbol $\sum_{j=1}^{n}$ means "add up, for j running from 1 to n", and $\mathbf{w} \cdot \mathbf{x}$, the *dot product*, is the short name for exactly that sum of products. Equation (31.1) is the whole "thinking" of the perceptron.

A worked example makes it concrete. Take two inputs $\mathbf{x} = (1,0)$, weights $\mathbf{w} = (0.2,0.1)$ and bias $b = -0.2$. Then

$$z = 0.2 \cdot 1 + 0.1 \cdot 0 + (-0.2) = 0.2 + 0 - 0.2 = 0.$$

31.3.2 The step function

The answer is obtained by passing z through the step function:

$$\hat{y} = \text{step}(z) = \begin{cases} 1 & \text{if } z \geq 0 \\ 0 & \text{if } z < 0 \end{cases} \tag{31.2}$$

For the example above $z = 0$, so by Equation (31.2) the perceptron answers $\hat{y} = 1$. Notice the "$\geq$": a total of exactly zero counts as "fire". That choice is a convention, but it must be applied consistently, and we will see in Section 31.5 that it decides which side of the line a point lying exactly on the line falls on.

31.3.3 The decision boundary is a straight line

With two inputs, the points where the perceptron is exactly undecided satisfy $w_1 x_1 + w_2 x_2 + b = 0$. If $w_2 \neq 0$ we can solve for x_2:

$$x_2 = -\frac{w_1}{w_2} x_1 - \frac{b}{w_2} \tag{31.3}$$

Equation (31.3) is the equation of a straight line with slope $-w_1/w_2$ and intercept $-b/w_2$. Every point on one side of the line gives $z > 0$ and is labeled 1; every point on the other side gives $z < 0$ and is labeled 0. This line is the *decision boundary*. With three inputs the boundary is a flat plane, and with more inputs it is a *hyperplane*, the same idea in more dimensions. Whatever the number of inputs, a perceptron can only ever cut the space into two halves with one flat cut.

> **DEFINITION.** A set of labeled examples is *linearly separable* if some straight line (plane, hyperplane) has all examples of class 1 strictly on one side and all examples of class 0 strictly on the other.

31.3.4 The learning rule

Let y be the true label of an example (0 or 1) and $\hat{y}$ the perceptron's answer. The *error* $y - \hat{y}$ can take only three values: 0 when the answer is right, $+1$ when the perceptron said 0 but should have said 1, and -1 when it said 1 but should have said 0. Rosenblatt's rule updates every weight and the bias like this:

$$w_j \leftarrow w_j + \eta\,(y - \hat{y})\,x_j, \qquad b \leftarrow b + \eta\,(y - \hat{y}) \tag{31.4}$$

The arrow $\leftarrow$ means "replace the old value by". The Greek letter η (eta) is the *learning rate*, a small positive number such as 0.1 that sets the size of each nudge.

Why does Equation (31.4) make sense? Look at what it does to z. Suppose the perceptron said 0 but should have said 1, so $y - \hat{y} = +1$. After the update, the new total for the same example is

$$z_{\text{new}} = \sum_j (w_j + \eta x_j)\,x_j + (b + \eta) = z_{\text{old}} + \eta\left(\sum_j x_j^2 + 1\right) \tag{31.5}$$

The bracket is a sum of squares plus one, so it is always positive. Equation (31.5) therefore says that z has grown, which is exactly what we wanted: we moved toward "yes". If the error was -1 the same computation shows that z shrinks. When the answer is right the error is zero and nothing changes. One more detail: an input $x_j = 0$ contributes nothing to the answer, and the rule correctly leaves its weight alone, because $\eta \cdot (y - \hat{y}) \cdot 0 = 0$. The rule only blames the inputs that took part.

31.3.5 Working an epoch by hand

Let us teach a perceptron the logical AND: the answer is 1 only when both inputs are 1. The four examples are $(0,0) \to 0$, $(0,1) \to 0$, $(1,0) \to 0$ and $(1,1) \to 1$. We start from $\mathbf{w} = (0,0)$, $b = 0$ and use $\eta = 0.1$, visiting the examples in that fixed order. **Table 31.1** records every step of the first two epochs; the arithmetic is small enough to check in your head.

Table 31.1 The first two epochs of learning AND with $\eta = 0.1$, starting from zero weights; the columns Sum, Answer and Error hold z, $\hat{y}$ and $y - \hat{y}$. Each row applies Equation (31.1), Equation (31.2) and Equation (31.4) once.

Epoch	Example	Label	Sum	Answer	Error	New weights	New bias
1	(0,0)	0	0	1	−1	(0,0)	−0.1
1	(0,1)	0	−0.1	0	0	(0,0)	−0.1
1	(1,0)	0	−0.1	0	0	(0,0)	−0.1
1	(1,1)	1	−0.1	0	+1	(0.1,0.1)	0
2	(0,0)	0	0	1	−1	(0.1,0.1)	−0.1
2	(0,1)	0	0	1	−1	(0.1,0)	−0.2
2	(1,0)	0	−0.1	0	0	(0.1,0)	−0.2
2	(1,1)	1	−0.1	0	+1	(0.2,0.1)	−0.1

Read the first row slowly. The weights and bias are all zero, so $z = 0$; by Equation (31.2) the answer is 1, but the truth is 0, so the error is -1. Both inputs are 0, so the weights stay at 0, and only the bias moves: $b = 0 + 0.1 \cdot (-1) = -0.1$. In the last row of epoch 1 the example (1,1) gives $z = 0 \cdot 1 + 0 \cdot 1 - 0.1 = -0.1$, the answer is 0 but should be 1, so every weight rises by $0.1 \cdot 1 \cdot 1 = 0.1$ and the bias rises by 0.1. Epoch 1 made two mistakes; epoch 2 made three. It does not

look like progress yet, but the weights are drifting in the right direction, and after a few more epochs the perceptron completes an epoch with no mistakes at all. The program in Section 31.4 visits the examples in a shuffled order, so its path is different, but it arrives at an equivalent line.

31.3.6 A promise that it will stop

Does this nudging ever end? For linearly separable data, yes, and we can even bound how long it takes. Suppose some boundary separates the classes with a *margin* $\gamma > 0$, meaning every example lies at distance at least γ from it, and suppose every example lies within distance R of the origin (counting the constant input 1 of the bias as one more coordinate). Then the perceptron makes at most

$$k \le \left(\frac{R}{\gamma}\right)^2 \tag{31.6}$$

mistakes in total, no matter in which order it sees the examples. This is the *perceptron convergence theorem*, proved by Novikoff in 1962 [4]. Two things are worth reading out of Equation (31.6). First, the bound does not contain the learning rate; starting from zero weights, η only rescales everything (Exercise 31.3 checks this). Second, a narrow margin, classes that almost touch, means a small γ and possibly very many mistakes before convergence. And when the data are *not* separable there is no γ at all, and the theorem promises nothing: the perceptron can wander forever.

31.3.7 Scaling the inputs

Real features come in different units. Petal length runs from about 1 cm to 7 cm, petal width from 0.1 cm to 2.5 cm. Before training we *standardize* each feature: subtract its mean μ and divide by its standard deviation σ, both computed on the training examples only,

$$x' = \frac{x - \mu}{\sigma} \tag{31.7}$$

so that every feature is centered on 0 with a spread of about 1. With the data centered, the boundary passes close to the origin, the bias no longer has to travel far, and one learning rate suits every weight. Equation (31.7) is exactly what scikit-learn's `StandardScaler` computes, written out by hand.

31.4 Building It Step by Step

The code for this chapter lives in the folder `Chapter031`. It needs only NumPy and, for the iris data and a comparison, scikit-learn. The versions used for every run in this chapter are Python 3.11 (the programs use no syntax newer than Python 3.10 and run unchanged on Python 3.14, the current release line [5]), NumPy 2.4.6, scikit-learn 1.9.1 [6] and, for the figures, matplotlib 3.11.2. Install them with `pip install -r requirements.txt` inside a virtual environment, as in Chapter 1.

31.4.1 The perceptron class

Listing 31.1 is the complete perceptron. Read it next to Equation (31.1), Equation (31.2) and Equation (31.4): every line of the mathematics has a line of code.

Listing 31.1 `perceptron.py`: a complete perceptron with the weighted sum, the step function and Rosenblatt's learning rule.

```
"""A perceptron written from scratch with NumPy (Chapter 31)."""
import numpy as np

class Perceptron:
    """Rosenblatt's perceptron for two classes labeled 0 and 1."""

    def __init__(self, learning_rate=0.1, max_epochs=50, seed=0):
        self.learning_rate = learning_rate
        self.max_epochs = max_epochs
        self.seed = seed
        self.w = None           # one weight per input feature
        self.b = 0.0            # the bias: the threshold moved to the left side
        self.errors_ = []       # number of mistakes in each epoch

    def net_input(self, X):
        """The weighted sum z = w . x + b for every row of X."""
        return X @ self.w + self.b

    def predict(self, X):
        """Fire (1) when z >= 0, stay silent (0) otherwise."""
        return np.where(self.net_input(X) >= 0.0, 1, 0)

    def fit(self, X, y):
        rng = np.random.default_rng(self.seed)
        self.w = np.zeros(X.shape[1])
        self.b = 0.0
        self.errors_ = []
        for epoch in range(self.max_epochs):
            mistakes = 0
            for i in rng.permutation(len(X)):   # visit the examples in a new order
                y_hat = 1 if X[i] @ self.w + self.b >= 0.0 else 0
                step = self.learning_rate * (y[i] - y_hat)   # 0 when correct
                if step != 0.0:
                    self.w += step * X[i]
                    self.b += step
                    mistakes += 1
            self.errors_.append(mistakes)
            if mistakes == 0:                   # a whole clean pass: converged
                break
        return self
```

Let us walk through it.

- The constructor stores three settings, the learning rate η, the maximum number of epochs, and a random `seed`, and prepares the three things the perceptron will learn or record: the weight vector `w`, the bias `b` and the list `errors_`. The trailing underscore in `errors_` follows the scikit-learn habit of marking attributes that exist only after training.
- `net_input` is Equation (31.1) for a whole table at once. `X` is a two-dimensional NumPy array with one row per example and one column per feature, and `X @ self.w` is the matrix product: it computes the dot product of every row with the weights in one go. Adding `self.b` adds the bias to every row.
- `predict` is Equation (31.2). `np.where(condition, 1, 0)` looks at every element of the condition and picks 1 where it is true and 0 where it is false.
- `fit` is the learning loop. It creates its own random generator from the seed, sets the weights and bias to zero, and then runs at most `max_epochs` epochs. Inside an epoch, `rng.permutation(len(X))` returns the numbers $0, 1, \ldots, m-1$ in a shuffled order, so the

examples are visited in a different order every epoch. Shuffling prevents the perceptron from falling into a rhythm tied to the order of the file.

- For one example, `y_hat` is the answer, and `step` is $\eta\,(y - \hat{y})$, which is zero when the answer is right. Only when it is not zero do we change the weights and the bias, exactly as in Equation (31.4), and count a mistake.
- After each epoch we record the number of mistakes. If it is zero, every example is on the correct side of the line, the weights will never change again, and we stop early.

Because we fixed the seed, the shuffling is the same on every run, and so are all the numbers printed below. Change `seed` and the path changes, although for separable data the destination is always a line with no mistakes.

31.4.2 First test: logic gates

The smallest possible test bed is a *logic gate*: two inputs that are 0 or 1 and a fixed answer for each of the four combinations. **Listing 31.2** trains a fresh perceptron on four gates, AND, OR, NAND (not-AND) and XOR (exclusive or: 1 when exactly one input is 1).

Listing 31.2 `logic_gates.py`: training the perceptron on four logic gates.

```
"""Teach the perceptron AND, OR, NAND and XOR (Chapter 31)."""
import numpy as np
from perceptron import Perceptron

X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)
GATES = {
    "AND":  np.array([0, 0, 0, 1]),
    "OR":   np.array([0, 1, 1, 1]),
    "NAND": np.array([1, 1, 1, 0]),
    "XOR":  np.array([0, 1, 1, 0]),
}

for name, y in GATES.items():
    p = Perceptron(learning_rate=0.1, max_epochs=20).fit(X, y)
    pred = p.predict(X)
    status = "learned" if (pred == y).all() else "FAILED"
    print(f"{name:4s} {status:7s} after {len(p.errors_):2d} epochs  "
          f"w={np.round(p.w, 2)} b={p.b:+.2f}  predictions={pred}")
    print(f"     mistakes/epoch: {p.errors_}")
```

The dictionary `GATES` maps a gate's name to its column of four answers, in the same order as the rows of `X`. For each gate we train for at most 20 epochs, predict all four rows, and report whether the predictions match the truth.

31.4.3 The application: a flower sorter

Now the flower stall. The scikit-learn library ships Fisher's famous iris data set inside the package, so no download is needed [7]. It has 150 flowers of three species, 50 each, with four measurements per flower. Our sorter uses two species, setosa and versicolor, and two measurements, petal length and petal width. **Listing 31.3** is the complete application.

Listing 31.3 `flower_sorter.py`: the flower sorter. It trains on 70 flowers, tests on 30, and classifies a flower given on the command line.

```
"""Flower sorter: a perceptron that tells setosa from versicolor (Chapter 31).

usage: python flower_sorter.py [petal_length_cm petal_width_cm]
"""
import sys
import numpy as np
from sklearn.datasets import load_iris
from sklearn.model_selection import train_test_split
from perceptron import Perceptron

def load_two_species():
    iris = load_iris()
    keep = iris.target < 2                      # 0 = setosa, 1 = versicolor
    X = iris.data[keep][:, 2:4]                 # petal length, petal width (cm)
    y = iris.target[keep]
    return X, y

def main():
    X, y = load_two_species()
    X_train, X_test, y_train, y_test = train_test_split(
        X, y, test_size=0.3, random_state=42, stratify=y)
    mean, std = X_train.mean(axis=0), X_train.std(axis=0)
    scale = lambda A: (A - mean) / std          # same scaling for every flower

    model = Perceptron(learning_rate=0.1, max_epochs=50).fit(scale(X_train),
                                                             y_train)
    print(f"training flowers: {len(X_train)}, test flowers: {len(X_test)}")
    print(f"mistakes per epoch: {model.errors_}")
    print(f"weights: {np.round(model.w, 3)}, bias: {model.b:+.3f}")
    acc = (model.predict(scale(X_test)) == y_test).mean()
    print(f"test accuracy: {acc:.3f}")

    names = ["setosa", "versicolor"]
    if len(sys.argv) == 3:
        flower = np.array([[float(sys.argv[1]), float(sys.argv[2])]])
        z = model.net_input(scale(flower))[0]
        guess = names[model.predict(scale(flower))[0]]
        print(f"petal {sys.argv[1]} cm x {sys.argv[2]} cm "
              f"-> z = {z:+.3f} -> {guess}")

if __name__ == "__main__":
    main()
```

- `load_two_species` keeps the rows whose target is 0 (setosa) or 1 (versicolor), and the columns 2 and 3, which are petal length and petal width.
- `train_test_split` puts 30% of the flowers aside as a *test set*. The perceptron never sees them during training; they tell us how well it does on flowers it has not met. `stratify=y` keeps the two species in the same proportion in both parts, and `random_state=42` fixes the split.
- The mean and standard deviation are computed from the training flowers only, and the small function `scale` applies Equation (31.7) to any table of flowers. Using the training statistics for the test flowers too is essential; Section 31.7 explains why.
- After training, the program prints the mistakes per epoch, the weights and the test accuracy, the fraction of test flowers classified correctly.
- If the user passes two numbers on the command line, they are read as petal length and width in centimeters, scaled with the same statistics, and classified. The program also prints z, so you can see how confidently the flower sits on its side of the line.

31.4.4 Tests

A short test file protects the class against future edits. **Listing 31.4** checks three facts we have just discussed: the perceptron learns AND and ends with a clean epoch; it cannot learn XOR even in 100 epochs; and the same seed gives the same weights.

Listing 31.4 `test_perceptron.py`: three unit tests with the standard `unittest` module.

```
"""Unit tests for the perceptron (run: python -m unittest -v)."""
import unittest
import numpy as np
from perceptron import Perceptron

X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)

class PerceptronTest(unittest.TestCase):
    def test_learns_and(self):
        p = Perceptron().fit(X, np.array([0, 0, 0, 1]))
        self.assertEqual(p.predict(X).tolist(), [0, 0, 0, 1])
        self.assertEqual(p.errors_[-1], 0)       # the last epoch was clean

    def test_cannot_learn_xor(self):
        p = Perceptron(max_epochs=100).fit(X, np.array([0, 1, 1, 0]))
        self.assertNotEqual(p.predict(X).tolist(), [0, 1, 1, 0])
        self.assertGreater(min(p.errors_), 0)    # never a clean epoch

    def test_same_seed_same_weights(self):
        y = np.array([0, 1, 1, 1])
        a, b = Perceptron(seed=3).fit(X, y), Perceptron(seed=3).fit(X, y)
        self.assertTrue(np.array_equal(a.w, b.w))

if __name__ == "__main__":
    unittest.main()
```

31.5 Running It

Open a terminal in `Chapter031` (in VS Code: **File → Open Folder**, then **Terminal → New Terminal**) and run the gates first.

```
python logic_gates.py
```

```
AND  learned after  7 epochs  w=[0.1 0.1] b=-0.20  predictions=[0 0 0 1]
     mistakes/epoch: [2, 2, 1, 1, 1, 3, 0]
OR   learned after  5 epochs  w=[0.1 0.1] b=-0.10  predictions=[0 1 1 1]
     mistakes/epoch: [2, 1, 1, 1, 0]
NAND learned after  5 epochs  w=[-0.1 -0.1] b=+0.10  predictions=[1 1 1 0]
     mistakes/epoch: [1, 2, 2, 2, 0]
XOR  FAILED  after 20 epochs  w=[0.  0.1] b=+0.10  predictions=[1 1 1 1]
     mistakes/epoch: [3, 2, 3, 4, 3, 4, 4, 3, 2, 4, 1, 4, 4, 2, 3, 2, 2, 3, 2, 2]
```

AND, OR and NAND are learned within seven epochs. XOR is not: after 20 epochs the perceptron is still making between one and four mistakes per epoch, and it has settled for answering 1 to everything. The weights for AND are $\mathbf{w} = (0.1, 0.1)$ and $b = -0.2$, so by Equation (31.3) the boundary is the line $x_2 = -x_1 + 2$. That line passes exactly through the point (1,1), where $z = 0.1 + 0.1 - 0.2 = 0$; the "$\geq$" in Equation (31.2) makes that point fire, which is correct for AND. **Figure 31.2** draws the four problems and the learned lines. Filled circles are examples whose answer is 1, open squares those whose answer is 0.

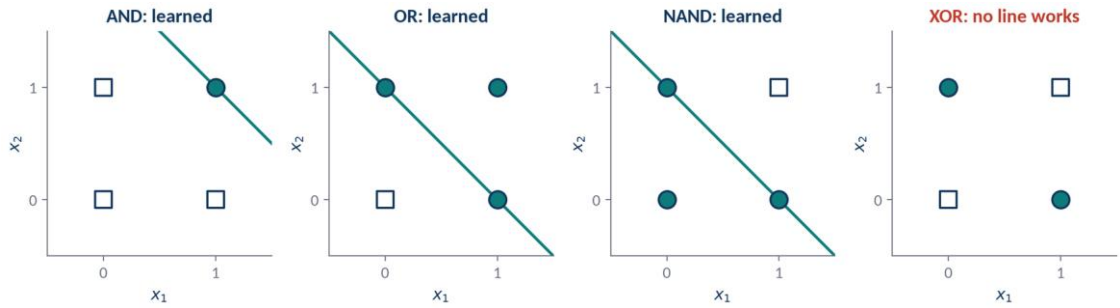

Figure 31.2 The lines learned for AND, OR and NAND, each passing through or beside the corner points so that the circles (answer 1) lie on the firing side. For XOR the circles sit on one diagonal and the squares on the other, and no single straight line can separate them.

31.5.1 Why XOR is impossible

Look at the XOR panel of **Figure 31.2**. The two circles, (0,1) and (1,0), sit on one diagonal; the two squares, (0,0) and (1,1), sit on the other. Any straight line that has both circles on one side must also have at least one square on that side. We can prove this with four inequalities. Suppose weights w_1, w_2 and bias b solved XOR. Then

$$\begin{aligned} (0,0) \to 0: &\quad b < 0 \\ (0,1) \to 1: &\quad w_2 + b \geq 0 \\ (1,0) \to 1: &\quad w_1 + b \geq 0 \\ (1,1) \to 0: &\quad w_1 + w_2 + b < 0 \end{aligned} \tag{31.8}$$

Add the middle two lines of Equation (31.8): $w_1 + w_2 + 2b \geq 0$, that is, $w_1 + w_2 + b \geq -b$. The first line says $b < 0$, so $-b > 0$, and therefore $w_1 + w_2 + b > 0$. That contradicts the last line. No choice of weights works, so no amount of training can find one. This little argument was one of the observations that Marvin Minsky and Seymour Papert made famous in their 1969 book *Perceptrons* [8], and it helped cool enthusiasm for neural networks for more than a decade. The cure, known long before and made practical in the 1980s, is to use more than one neuron; Exercise 31.4 builds XOR from three perceptrons, and Chapter 32 learns such a network automatically.

The left panel of **Figure 31.3** shows the difference in behavior: for AND the number of mistakes per epoch falls to zero and training stops; for XOR it jumps around forever.

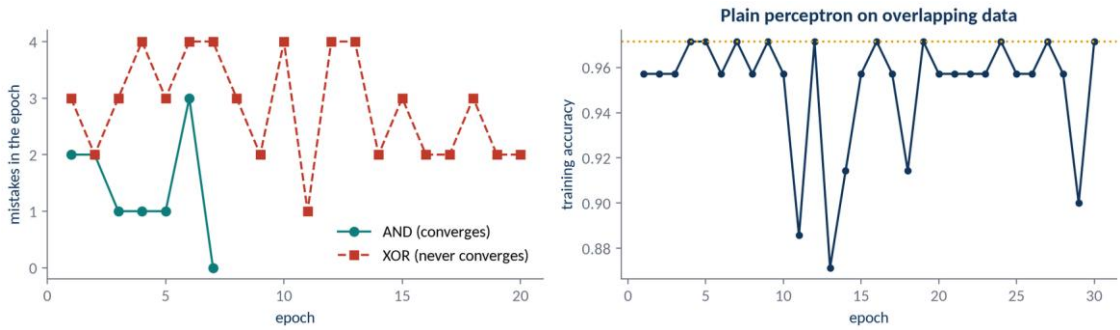

Figure 31.3 Left: mistakes per epoch while learning AND and XOR, from the run of **Listing 31.2**. Right: training accuracy after each epoch of the plain perceptron on overlapping flowers, from the run of **Listing 31.5**; the dotted line marks the best epoch.

31.5.2 Sorting flowers

Now the application, first with a versicolor-sized flower (petal 4.5 cm long, 1.4 cm wide):

```
python flower_sorter.py 4.5 1.4
```

```
training flowers: 70, test flowers: 30
mistakes per epoch: [2, 0]
weights: [0.141 0.144], bias: +0.000
test accuracy: 1.000
petal 4.5 cm x 1.4 cm -> z = +0.326 -> versicolor
```

And with a small setosa-like flower:

```
python flower_sorter.py 1.6 0.3
```

```
petal 1.6 cm x 0.3 cm -> z = -0.249 -> setosa
```

Only two mistakes, both in the first epoch, and then a clean epoch: the two species are far apart, so the margin γ in Equation (31.6) is large and convergence is fast. All 30 test flowers are sorted correctly. The bias came out exactly zero: the two updates in epoch 1 happened to be one in each direction, so they cancelled, and because the data are centered by Equation (31.7) a line through the origin is good enough. The two weights are almost equal, which means the perceptron has decided that petal length and petal width matter about equally after scaling. The left panel of **Figure 31.4** shows the flowers and the learned boundary.

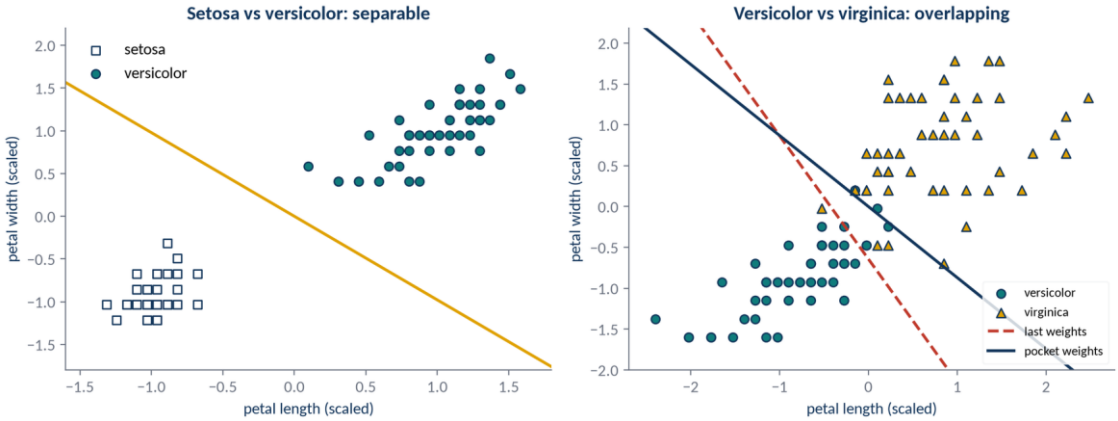

Figure 31.4 Left: setosa and versicolor after scaling, with the boundary learned by `flower_sorter.py`. Right: versicolor and virginica overlap; the dashed line is where the plain perceptron happened to stop, the solid line the best weights it met on the way (the pocket).

Finally, the tests:

```
python -m unittest
```

```
...
----------------------------------------------------------------------
Ran 3 tests in 0.042s

OK
```

The three dots are the three passing tests. The whole chapter's code, gates, sorter and tests together, runs in about a second and a half on the machine used for this book.

31.6 Improving It: When No Line Is Perfect

Setosa is easy. Versicolor and virginica are not: some versicolor flowers have larger petals than some virginica flowers, so the two clouds overlap, as the right panel of **Figure 31.4** shows. The data are not linearly separable, the convergence theorem does not apply, and the plain

perceptron keeps changing its mind. Worse, it stops wherever the last epoch leaves it, which may be a good line or a bad one, purely by luck.

Two classic repairs fix this without changing the learning rule at all.

- The **pocket perceptron** of Stephen Gallant [9] keeps a copy of the best weights seen so far "in its pocket". After each epoch it measures the training accuracy of the current weights; if they beat the pocket, they replace it. At the end we use the pocket weights, not the last ones.
- The **averaged perceptron**, analyzed by Freund and Schapire [10], keeps a running sum of the weights after every example and at the end uses their average. A weight vector that survived many examples without change counts many times, so the average leans toward the weights that were right for long stretches.

Listing 31.5 trains once and extracts all three answers: the last weights, the pocket weights and the averaged weights. For comparison it also trains scikit-learn's own `Perceptron`, which implements the same rule inside the stochastic gradient framework [6].

Listing 31.5 `pocket.py`: the plain, pocket and averaged perceptrons on versicolor versus virginica, compared with scikit-learn's `Perceptron`.

```
"""When no line is perfect: plain, pocket and averaged perceptrons (Chapter 31).

Versicolor and virginica overlap, so the plain perceptron never settles.
"""
import numpy as np
from sklearn.datasets import load_iris
from sklearn.linear_model import Perceptron as SkPerceptron
from sklearn.model_selection import train_test_split

def train(X, y, epochs=30, lr=0.1, seed=0):
    """Return the last, the pocket and the averaged weights, plus a history."""
    rng = np.random.default_rng(seed)
    w, b = np.zeros(X.shape[1]), 0.0
    best = (w.copy(), b, -1.0)                  # the pocket: best weights so far
    w_sum, b_sum, count = np.zeros_like(w), 0.0, 0
    history = []
    for epoch in range(epochs):
        for i in rng.permutation(len(X)):
            y_hat = 1 if X[i] @ w + b >= 0 else 0
            step = lr * (y[i] - y_hat)
            w, b = w + step * X[i], b + step
            w_sum, b_sum, count = w_sum + w, b_sum + b, count + 1
        acc = ((X @ w + b >= 0).astype(int) == y).mean()
        if acc > best[2]:
            best = (w.copy(), b, acc)
        history.append(acc)
    return (w, b), best[:2], (w_sum / count, b_sum / count), history

def accuracy(wb, X, y):
    w, b = wb
    return ((X @ w + b >= 0).astype(int) == y).mean()

iris = load_iris()
keep = iris.target > 0                          # 1 = versicolor, 2 = virginica
X = iris.data[keep][:, 2:4]                    # petal length and width
y = (iris.target[keep] == 2).astype(int)
X_tr, X_te, y_tr, y_te = train_test_split(X, y, test_size=0.3,
                                          random_state=42, stratify=y)
mean, std = X_tr.mean(axis=0), X_tr.std(axis=0)
X_tr, X_te = (X_tr - mean) / std, (X_te - mean) / std
```

Listing 31.5 (Continued) *pocket.py: the plain, pocket and averaged perceptrons on versicolor versus virginica, compared with scikit-learn's Perceptron.*

```
last, pocket, averaged, history = train(X_tr, y_tr)
print("training accuracy, epoch by epoch:")
for start in range(0, len(history), 10):
    print(" ".join(f"{a:.2f}" for a in history[start:start + 10]))
for name, wb in [("last", last), ("pocket", pocket), ("averaged", averaged)]:
    print(f"{name:9s} train {accuracy(wb, X_tr, y_tr):.3f}"
          f"  test {accuracy(wb, X_te, y_te):.3f}")
sk = SkPerceptron(max_iter=30, random_state=0).fit(X_tr, y_tr)
print(f"sklearn   train {sk.score(X_tr, y_tr):.3f}"
      f"  test {sk.score(X_te, y_te):.3f}")
```

The function `train` is the loop of **Listing 31.1** with two additions. The tuple `best` holds the pocket: weights, bias and their training accuracy. The sums `w_sum` and `b_sum` add up the weights after every single example, and `count` counts the examples, so `w_sum / count` is the average. The variable `history` keeps the accuracy after each epoch so we can plot it. Run it:

```
python pocket.py
```

```
training accuracy, epoch by epoch:
0.96 0.96 0.96 0.97 0.97 0.96 0.97 0.96 0.97 0.96
0.89 0.97 0.87 0.91 0.96 0.97 0.96 0.91 0.97 0.96
0.96 0.96 0.96 0.97 0.96 0.96 0.97 0.96 0.90 0.97
last      train 0.971  test 0.867
pocket    train 0.971  test 0.900
averaged  train 0.957  test 0.900
sklearn   train 0.957  test 0.900
```

The right panel of **Figure 31.3** plots the thirty accuracies. The plain perceptron bounces between 0.87 and 0.97; the dips are epochs in which one unlucky update near the overlap tilted the line badly. On the test flowers, the last weights score 0.867, while the pocket and averaged weights score 0.900, the same as scikit-learn. The right panel of **Figure 31.4** shows why: the last line (dashed) cuts steeply through the versicolor cloud, while the pocket line (solid) runs along the gap between the clouds. A few test flowers sit right in the overlap, and no straight line can get them all; 0.9 is about as good as a single flat cut does here.

> **KEY INSIGHT.** When data are not separable, the question "which line did training end on?" has a random answer. Keep the best (pocket) or the average (averaged perceptron), and judge them on a test set that training never saw.

What else could we improve? We could replace the hard step by a smooth S-shaped curve and learn by following a gradient; that turns the perceptron into logistic regression, which you met in Chapter 12, and it is the road Chapter 32 follows. And we could give the model more than one neuron, which removes the straight-line limit altogether.

31.7 Common Mistakes, and How to Avoid Them

Forgetting the bias. Without b, the boundary of Equation (31.3) must pass through the origin. On raw, uncentered data that is usually impossible, and the perceptron never converges. Always learn a bias, or add a constant input 1, which amounts to the same thing.

Scaling with the test set's statistics. If you compute the mean and standard deviation on all the data, or separately on the test set, information from the test flowers leaks into training, and the test accuracy is no longer an honest estimate. Compute μ and σ on the training set and apply them to everything, as `scale` does in **Listing 31.3**.

Expecting convergence on overlapping data. The loop in **Listing 31.1** stops early only after a clean epoch. On data such as versicolor versus virginica that never happens, so the loop always runs to `max_epochs`, and the weights it ends with are arbitrary. Use the pocket or the averaged variant, or a model with a smooth loss.

Labels in the wrong code. Our perceptron expects labels 0 and 1. Many textbooks use -1 and $+1$ instead, with the update $w \leftarrow w + \eta\, y\, x$ applied only on mistakes. Both are correct, but mixing them, for instance feeding $-1/+1$ labels into Equation (31.4) with a $0/1$ step, silently doubles some updates and breaks others.

Reading the learning rate as a speed dial. Starting from zero weights, multiplying η by ten multiplies every weight and the bias by ten and changes nothing else, not the mistakes and not the boundary. The learning rate matters for other models (Chapter 32), but not here.

Testing on the training data. A perceptron that scores 1.0 on the flowers it trained on has proved only that the data were separable. Report accuracy on held-out data.

31.8 Chapter Summary

- A perceptron computes a weighted sum $z = \mathbf{w} \cdot \mathbf{x} + b$ (Equation (31.1)) and answers 1 when $z \geq 0$, 0 otherwise (Equation (31.2)).
- Its decision boundary is a straight line, plane or hyperplane (Equation (31.3)); it can only separate classes that one flat cut can separate.
- It learns with Rosenblatt's rule (Equation (31.4)): on a mistake, move every weight by $\eta\,(y - \hat{y})\,x_j$ and the bias by $\eta\,(y - \hat{y})$. On separable data it stops after at most $(R/\gamma)^2$ mistakes (Equation (31.6)).
- Standardizing features with training statistics (Equation (31.7)) keeps the boundary near the origin and makes one learning rate fit all weights.
- XOR is not linearly separable, as the four inequalities of Equation (31.8) prove; a single perceptron can never learn it, but three perceptrons in two layers can.
- On overlapping data, keep the best weights (pocket) or the average weights; judge every model on a test set.

31.9 Exercises

1. Continue **Table 31.1** by hand for epoch 3, visiting the examples in the same fixed order. Write z, $\hat{y}$ and the new weights after every example. How many mistakes does epoch 3 make?
2. The OR gate has answers 0,1,1,1. Write the four inequalities that weights w_1, w_2 and bias b must satisfy, like Equation (31.8), and find one solution with small whole numbers.
3. Show on paper that if training starts from $\mathbf{w} = \mathbf{0}$ and $b = 0$, then running with learning rate $c\,\eta$ produces weights exactly c times those produced with η, with identical mistakes. Then confirm it with a program that trains AND with $\eta = 0.1$, 1 and 10.
4. Build XOR from three perceptrons: train one on OR and one on NAND, feed their two answers into a third trained on AND, and print the truth table. Explain in one sentence why this works when Equation (31.8) says one perceptron cannot.
5. Run the flower sorter without scaling the features (raw centimeters) and compare the mistakes per epoch and the test accuracy with the scaled version. Explain the difference in the number of mistakes.
6. In **Listing 31.5** the pocket keeps the weights with the best *training* accuracy. Why would it be a mistake to keep the weights with the best *test* accuracy instead?

31.10 Solutions to the Exercises

Solution 1. Epoch 2 ended with $\mathbf{w} = (0.2, 0.1)$, $b = -0.1$. Example (0,0): $z = -0.1$, $\hat{y} = 0$, correct, no change. Example (0,1): $z = 0.1 - 0.1 = 0$, $\hat{y} = 1$, but $y = 0$, so the error is -1: $\mathbf{w} = (0.2, 0.1 - 0.1) = (0.2, 0)$, $b = -0.2$. Example (1,0): $z = 0.2 - 0.2 = 0$, $\hat{y} = 1$, error -1: $\mathbf{w} = (0.1, 0)$, $b = -0.3$. Example (1,1): $z = 0.1 + 0 - 0.3 = -0.2$, $\hat{y} = 0$, error $+1$: $\mathbf{w} = (0.2, 0.1)$, $b = -0.2$. Epoch 3 makes three mistakes. In epoch 4 the totals are -0.2, -0.1, 0 and 0.1. In exact arithmetic the third one, $z = 0$ for (1,0), fires and is one more mistake, which is why the line keeps shifting a little longer; on a computer $0.2 - 0.2$ computed through several rounded additions can come out as a tiny negative number, a first reminder that floating-point numbers are not exact and that ties on the boundary are fragile.

Solution 2. The conditions are $b < 0$ for (0,0), $w_2 + b \geq 0$ for (0,1), $w_1 + b \geq 0$ for (1,0) and $w_1 + w_2 + b \geq 0$ for (1,1). The choice $w_1 = w_2 = 2$, $b = -1$ satisfies all four: $-1 < 0$, $1 \geq 0$, $1 \geq 0$, $3 \geq$

0. The program found the proportional solution $w = (0.1, 0.1)$, $b = -0.1$, which puts the points (0,1) and (1,0) exactly on the boundary; any positive multiple of a solution is a solution.

Solution 3. By induction on the number of updates. Before any update both runs have all-zero weights, so they give the same $z = 0$ and the same answers. Suppose that after some updates the weights and bias of the second run are c times those of the first. For the next example, the second run computes $z' = c\,z$ with $c > 0$, so z' has the same sign as z (and is zero exactly when z is), the answers agree, the errors agree, and the update of the second run, $c\,\eta\,(y - \hat{y})\,x_j$, is c times the update of the first. So the proportion is kept. The program **Listing 31.6** confirms it: the mistakes are identical and the weights divided by η are identical.

Listing 31.6 `sol_learning_rate.py`: training AND with three learning rates.

```
"""Exercise 31.3: the learning rate only rescales the weights (from zero)."""
import numpy as np
from perceptron import Perceptron

X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)
y = np.array([0, 0, 0, 1])                          # AND
for lr in (0.1, 1.0, 10.0):
    p = Perceptron(learning_rate=lr, max_epochs=20).fit(X, y)
    print(f"lr={lr:5.1f}  epochs={len(p.errors_)}  mistakes={p.errors_}  "
          f"w/lr={p.w / lr}  b/lr={p.b / lr:+.1f}")
```

```
lr=  0.1  epochs=7  mistakes=[2, 2, 1, 1, 1, 3, 0]  w/lr=[1. 1.]  b/lr=-2.0
lr=  1.0  epochs=7  mistakes=[2, 2, 1, 1, 1, 3, 0]  w/lr=[1. 1.]  b/lr=-2.0
lr= 10.0  epochs=7  mistakes=[2, 2, 1, 1, 1, 3, 0]  w/lr=[1. 1.]  b/lr=-2.0
```

Solution 4. Listing 31.7 trains the three perceptrons and wires them together.

Listing 31.7 `sol_xor_two_layers.py`: XOR as AND(OR, NAND).

```
"""Exercise 31.4: XOR from three perceptrons wired in two layers."""
import numpy as np
from perceptron import Perceptron

X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)
p_or = Perceptron().fit(X, np.array([0, 1, 1, 1]))
p_nand = Perceptron().fit(X, np.array([1, 1, 1, 0]))
hidden = np.column_stack([p_or.predict(X), p_nand.predict(X)])
p_and = Perceptron().fit(X, np.array([0, 0, 0, 1]))   # AND on its own table
print("x1 x2 | OR NAND | XOR")
for x, h, out in zip(X.astype(int), hidden, p_and.predict(hidden)):
    print(f" {x[0]}  {x[1]} |  {h[0]}   {h[1]}  |  {out}")
```

```
x1 x2 | OR NAND | XOR
 0  0 |  0   1  |  0
 0  1 |  1   1  |  1
 1  0 |  1   1  |  1
 1  1 |  1   0  |  0
```

It works because the first layer moves the four points to new coordinates, (OR,NAND): the XOR-true points (0,1) and (1,0) both become (1,1), and the XOR-false points become (0,1) and (1,0), which *are* separable from (1,1) by a line, the AND line. A hidden layer can change the geometry of the problem until one straight cut is enough. That is the central idea of Chapter 32.

Solution 5. Listing 31.8 trains on the raw centimeters and on the scaled values.

Listing 31.8 `sol_no_scaling.py`: the flower sorter with and without scaling.

```
"""Exercise 31.5: the flower sorter without feature scaling."""
from sklearn.model_selection import train_test_split
from flower_sorter import load_two_species
from perceptron import Perceptron

X, y = load_two_species()
X_train, X_test, y_train, y_test = train_test_split(
    X, y, test_size=0.3, random_state=42, stratify=y)
for label, A, B in [("raw cm", X_train, X_test),
                    ("scaled", (X_train - X_train.mean(0)) / X_train.std(0),
                     (X_test - X_train.mean(0)) / X_train.std(0))]:
    p = Perceptron(learning_rate=0.1, max_epochs=50).fit(A, y_train)
    acc = (p.predict(B) == y_test).mean()
    print(f"{label:7s} epochs={len(p.errors_):2d} mistakes={p.errors_} "
          f"test accuracy={acc:.3f}")
```

```
raw cm  epochs= 2 mistakes=[7, 0] test accuracy=1.000
scaled  epochs= 2 mistakes=[2, 0] test accuracy=1.000
```

Both versions reach a clean second epoch and a perfect test score, because setosa and versicolor are very far apart. But the raw version makes seven mistakes instead of two. On raw data every flower has positive measurements of a few centimeters, so the boundary must lie far from the origin, and the bias, which moves only $\eta = 0.1$ per mistake, needs several mistakes to travel there. On centered data the boundary through the origin is almost right from the start. On harder data sets the gap between the two versions grows much larger.

Solution 6. The test set is our only honest estimate of how the model behaves on new flowers. If we use it to choose the weights, it has become part of training, and the accuracy it reports is optimistic. If we need a set for choosing, we split the training data again into a training part and a *validation* part, and keep the test set untouched until the very end.

Chapter 32
Multilayer Network in NumPy

Chapter 31 ended with a wall: a single perceptron can only draw one straight line, so it can never learn XOR, and it could not cleanly separate two overlapping flower species. This chapter climbs over that wall. We build a *multilayer network*, a network with a hidden layer between its inputs and its outputs, in plain NumPy, with every derivative worked out by hand. By the end of the chapter you will be able to explain what a hidden layer does to the geometry of a problem, write the forward pass of a two-layer network as four equations, derive the famous *backpropagation* formulas with nothing more than the chain rule from school calculus, check those formulas numerically so that you never have to trust a derivative blindly, and use the network in a small application that separates two interleaved half-moons of points, a task on which a straight line is stuck at 93% while our network reaches 98%. Along the way you will meet the three training knobs that come back in every later chapter: the learning rate, the batch size and momentum. Every program in the chapter runs in a few seconds.

32.1 Why Stack Neurons?

Solution 31.4 gave a hint of what is coming. We took three perceptrons, trained one on OR and one on NAND, fed their two answers into a third one trained on AND, and the little team computed XOR, the function no single perceptron can learn. The first two perceptrons did something clever without being told: they moved the four input points to new positions where one straight line was enough.

That is the whole idea of a hidden layer. The inputs are transformed into new features, the network's own private description of the data, and the output layer only has to draw a simple boundary in the new description. But in Solution 31.4 *we* decided that the helpers should learn OR and NAND. For real data we have no idea what helpers would be useful. What does a good intermediate feature for recognizing a handwritten 7 look like? Nobody knows, and nobody wants to design it by hand.

The breakthrough, published by Rumelhart, Hinton and Williams in 1986, was a practical way to train all layers at once from examples, including the hidden ones whose correct outputs nobody knows [1]. The method is called *backpropagation*, because it sends the error at the output backward through the network, layer by layer, and tells every weight in which direction to move. The mathematics behind it is the chain rule for derivatives, which had been applied to such networks earlier as well, notably by Paul Werbos in 1974 [2]. Almost every neural network trained today, including the language models of Part 9, is trained with this same algorithm. Libraries like PyTorch compute the derivatives automatically (Chapter 33), but those libraries are much easier to trust, and to debug, once you have written backpropagation yourself at least once. That is what this chapter does.

Our application is deliberately small. The *two moons* data set is a cloud of 400 points in the plane, shaped like two interlocking crescents, generated by scikit-learn with a little noise [3]. It plays the role that a real problem such as "is this laundry order at risk of being late?" would play later: two classes that no straight line can separate well. **Figure 32.4** previews the result of this chapter.

32.2 The Idea in Plain Words

Think of a network with one hidden layer as a small office with two rows of clerks.

The first row, the *hidden layer*, contains several clerks. Each of them looks at all the inputs and computes a weighted sum, exactly like a perceptron. Instead of the hard yes/no step, however, each clerk passes the sum through a smooth squashing curve, the *tanh* function, which turns any number into a value between -1 and $+1$. A clerk's answer is therefore not "yes" or "no" but "how strongly yes or no". These answers are the new features.

The second row, the *output layer*, has one clerk per class. Each of them computes a weighted sum of the hidden clerks' answers. The output clerks' sums are finally turned into probabilities by the *softmax* function: big sums become big probabilities, and all the probabilities add up to 1. The network's answer is the class with the highest probability.

Learning works like a manager reviewing the office's mistakes. We show the network an example. We look at how much probability it gave to the correct class; the less it gave, the larger the *loss*, a single number that measures how wrong the network was. Then the manager goes backward through the office. First, the output clerks are told how their sums should change to reduce the loss. Then each hidden clerk is told how much of the blame is theirs: a hidden clerk whose answer was heavily used by an output clerk that got it wrong receives a large share of the blame, and one whose answer was barely used receives little. Finally every clerk adjusts their own weights a little in the direction that reduces the blame. Doing this for many examples, many times, is training [4].

Figure 32.1 shows the network we use for XOR: two inputs, three hidden units and two outputs, written *2-3-2*. The forward pass computes predictions from left to right; the backward pass sends the error from right to left.

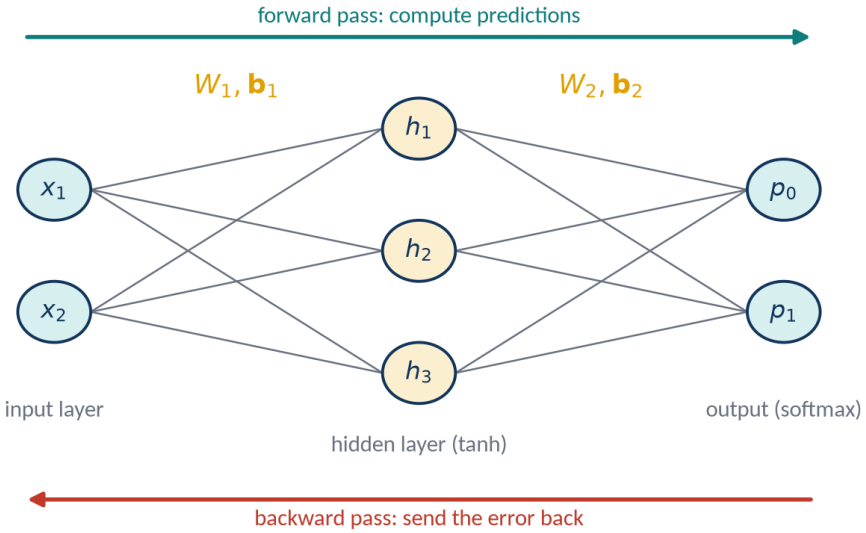

Figure 32.1 A 2-3-2 network. Every input is connected to every hidden unit through the weights W_1 and biases $\mathbf{b}_1$, and every hidden unit to every output through W_2 and $\mathbf{b}_2$. Predictions flow forward; the error flows backward.

> **KEY INSIGHT.** A hidden layer is a learned change of coordinates. The output layer is still only a set of linear boundaries, but it draws them in the space of hidden features, and in that space the problem can become easy.

32.3 The Mathematics, Gently

We need some notation. It looks heavy at first, but every symbol is a table of numbers you can print with NumPy.

32.3.1 The forward pass

We process m examples at once. Put them into a matrix X with m rows and n columns: row i is example i, column j is feature j. The hidden layer has h units. Its weights form a matrix W_1 with n rows and h columns (entry (j, k) is the weight from input j to hidden unit k), and its biases form a vector $\mathbf{b}_1$ of length h. The hidden layer computes

$$A = XW_1 + \mathbf{b}_1, \qquad H = \tanh(A) \tag{32.1}$$

Here XW_1 is a matrix product, $m \times n$ times $n \times h$, giving an $m \times h$ table: entry (i, k) is the weighted sum of example i for hidden unit k, the same z as in Equation (31.1) of Chapter 31 but for many units and examples at once. Adding $\mathbf{b}_1$ adds unit k's bias to every entry of column k (NumPy calls this *broadcasting*). The function tanh is applied to each entry separately. Its formula is $\tanh(a) = (e^a - e^{-a})/(e^a + e^{-a})$, but all you need to know is its shape, shown in the left panel of **Figure 32.2**: close to a itself near zero, flattening to -1 and $+1$ far away.

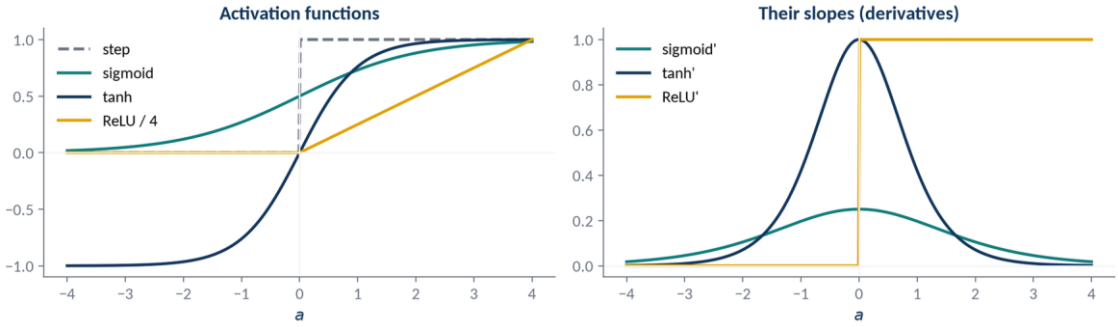

Figure 32.2 Left: the step function of Chapter 31 and three smooth activation functions (ReLU is shrunk by 4 to fit). Right: their slopes. The slope of tanh is largest at 0 and fades away on both sides; the step has slope 0 everywhere except at the jump, which is why it cannot be trained by gradients.

The output layer does the same with its own weights W_2 ($h \times c$, where c is the number of classes) and biases $\mathbf{b}_2$:

$$O = HW_2 + \mathbf{b}_2, \qquad P = \text{softmax}(O) \tag{32.2}$$

The entries of O are called *scores* or *logits*. The softmax turns each row of scores $o_1, \ldots, o_c$ into probabilities:

$$p_k = \frac{e^{o_k}}{\sum_{j=1}^{c} e^{o_j}} \tag{32.3}$$

Every e^{o_k} is positive, and dividing by their sum makes the row add up to 1, so P has one probability per example and class. A worked example: scores $(0.4621, -0.4621)$ give $e^{0.4621} = 1.5874$ and $e^{-0.4621} = 0.6300$, whose sum is 2.2174, so the probabilities are $1.5874/2.2174 = 0.7159$ and $0.6300/2.2174 = 0.2841$.

32.3.2 The loss

How wrong is the network? For example i with true class y_i, look at the probability P_{i,y_i} that the network gave to the correct class. If it is close to 1, all is well; if it is close to 0, the network was confidently wrong. The *cross-entropy loss* averages minus the logarithm of that probability over the m examples:

$$L = -\frac{1}{m}\sum_{i=1}^{m} \log P_{i,y_i} \tag{32.4}$$

Since $\log 1 = 0$ and $\log p$ plunges toward $-\infty$ as p approaches 0, the loss is 0 for perfect confidence in the right class and grows without limit for confident mistakes. In the example above, if the correct class is the second one, $L = -\log 0.2841 = 1.2584$. A network that knows nothing and gives probability $\frac{1}{2}$ to each of two classes has $L = \log 2 \approx 0.6931$; remember that number, because you will see it in the outputs of this chapter.

32.3.3 Gradient descent

Training means choosing $W_1, \mathbf{b}_1, W_2, \mathbf{b}_2$ to make L small. Imagine the loss as a hilly landscape over the space of all weights, and the network standing somewhere on it. The *gradient* $\partial L / \partial \theta$ of the loss with respect to a weight θ says how fast the loss rises when θ increases a little. To go downhill we step against it:

$$\theta \leftarrow \theta - \eta \frac{\partial L}{\partial \theta} \tag{32.5}$$

for every weight θ at once, with the learning rate η setting the step size. This is *gradient descent*. It is the smooth cousin of the perceptron rule, Equation (31.4) of Chapter 31: there we moved weights only after a mistake, by a fixed amount; here every example contributes, in proportion to how much each weight could reduce the loss. And this is exactly why we replaced the step by tanh: the right panel of **Figure 32.2** shows that the step has slope zero everywhere, so its gradient would tell us nothing, while tanh always has a useful slope.

The only question left is how to compute $\partial L / \partial \theta$ for every one of the network's weights. That is what backpropagation does.

32.3.4 The chain rule

The chain rule says: if L depends on u and u depends on θ, then

$$\frac{\partial L}{\partial \theta} = \frac{\partial L}{\partial u} \cdot \frac{\partial u}{\partial \theta} \tag{32.6}$$

In words: how fast L changes with θ is how fast L changes with u, times how fast u changes with θ. If turning a tap one notch raises the water level by 2 cm, and each centimeter of water raises the bill by 300 rupiah, then one notch costs $2 \times 300 = 600$ rupiah. The network is a long chain $W_1 \to A \to H \to O \to P \to L$, and backpropagation applies Equation (32.6) along it from the right end to the left, reusing every intermediate result.

32.3.5 Backpropagation, step by step

Step 1: the output scores. Take one example and write its loss with Equation (32.3): $L = -\log p_y = -o_y + \log \sum_j e^{o_j}$. Differentiate with respect to one score o_k. The first term gives -1 if $k = y$ and 0 otherwise. The second term gives $e^{o_k} / \sum_j e^{o_j} = p_k$. So $\partial L / \partial o_k = p_k - [k = y]$, where $[k = y]$ is 1 when k is the true class and 0 otherwise. For the whole batch, with the average of Equation (32.4) and the matrix Y that has a 1 in column y_i of row i and 0 elsewhere (the *one-hot* encoding of the labels),

$$\Delta_2 = \frac{\partial L}{\partial O} = \frac{1}{m}(P - Y) \tag{32.7}$$

This is one of the most beautiful results in machine learning: the gradient of softmax plus cross-entropy is simply "what the network said minus what it should have said". If the network gave the true class probability 0.28, the score of that class receives the push $0.28 - 1 = -0.72$ (per example, before averaging): raise me. The wrong class that got 0.72 receives $+0.72$: lower me.

Step 2: the output weights. Score $O_{i,k}$ is $\sum_r H_{i,r} (W_2)_{r,k} + (b_2)_k$, so by Equation (32.6) the weight $(W_2)_{r,k}$ collects the push on $O_{i,k}$ times $H_{i,r}$, summed over the examples. In matrix form,

$$\frac{\partial L}{\partial W_2} = H^\top \Delta_2, \qquad \frac{\partial L}{\partial \mathbf{b}_2} = \sum_{i=1}^{m} (\Delta_2)_{i,:} \tag{32.8}$$

where $H^\top$ is the transpose of H (rows and columns swapped) and the bias gradient is the column sum of Δ_2, because a bias is multiplied by an input that is always 1. Notice the pattern, which repeats in every layer: *the gradient of a weight is its input times the error signal at its output*.

Step 3: back into the hidden layer. Hidden value $H_{i,r}$ influences every score of its row through the weights $(W_2)_{r,k}$, so its share of the blame is $\sum_k (\Delta_2)_{i,k} (W_2)_{r,k}$, the matrix product $\Delta_2 W_2^\top$. To go from H back to A we multiply by the slope of tanh. That slope has a pleasant form:

$$\frac{d}{da}\tanh(a) = 1 - \tanh^2(a) \tag{32.9}$$

so we can compute it from H itself, without keeping A. Putting both together, with $\odot$ meaning "multiply entry by entry",

$$\Delta_1 = \frac{\partial L}{\partial A} = (\Delta_2 W_2^\top) \odot (1 - H \odot H) \tag{32.10}$$

Step 4: the hidden weights. Exactly as in Step 2, with X in the role of H:

$$\frac{\partial L}{\partial W_1} = X^\top \Delta_1, \qquad \frac{\partial L}{\partial \mathbf{b}_1} = \sum_{i=1}^{m} (\Delta_1)_{i,:} \tag{32.11}$$

That is all of backpropagation for this network: Equation (32.7), Equation (32.8), Equation (32.10) and Equation (32.11), four lines, each of which becomes one or two lines of NumPy. A deeper network simply repeats Steps 3 and 4 once per extra layer.

32.3.6 A worked example with real numbers

Let us run the four steps on the smallest possible network: one input, one hidden unit, two outputs. Take $x = 1$, $W_1 = 0.5$, $b_1 = 0$, $W_2 = (1, -1)$, $\mathbf{b}_2 = (0,0)$, and the true class $y = 1$ (the second output).

- Forward, Equation (32.1): $a = 0.5$, $h = \tanh(0.5) = 0.4621$.
- Forward, Equation (32.2): $O = (0.4621, -0.4621)$; the softmax computed in Section 32.3.1 gives $P = (0.7159, 0.2841)$.
- Loss, Equation (32.4): $L = -\log 0.2841 = 1.2584$.
- Step 1, Equation (32.7): $\Delta_2 = P - Y = (0.7159, 0.2841 - 1) = (0.7159, -0.7159)$.
- Step 2, Equation (32.8): $\partial L / \partial W_2 = h\,\Delta_2 = (0.3308, -0.3308)$ and $\partial L / \partial \mathbf{b}_2 = (0.7159, -0.7159)$.
- Step 3, Equation (32.10): $\Delta_2 W_2^{\top} = 0.7159 \cdot 1 + (-0.7159) \cdot (-1) = 1.4318$, and $1 - h^2 = 1 - 0.2135 = 0.7865$, so $\Delta_1 = 1.4318 \times 0.7865 = 1.1261$.
- Step 4, Equation (32.11): $\partial L / \partial W_1 = x\,\Delta_1 = 1.1261$ and $\partial L / \partial b_1 = 1.1261$.

Does it make sense? The true class is the second output, whose score is $-h$. To raise it, h must go *down*, so W_1 must go down; the gradient $+1.1261$ is positive, and Equation (32.5) subtracts it, so indeed W_1 decreases. With $\eta = 0.1$ one step gives $W_1 = 0.5 - 0.1126 = 0.3874$, and after updating all four parameters the loss falls from 1.2584 to 0.8983, while the probability of the correct class rises from 0.2841 to 0.4073. One step of gradient descent, computed by hand, moved the network the right way.

32.3.7 Checking a gradient numerically

Hand-derived gradients are easy to get subtly wrong: a missing transpose, a forgotten $1/m$. Fortunately we can check them. The definition of a derivative says that for a tiny ε,

$$\frac{\partial L}{\partial \theta} \approx \frac{L(\theta + \varepsilon) - L(\theta - \varepsilon)}{2\varepsilon} \tag{32.12}$$

This *central difference* needs two extra forward passes per weight, far too slow for training, but perfect for testing. If the analytic gradient from backpropagation and the numerical one agree to many digits, the derivation is right.

32.3.8 Momentum

Plain gradient descent in a long, narrow valley zigzags from wall to wall and makes slow progress along the valley floor. *Momentum* keeps a running velocity $\mathbf{v}$ for every weight, a memory of recent steps:

$$\mathbf{v} \leftarrow \beta \mathbf{v} - \eta \frac{\partial L}{\partial \theta}, \qquad \theta \leftarrow \theta + \mathbf{v} \tag{32.13}$$

With $\beta = 0.9$, consistent gradients add up and the steps grow, like a ball gathering speed down a slope, while gradients that flip sign cancel out. With $\beta = 0$, Equation (32.13) is exactly Equation (32.5). The idea goes back to Polyak [5]; its use for neural networks was popularized by Rumelhart and colleagues [1] and studied carefully by Sutskever and colleagues [6].

32.4 Building It Step by Step

The code is in `Chapter032` and needs NumPy 2.4.6 [7] and scikit-learn 1.9.1 (for generating the moons and for the logistic-regression comparison). No deep-learning library is used: every derivative is ours.

32.4.1 The network

Listing 32.1 is the whole network and its training loop.

Listing 32.1 `mlp.py`: a two-layer network with a tanh hidden layer and a softmax output, its hand-written backward pass, and a training loop with mini-batches and momentum.

```
"""A two-layer neural network in NumPy with backpropagation by hand (Chapter 32)."""
import numpy as np

def softmax(O):
    """Turn each row of scores into probabilities that add up to 1."""
    E = np.exp(O - O.max(axis=1, keepdims=True))    # shift for numerical safety
    return E / E.sum(axis=1, keepdims=True)

class MLP:
    """input -> tanh hidden layer -> softmax output."""

    def __init__(self, n_in, n_hidden, n_out, seed=0):
        rng = np.random.default_rng(seed)
        # small random weights break the symmetry between hidden units
        self.W1 = rng.normal(0.0, 1.0 / np.sqrt(n_in), (n_in, n_hidden))
        self.b1 = np.zeros(n_hidden)
        self.W2 = rng.normal(0.0, 1.0 / np.sqrt(n_hidden), (n_hidden, n_out))
        self.b2 = np.zeros(n_out)

    def params(self):
        return [self.W1, self.b1, self.W2, self.b2]

    def forward(self, X):
        """Return the class probabilities and remember what backward needs."""
        self.X = X
        self.H = np.tanh(X @ self.W1 + self.b1)      # hidden activations
        self.P = softmax(self.H @ self.W2 + self.b2)  # output probabilities
        return self.P

    def loss(self, X, y):
        """Average cross-entropy: -log of the probability of the true class."""
        P = self.forward(X)
        return -np.mean(np.log(P[np.arange(len(y)), y] + 1e-12))
```

Listing 32.1 (Continued) *mlp.py: a two-layer network with a tanh hidden layer and a softmax output, its hand-written backward pass, and a training loop with mini-batches and momentum.*

```
    def backward(self, y):
        """Gradients of the average loss, by the chain rule, layer by layer."""
        m = len(y)
        D2 = self.P.copy()
        D2[np.arange(m), y] -= 1.0                    # dL/dO = P - Y
        D2 /= m
        dW2 = self.H.T @ D2
        db2 = D2.sum(axis=0)
        D1 = (D2 @ self.W2.T) * (1.0 - self.H ** 2)  # tanh'(a) = 1 - tanh(a)^2
        dW1 = self.X.T @ D1
        db1 = D1.sum(axis=0)
        return [dW1, db1, dW2, db2]

    def predict(self, X):
        return self.forward(X).argmax(axis=1)

def train(net, X, y, epochs, lr, batch_size=None, momentum=0.0, seed=0):
    """Gradient descent (full batch or mini-batch), optionally with momentum."""
    rng = np.random.default_rng(seed)
    velocity = [np.zeros_like(p) for p in net.params()]
    batch_size = batch_size or len(X)
    history = []
    for epoch in range(epochs):
        order = rng.permutation(len(X))
        for start in range(0, len(X), batch_size):
            idx = order[start:start + batch_size]
            net.forward(X[idx])
            grads = net.backward(y[idx])
            for p, g, v in zip(net.params(), grads, velocity):
                v *= momentum
                v -= lr * g
                p += v                                # update in place
        history.append(net.loss(X, y))
    return history
```

Match the code with the mathematics:

- `softmax` is Equation (32.3), with one safety trick. e^{1000} overflows to infinity, and infinity divided by infinity is not a number. Subtracting the largest score of each row first changes nothing mathematically (the factor $e^{-\max}$ cancels between numerator and denominator) but keeps every exponent at most $e^0 = 1$.
- The constructor draws the weights from a normal distribution with standard deviation $1/\sqrt{n_{\text{in}}}$, so that a weighted sum of n_{in} inputs starts at a sensible size, a simple form of the initialization studied by Glorot and Bengio [8]. The weights must be random: if all hidden units started identical, they would receive identical gradients and stay identical forever. Exercise 32.4 lets you watch that happen.
- `forward` is Equation (32.1) and Equation (32.2). It stores `X`, `H` and `P` in the object, because the backward pass needs them.
- `loss` is Equation (32.4). `P[np.arange(len(y)), y]` picks, from each row i, the entry in column y_i: the probability of the true class. The tiny `1e-12` prevents log0.
- `backward` is the heart of the chapter. `D2` is Δ_2 from Equation (32.7): a copy of P with 1 subtracted at each true class, divided by m. `dW2` and `db2` are Equation (32.8). `D1` is Equation (32.10), using Equation (32.9). `dW1` and `db1` are Equation (32.11).
- `train` loops over epochs. In each epoch it shuffles the examples and cuts them into *mini-batches* of `batch_size` rows (the whole set when `batch_size` is `None`). For each batch it runs forward,

backward, and the update Equation (32.13); with `momentum=0.0` that is plain Equation (32.5). The in-place operations `v *= ...`, `v -= ...` and `p += v` change the arrays inside the network, so no copying is needed. After each epoch it records the loss on the whole training set.

32.4.2 Solving XOR

Listing 32.2 trains a 2-3-2 network on the four XOR examples with full-batch gradient descent and prints what the hidden units learned.

Listing 32.2 `xor_mlp.py`: training a 2-3-2 network on XOR and printing the hidden activations.

```
"""The XOR problem that defeated one perceptron, solved by a hidden layer."""
import numpy as np
from mlp import MLP, train

X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)
y = np.array([0, 1, 1, 0])

net = MLP(n_in=2, n_hidden=3, n_out=2, seed=1)
print(f"loss before training: {net.loss(X, y):.4f}")
history = train(net, X, y, epochs=2000, lr=0.5)
for epoch in (1, 10, 100, 500, 1000, 2000):
    print(f"epoch {epoch:4d}  loss {history[epoch - 1]:.4f}")

P = net.forward(X)
print("x1 x2 | hidden units         | P(class 1) | answer")
for x, h, p in zip(X.astype(int), net.H, P[:, 1]):
    hs = " ".join(f"{v:+.2f}" for v in h)
    print(f" {x[0]}  {x[1]} | {hs:20s} |   {p:.3f}    |   {int(p > 0.5)}")
```

32.4.3 Checking the gradients

Listing 32.3 applies Equation (32.12) to every weight of a random 3-6-4 network on five random examples and compares the result with `backward`.

Listing 32.3 `gradcheck.py`: comparing backpropagation with central differences for every weight.

```
"""Check the hand-written gradients against numerical ones (Chapter 32)."""
import numpy as np
from mlp import MLP

rng = np.random.default_rng(7)
X = rng.normal(size=(5, 3))
y = rng.integers(0, 4, size=5)
net = MLP(n_in=3, n_hidden=6, n_out=4, seed=7)

net.forward(X)
analytic = net.backward(y)
eps = 1e-5
for name, p, g in zip(["W1", "b1", "W2", "b2"], net.params(), analytic):
    numeric = np.zeros_like(p)
    for i in np.ndindex(p.shape):
        old = p[i]
        p[i] = old + eps
        up = net.loss(X, y)
        p[i] = old - eps
        down = net.loss(X, y)
        p[i] = old                                  # put the weight back
        numeric[i] = (up - down) / (2 * eps)        # central difference
    rel = np.abs(g - numeric).max() / max(np.abs(g).max(), np.abs(numeric).max())
    print(f"{name}: shape {str(p.shape):7s} max relative difference {rel:.1e}")
```

The loop `for i in np.ndindex(p.shape)` visits every index of a weight array, whatever its shape. We nudge one weight up by ε, compute the loss, nudge it down, compute again, and put the weight back. The printed number is the largest difference between the two gradients relative to the largest gradient, so it does not depend on the scale of the gradients.

32.4.4 The application: a two-moons classifier

Listing 32.4 is the application. It generates the moons, holds out a quarter of the points for testing, trains a logistic-regression model (a single smooth neuron, the best a straight line can do) and our 2-16-2 network, and classifies a point from the command line.

Listing 32.4 `moons_app.py`: two moons, a straight line and a 2-16-2 network.

```
"""Two-moons classifier: a line cannot do it, a hidden layer can (Chapter 32).

usage: python moons_app.py [x1 x2]
"""
import sys
import numpy as np
from sklearn.datasets import make_moons
from sklearn.linear_model import LogisticRegression
from sklearn.model_selection import train_test_split
from mlp import MLP, train

X, y = make_moons(n_samples=400, noise=0.2, random_state=0)   # generated data
X_train, X_test, y_train, y_test = train_test_split(
    X, y, test_size=0.25, random_state=0, stratify=y)

line = LogisticRegression().fit(X_train, y_train)
print(f"straight line (logistic regression): test accuracy "
      f"{line.score(X_test, y_test):.3f}")

net = MLP(n_in=2, n_hidden=16, n_out=2, seed=0)
history = train(net, X_train, y_train, epochs=300, lr=0.1, batch_size=16)
for epoch in (1, 50, 100, 200, 300):
    print(f"epoch {epoch:3d}  training loss {history[epoch - 1]:.4f}")
train_acc = (net.predict(X_train) == y_train).mean()
test_acc = (net.predict(X_test) == y_test).mean()
print(f"network 2-16-2: train accuracy {train_acc:.3f}, "
      f"test accuracy {test_acc:.3f}")

if len(sys.argv) == 3:
    point = np.array([[float(sys.argv[1]), float(sys.argv[2])]])
    p = net.forward(point)[0]
    print(f"point ({sys.argv[1]}, {sys.argv[2]}): P(moon 0) = {p[0]:.3f}, "
          f"P(moon 1) = {p[1]:.3f} -> moon {p.argmax()}")
```

`make_moons` generates the data inside the program, so nothing is downloaded, and `random_state=0` makes the 400 points the same on every machine. The network trains for 300 epochs on mini-batches of 16 points with $\eta = 0.1$.

32.4.5 Tests

Listing 32.5 pins down three properties: softmax rows add up to 1 even for huge scores, one entry of the backpropagated gradient matches its central difference to seven decimal places, and the network learns XOR.

Listing 32.5 `test_mlp.py`: unit tests for the NumPy network.

```
"""Unit tests for the NumPy network (run: python -m unittest)."""
import unittest
import numpy as np
from mlp import MLP, softmax, train

class MLPTest(unittest.TestCase):
    def test_softmax_rows_sum_to_one(self):
        P = softmax(np.array([[1.0, 2.0, 3.0], [1000.0, 1000.0, 0.0]]))
        self.assertTrue(np.allclose(P.sum(axis=1), 1.0))
        self.assertAlmostEqual(P[1, 0], 0.5)         # no overflow on 1000

    def test_gradient_matches_numerical(self):
        rng = np.random.default_rng(0)
        X, y = rng.normal(size=(4, 2)), np.array([0, 1, 1, 0])
        net = MLP(2, 3, 2, seed=0)
        net.forward(X)
        dW1 = net.backward(y)[0]
        eps, old = 1e-5, net.W1[0, 0]
        net.W1[0, 0] = old + eps
        up = net.loss(X, y)
        net.W1[0, 0] = old - eps
        down = net.loss(X, y)
        net.W1[0, 0] = old
        self.assertAlmostEqual(dW1[0, 0], (up - down) / (2 * eps), places=7)

    def test_learns_xor(self):
        X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)
        y = np.array([0, 1, 1, 0])
        net = MLP(2, 3, 2, seed=1)
        train(net, X, y, epochs=2000, lr=0.5)
        self.assertEqual(net.predict(X).tolist(), [0, 1, 1, 0])

if __name__ == "__main__":
    unittest.main()
```

32.5 Running It

Start with XOR:

```
python xor_mlp.py
```

```
loss before training: 0.6933
epoch    1  loss 0.6892
epoch   10  loss 0.6734
epoch  100  loss 0.4022
epoch  500  loss 0.0111
epoch 1000  loss 0.0036
epoch 2000  loss 0.0015
x1 x2 | hidden units         | P(class 1) | answer
 0  0 | -0.81 -0.70 -0.16    |   0.000    |   0
 0  1 | -1.00 +0.99 -0.89    |   0.998    |   1
 1  0 | +0.93 +0.96 +1.00    |   0.998    |   1
 1  1 | -0.97 +1.00 +0.95    |   0.002    |   0
```

The loss starts at 0.6933, almost exactly log2: with small random weights both classes get probability close to $\frac{1}{2}$. For the first hundred epochs little seems to happen; then the loss drops, and after 2000 epochs it is 0.0015, which means the correct class receives probability about $e^{-0.0015} \approx 0.9985$. All four answers are right. The hidden columns show *how*: look at the second hidden unit. It is -0.70 for (0,0) and close to $+1$ for the other three inputs, so it has learned roughly OR. The third unit is strongly positive only when $x_1 = 1$. From such features, the output

layer can separate the XOR classes with a line in hidden space, just as our hand-made OR/NAND network did in Solution 31.4, but here nobody told the network which features to invent. The left panel of **Figure 32.3** shows the regions the network carved out of the input plane: two curved bands, something no perceptron can draw. The right panel shows the loss on a logarithmic epoch axis, with its long flat start and a second plateau before the last plunge, typical of small networks.

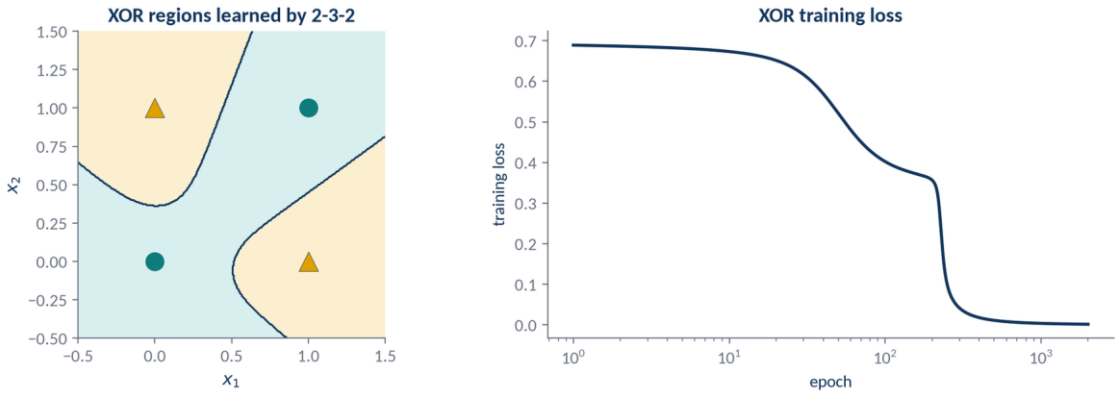

Figure 32.3 Left: the decision regions of the trained 2-3-2 network for XOR; triangles are class 1, circles class 0. Right: the training loss per epoch (logarithmic axis) from the run of **Listing 32.2**.

Now the gradient check:

```
python gradcheck.py
```

```
W1: shape (3, 6)  max relative difference 2.5e-10
b1: shape (6,)    max relative difference 4.5e-11
W2: shape (6, 4)  max relative difference 9.4e-11
b2: shape (4,)    max relative difference 1.2e-11
```

Relative differences around 10^{-10} mean that the hand-derived gradients agree with the numerical ones to about ten significant digits, which is as close as the rounding in Equation (32.12) allows. If you break `backward`, for instance by deleting the `(1.0 - self.H ** 2)` factor, the differences jump to around 10^{-1}, and you know at once that something is wrong.

Then the application, with a point near the tips of the moons:

```
python moons_app.py 0.5 0.25
```

```
straight line (logistic regression): test accuracy 0.930
epoch   1  training loss 0.4105
epoch  50  training loss 0.1927
epoch 100  training loss 0.1257
epoch 200  training loss 0.1010
epoch 300  training loss 0.0963
network 2-16-2: train accuracy 0.967, test accuracy 0.980
point (0.5, 0.25): P(moon 0) = 0.772, P(moon 1) = 0.228 -> moon 0
```

The straight line reaches 93.0% on the test points, which sounds good until you look at **Figure 32.4**: its errors are exactly the tips of the crescents, the points that most need a curved boundary. The network reaches 98.0% on the test points (and 96.7% on the training points, a sign that it is not memorizing). The right panel of **Figure 32.4** shows the boundary it learned, a smooth S-curve that follows the gap between the moons. The point (0.5,0.25) lies near the curve, and the network says so honestly: 77% moon 0, not 100%.

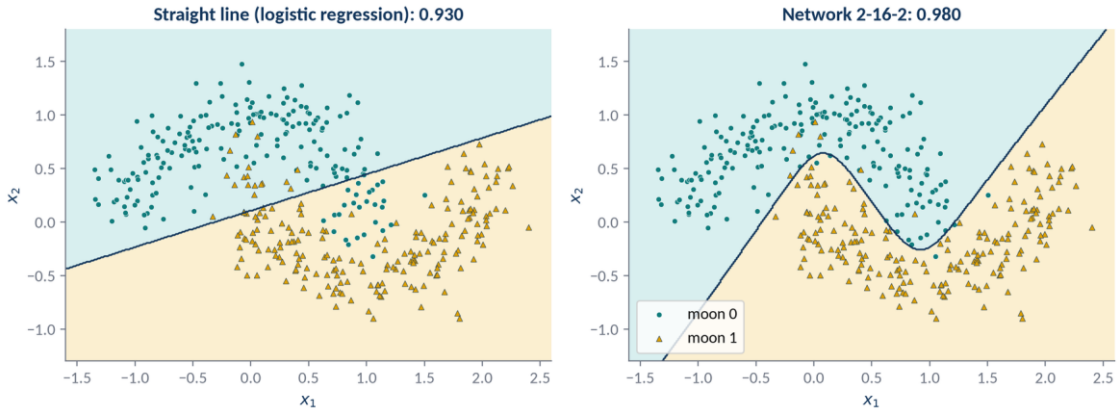

Figure 32.4 The two moons with the decision regions of logistic regression (left) and of the 2-16-2 network trained by **Listing 32.4** (right). The titles give the test accuracy.

Finally the tests:

```
python -m unittest
```

```
...
----------------------------------------------------------------------
Ran 3 tests in 0.265s

OK
```

32.6 Improving It

The network works; now let us make it train better and understand the knobs. **Listing 32.6** runs two small experiments on the moons.

Listing 32.6 `improve.py`: comparing full-batch, mini-batch and momentum training, and five sizes of hidden layer.

```
"""Improving training: mini-batches, momentum and the size of the hidden layer."""
import numpy as np
from sklearn.datasets import make_moons
from sklearn.model_selection import train_test_split
from mlp import MLP, train

X, y = make_moons(n_samples=400, noise=0.2, random_state=0)
X_train, X_test, y_train, y_test = train_test_split(
    X, y, test_size=0.25, random_state=0, stratify=y)

print("how to take the steps (16 hidden units, 100 epochs, lr 0.1):")
settings = [("full batch", None, 0.0), ("mini-batch 16", 16, 0.0),
            ("mini-batch 16 + momentum 0.9", 16, 0.9)]
for name, batch, mom in settings:
    net = MLP(2, 16, 2, seed=0)
    h = train(net, X_train, y_train, epochs=100, lr=0.1,
              batch_size=batch, momentum=mom)
    acc = (net.predict(X_test) == y_test).mean()
    print(f"  {name:30s} final loss {h[-1]:.4f}  test acc {acc:.3f}")

print("how many hidden units (mini-batch 16 + momentum 0.9, 100 epochs):")
for n_hidden in (1, 2, 4, 16, 64):
    net = MLP(2, n_hidden, 2, seed=0)
    h = train(net, X_train, y_train, epochs=100, lr=0.1, batch_size=16,
              momentum=0.9)
    acc = (net.predict(X_test) == y_test).mean()
    print(f"  hidden {n_hidden:2d}: final loss {h[-1]:.4f}  test acc {acc:.3f}")
```

```
python improve.py
```

```
how to take the steps (16 hidden units, 100 epochs, lr 0.1):
  full batch                    final loss 0.3352  test acc 0.930
  mini-batch 16                 final loss 0.1257  test acc 0.950
  mini-batch 16 + momentum 0.9  final loss 0.0936  test acc 0.980
how many hidden units (mini-batch 16 + momentum 0.9, 100 epochs):
  hidden  1: final loss 0.3344  test acc 0.930
  hidden  2: final loss 0.3205  test acc 0.890
  hidden  4: final loss 0.0915  test acc 0.970
  hidden 16: final loss 0.0936  test acc 0.980
  hidden 64: final loss 0.1180  test acc 0.970
```

Mini-batches. With the full batch, each epoch makes exactly one step, computed from all 300 training points. With mini-batches of 16, each epoch makes 19 steps, each computed from 16 points. The individual steps are noisier, because 16 points are a rough sample of the whole, but there are nineteen times as many of them, and in 100 epochs the loss falls to 0.1257 instead of 0.3352. This is *stochastic* (or mini-batch) gradient descent, the way essentially all modern networks are trained.

Momentum. Adding momentum 0.9 with Equation (32.13) brings the loss down to 0.0936 in the same 100 epochs and the test accuracy up to 98%. **Figure 32.5** shows the three loss curves. The momentum curve falls fastest but wobbles: a heavy ball overshoots a little before it settles.

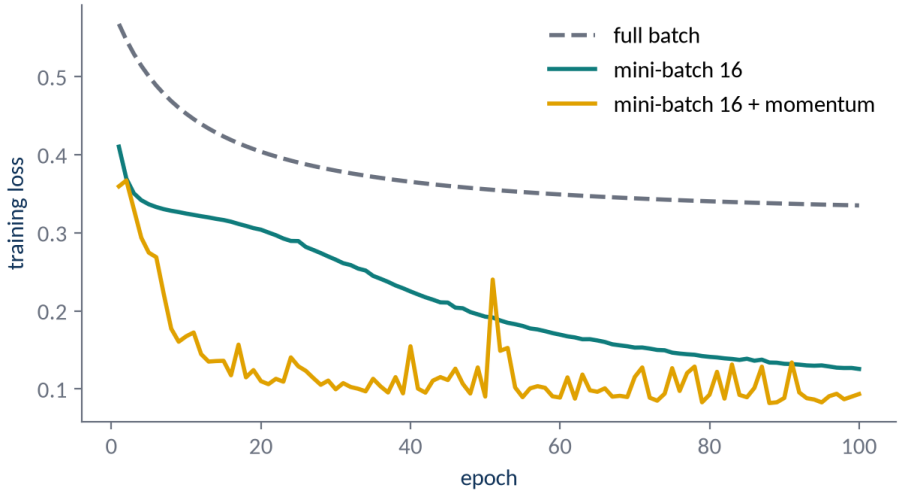

Figure 32.5 Training loss per epoch on the moons for full-batch gradient descent, mini-batches of 16, and mini-batches with momentum 0.9, from the run of **Listing 32.6**.

Hidden layer size. With one or two hidden units the network can bend its boundary only a little, and the loss stays above 0.32; the test accuracy of 0.93 for one unit is no better than the straight line, and two units happen to do worse. Four units are enough for a good curve. Sixteen units do slightly better on the test points, and sixty-four gain nothing more on this small problem. More capacity is not automatically better: past the point where the model can represent the pattern, extra units only add more ways to fit the noise. Chapter 33 meets this again with a validation set.

Other activations. Most modern networks use the *ReLU* activation, $\max(0, a)$, whose slope is simply 0 or 1 (**Figure 32.2**). It is cheaper and does not flatten out for large positive inputs. Exercise 32.3 swaps it in.

32.7 Common Mistakes, and How to Avoid Them

Initializing all weights to zero. Then every hidden unit computes the same thing and receives the same gradient, and with tanh the gradients are exactly zero: the network is frozen at $L = \log 2$. Use small random weights.

Forgetting the $1/m$. If the gradient is a sum over the batch instead of an average, the effective learning rate grows with the batch size, and a setting that worked with 16 examples explodes with 300. Our `backward` divides once, in `D2 /= m`, and every later gradient inherits it.

Shape errors that NumPy silently broadcasts. A bias gradient of shape (m, h) instead of $(h,)$, or a label vector of shape $(m, 1)$ instead of $(m,)$, will often not raise an error but produce nonsense. Print shapes, and run the gradient check after every change to `backward`.

Computing softmax without the shift. `np.exp(1000)` is `inf`, and the loss becomes `nan`. Always subtract the row maximum.

A learning rate that is too large. Gradient descent assumes that the landscape is roughly flat over one step. Too large a step jumps across valleys, and the loss rises instead of falling. Exercise 32.5 shows it: with $\eta = 20$ the loss climbs to around 8.

Trusting a rising test accuracy blindly. Our moons are generated and clean. On real data, compare several settings on a validation set, not on the test set, as Chapter 31 explained.

32.8 Chapter Summary

- A hidden layer transforms the inputs into learned features (Equation (32.1)); the output layer turns features into scores and, through softmax (Equation (32.3)), into probabilities (Equation (32.2)).
- Cross-entropy (Equation (32.4)) measures how little probability the true class received; gradient descent (Equation (32.5)) lowers it by stepping against the gradient.
- Backpropagation is the chain rule (Equation (32.6)) applied from the output back: $\Delta_2 = (P - Y)/m$ (Equation (32.7)), weight gradients are inputs times error signals (Equation (32.8), Equation (32.11)), and the error travels back through $W_2^\top$ and the slope of tanh (Equation (32.9), Equation (32.10)).
- Always check hand-written gradients numerically with central differences (Equation (32.12)).
- Mini-batches and momentum (Equation (32.13)) make training much faster; a moderate hidden layer is enough for a moderate problem.
- A 2-3-2 network learns XOR, and a 2-16-2 network separates the two moons with 98% test accuracy where a straight line reaches 93%.

32.9 Exercises

1. Repeat the worked example of Section 32.3.6 with the true class $y = 0$ instead of $y = 1$. Compute L, Δ_2, Δ_1 and $\partial L / \partial W_1$, and say in which direction W_1 moves and why.
2. Derive $\partial L / \partial o_k = p_k - [k = y]$ for a network with three classes by writing out $L = -\log p_y$ in full for $y = 2$ and differentiating with respect to o_1, o_2 and o_3 separately.
3. Replace tanh by ReLU, $\max(0, a)$, in the hidden layer. Which lines of `forward` and `backward` change, and what does the slope used in Equation (32.10) become? Compare the two activations on the moons with mini-batches and momentum.

4. Set all weights and biases of the XOR network to zero before training. Predict what happens, run it, and explain the output using Equation (32.8) and Equation (32.10).
5. Train the 2-16-2 network on all 400 moon points for 50 epochs with mini-batches of 16 and learning rates 0.001, 0.1, 1 and 20, and print the loss every 10 epochs. Describe the four behaviors.
6. Count the weights and biases of a network with 64 inputs, one hidden layer of 32 units and 10 outputs. How many multiplications does one forward pass of a single example need?

32.10 Solutions to the Exercises

Solution 1. The forward pass is unchanged: $h = 0.4621$, $P = (0.7159, 0.2841)$. Now the correct class is the first one, so $L = -\log 0.7159 = 0.3342$, and $\Delta_2 = (0.7159 - 1, 0.2841) = (-0.2841, 0.2841)$. Then $\Delta_2 W_2^\top = -0.2841 \cdot 1 + 0.2841 \cdot (-1) = -0.5682$ and $\Delta_1 = -0.5682 \times 0.7865 = -0.4469$, so $\partial L / \partial W_1 = -0.4469$. The gradient is negative, so Equation (32.5) *increases* W_1. That is right: the first class has score $+h$, and to raise it h must grow. The loss is smaller than before (0.33 against 1.26) because the network was already leaning the right way, and the gradient is correspondingly smaller.

Solution 2. With three classes, $L = -\log \frac{e^{o_2}}{e^{o_1} + e^{o_2} + e^{o_3}} = -o_2 + \log(e^{o_1} + e^{o_2} + e^{o_3})$. Differentiating the logarithm gives $\frac{e^{o_k}}{e^{o_1} + e^{o_2} + e^{o_3}} = p_k$ for each k. The term $-o_2$ contributes -1 only for $k = 2$. So $\partial L / \partial o_1 = p_1$, $\partial L / \partial o_2 = p_2 - 1$ and $\partial L / \partial o_3 = p_3$, which is $p_k - [k = 2]$.

Solution 3. Only the activation and its slope change. In Equation (32.10) the factor $1 - H \odot H$ becomes the slope of ReLU, which is 1 where $a > 0$ and 0 elsewhere. (We use 0 at exactly $a = 0$, where the slope is undefined; it almost never happens.) Since $H > 0$ exactly where $A > 0$, either could be tested, but keeping A and testing `A > 0` makes the code read like the mathematics. **Listing 32.7** subclasses `MLP` and overrides the two methods.

Listing 32.7 `sol_relu.py`: a ReLU hidden layer.

```
"""Exercise 32.3: the same network with a ReLU hidden layer."""
import numpy as np
from sklearn.datasets import make_moons
from sklearn.model_selection import train_test_split
from mlp import MLP, softmax, train

class ReluMLP(MLP):
    def forward(self, X):
        self.X = X
        self.A = X @ self.W1 + self.b1
        self.H = np.maximum(self.A, 0.0)              # ReLU
        self.P = softmax(self.H @ self.W2 + self.b2)
        return self.P

    def backward(self, y):
        m = len(y)
        D2 = self.P.copy()
        D2[np.arange(m), y] -= 1.0
        D2 /= m
        D1 = (D2 @ self.W2.T) * (self.A > 0)          # ReLU'(a) = 1 if a > 0
        return [self.X.T @ D1, D1.sum(axis=0), self.H.T @ D2, D2.sum(axis=0)]

X, y = make_moons(n_samples=400, noise=0.2, random_state=0)
X_train, X_test, y_train, y_test = train_test_split(
    X, y, test_size=0.25, random_state=0, stratify=y)
for cls in (MLP, ReluMLP):
    net = cls(2, 16, 2, seed=0)
    h = train(net, X_train, y_train, epochs=100, lr=0.1, batch_size=16,
              momentum=0.9)
    acc = (net.predict(X_test) == y_test).mean()
    print(f"{cls.__name__:8s} final loss {h[-1]:.4f}  test acc {acc:.3f}")
```

```
MLP      final loss 0.0936  test acc 0.980
ReluMLP  final loss 0.0789  test acc 0.980
```

On this problem both reach 98% on the test points; ReLU reaches a slightly lower training loss. The differences between activations matter more in deep networks, where the fading slope of tanh far from zero (**Figure 32.2**) makes the error signal shrink layer after layer.

Solution 4. Listing 32.8 zeroes every parameter before training.

Listing 32.8 `sol_zero_init.py`: training XOR from all-zero weights.

```
"""Exercise 32.4: what happens when every weight starts at zero."""
import numpy as np
from mlp import MLP, train

X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]], dtype=float)
y = np.array([0, 1, 1, 0])
net = MLP(2, 3, 2, seed=1)
for p in net.params():
    p[...] = 0.0                                      # overwrite in place
history = train(net, X, y, epochs=2000, lr=0.5)
print(f"loss after 2000 epochs: {history[-1]:.4f}")
print("W1 =", net.W1.round(3).tolist())
print("W2 =", net.W2.round(3).tolist())
print("predictions:", net.predict(X).tolist())
```

```
loss after 2000 epochs: 0.6931
W1 = [[0.0, 0.0, 0.0], [0.0, 0.0, 0.0]]
W2 = [[0.0, 0.0], [0.0, 0.0], [0.0, 0.0]]
predictions: [0, 0, 0, 0]
```

Nothing is learned. With $W_1 = 0$ and $\mathbf{b}_1 = 0$, every hidden value is $\tanh(0) = 0$, so by Equation (32.8) $\partial L / \partial W_2 = H^\top \Delta_2 = 0$. With $W_2 = 0$, by Equation (32.10) $\Delta_1 = (\Delta_2 W_2^\top) \odot (\dots) = 0$, so $\partial L / \partial W_1 = 0$. Only $\mathbf{b}_2$ receives a gradient, and since XOR has two examples of each class, even that averages to zero. The loss stays at $\log 2 = 0.6931$ and every prediction is class 0 (the first of two equal probabilities). Even with nonzero but *equal* starting weights the hidden units would stay copies of one another. Random initialization is what lets hidden units become different.

Solution 5. **Listing 32.9** trains four networks.

Listing 32.9 `sol_learning_rate.py`: four learning rates on the moons.

```
"""Exercise 32.5: learning rates that are too small, right, and too large."""
from sklearn.datasets import make_moons
from mlp import MLP, train

X, y = make_moons(n_samples=400, noise=0.2, random_state=0)
for lr in (0.001, 0.1, 1.0, 20.0):
    net = MLP(2, 16, 2, seed=0)
    h = train(net, X, y, epochs=50, lr=lr, batch_size=16)
    shown = " ".join(f"{v:.3f}" for v in h[::10])
    print(f"lr {lr:6.3f}: loss every 10 epochs {shown}")
```

```
lr  0.001: loss every 10 epochs 0.581 0.527 0.488 0.460 0.438
lr  0.100: loss every 10 epochs 0.370 0.296 0.263 0.220 0.182
lr  1.000: loss every 10 epochs 0.313 0.122 0.126 0.115 0.112
lr 20.000: loss every 10 epochs 7.951 3.730 2.700 3.183 8.151
```

With $\eta = 0.001$ the loss falls, but so slowly that after 50 epochs it is still 0.438. With $\eta = 0.1$ it falls steadily. With $\eta = 1$ it falls fastest and flattens near 0.11. With $\eta = 20$ the steps are so large that the network jumps back and forth across the landscape: the loss starts near 8, much *worse* than the log2 of an untrained network, and never settles. Choosing the learning rate is the first thing to tune on any new problem.

Solution 6. W_1 has $64 \times 32 = 2048$ weights and $\mathbf{b}_1$ has 32 biases; W_2 has $32 \times 10 = 320$ weights and $\mathbf{b}_2$ has 10 biases. The total is $2048 + 32 + 320 + 10 = 2410$ parameters. A forward pass of one example needs one multiplication per weight, $2048 + 320 = 2368$ multiplications, plus 32 tanh and 10 exponentials. This is exactly the network Chapter 33 trains on handwritten digits, there with PyTorch.

Chapter 33
Digit Recognizer in PyTorch

In Chapter 32 we wrote every derivative of a neural network by hand. It was worth doing once, and once is enough. This chapter hands the calculus to *PyTorch*, the open-source deep-learning library used in most research papers and in a large share of industry, and uses it to build a program that reads handwritten digits. By the end of the chapter you will be able to create PyTorch *tensors* and let *autograd* compute gradients for you, check that autograd gives exactly the numbers we computed by hand in Chapter 32, describe a network as an `nn.Module`, feed it mini-batches with a `DataLoader`, write the five-line training loop that every PyTorch program shares, keep a *validation set* apart to decide when to stop training, save a trained model to a file and load it again in a separate application, read a *confusion matrix* to see which digits the model mixes up, and compare the SGD and Adam optimizers, ReLU and tanh, and dropout on an honest footing. The model has 2,410 weights, reaches about 97% on digits it has never seen, and trains in about two seconds on one CPU core.

33.1 Why Recognize Digits?

Every day, in every post office, bank and laundry in the country, someone reads handwritten numbers: a postal code on an envelope, an amount on a deposit slip, a phone number on a laundry tag written in a hurry by the person at the counter. Reading them is dull work, and mistakes are expensive: a wrong digit in a phone number means the "your laundry is ready" message never arrives. Machines that read handwritten digits were one of the first big commercial successes of neural networks: in the 1990s, convolutional networks trained on the MNIST collection of handwritten digits were reading a large fraction of the checks written in the United States [1].

MNIST's images are 28 × 28 pixels and need a download. We use its little sibling, which ships inside scikit-learn: 1,797 handwritten digits, each a small 8 × 8 grid of gray levels from 0 (white) to 16 (black), taken from the UCI *Optical Recognition of Handwritten Digits* collection [2], [3]. **Figure 33.1** shows three examples of each digit. They are rough, but a person reads most of them at once, and so, by the end of this chapter, will our program.

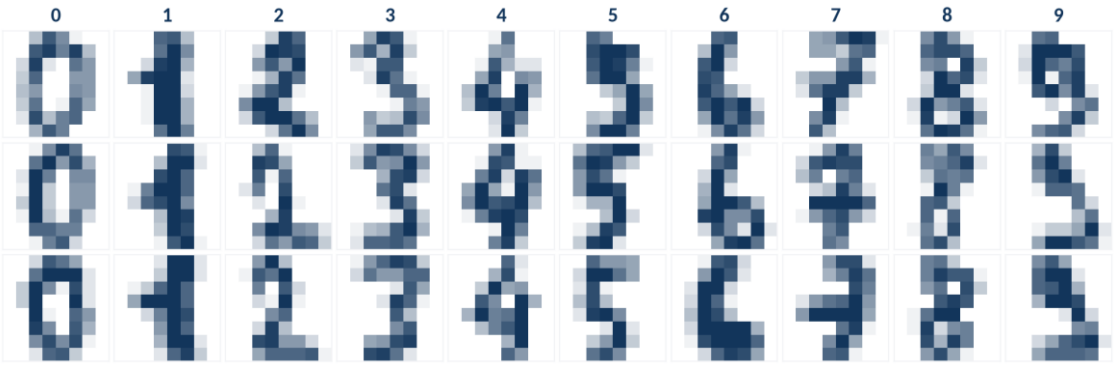

Figure 33.1 Three examples of each digit from the scikit-learn digits data set. Each image is only 8 × 8 pixels with 17 gray levels.

Why a new library, when Chapter 32 already trained a network with NumPy? Because Chapter 32's network had exactly one hidden layer, and its backward pass was written for exactly that

shape. Add a layer, swap tanh for ReLU, add dropout, and you must derive and debug new gradients by hand every time. PyTorch records every operation you perform on its tensors and can run the chain rule backward through any sequence of operations automatically [4]. You describe only the forward pass; the backward pass is free. PyTorch also brings ready-made layers, loss functions, optimizers and data loaders, so that the code you write is about your problem rather than about calculus. The current release, PyTorch 2.14, came out on September 2, 2026 and supports Python 3.10 to 3.15 [5]. It is also the library the rest of Part 4 uses.

33.2 The Idea in Plain Words

Nothing about the network itself is new. An image is 64 numbers, one per pixel, so the input layer has 64 inputs. A hidden layer of 32 tanh units turns them into 32 features. An output layer turns those into 10 scores, one per digit, and softmax turns the scores into probabilities. The digit with the highest probability is the answer. This is exactly the 64-32-10 network whose 2,410 parameters we counted in Solution 32.6.

What is new is the division of labor. In Chapter 32 we were both the architect and the accountant: we designed the network and computed every gradient. Now we are only the architect. We tell PyTorch what the forward pass is. PyTorch keeps a record of every step it takes, like a clerk writing each calculation in a ledger. When we call `loss.backward()`, PyTorch reads the ledger backward, applying the chain rule at each line, and writes the gradient of the loss into every weight. Then an *optimizer* object takes those gradients and updates the weights, with plain gradient descent, with momentum, or with a cleverer rule called Adam.

The second new idea is about honesty. We split the 1,797 digits three ways. The *training set* (60%) is what the network learns from. The *validation set* (20%) is what we look at while making decisions: how many epochs to train, which settings are best. The *test set* (20%) is locked away and used once, at the very end, to report how good the finished model is. Chapter 31 hinted at this in its Solution 31.6; in this chapter it becomes a habit.

> **KEY INSIGHT.** With automatic differentiation, a network is just a function you write in the forward direction. Any combination of differentiable operations can be trained, and the training loop does not change when the network does.

33.3 The Mathematics, Gently

33.3.1 Tensors and linear layers

A *tensor* is PyTorch's name for an array of numbers with any number of dimensions: a single number is a 0-dimensional tensor, a list is 1-dimensional, a table 2-dimensional, a batch of color images 4-dimensional. Tensors behave much like NumPy arrays, with two extra powers: they can live on a graphics card, and they can remember how they were computed.

A fully connected layer, `nn.Linear(n_in, n_out)`, holds a weight matrix W of shape $n_{\text{out}} \times n_{\text{in}}$ and a bias vector $\mathbf{b}$ of length n_{out}, and computes, for a batch X with one example per row,

$$Y = XW^{\top} + \mathbf{b} \tag{33.1}$$

This is the $XW_1 + \mathbf{b}_1$ of Equation (32.1) in Chapter 32 with one difference in bookkeeping: PyTorch stores the weights "output by input", so the matrix is transposed in the formula. The

number of parameters of a layer is $n_{\text{in}} \cdot n_{\text{out}} + n_{\text{out}}$, and for a network with one hidden layer of h units, n inputs and c classes

$$N_{\text{params}} = (nh + h) + (hc + c) \tag{33.2}$$

For our digits, $n = 64$, $h = 32$, $c = 10$: $N = 2048 + 32 + 320 + 10 = 2410$.

33.3.2 The loss from raw scores

PyTorch's `nn.CrossEntropyLoss` takes the raw scores $o_1, \dots, o_c$ (the logits, before softmax) and the true class y, and computes, averaged over the batch,

$$L = -\log \frac{e^{o_y}}{\sum_j e^{o_j}} = -o_y + \log \sum_{j=1}^{c} e^{o_j} \tag{33.3}$$

which is the softmax of Equation (32.3) followed by the cross-entropy of Equation (32.4), fused into one operation. The fused form is both faster and numerically safer, because the library can apply the "subtract the maximum" trick internally. The practical consequence is important: **the network must output raw scores, not probabilities**. If you add a softmax layer at the end of the model and then use `CrossEntropyLoss`, softmax is applied twice and training becomes sluggish.

33.3.3 Automatic differentiation

When a tensor is created with `requires_grad=True`, every operation that uses it adds a node to a *computation graph*: a record of which inputs produced which output by which function. For the tiny network of Section 32.3.6 the graph is $W_1 \to (\times x) \to (+b_1) \to \tanh \to (\times W_2) \to (+\mathbf{b}_2) \to$ cross-entropy $\to L$. Each kind of node knows its own local derivative; for example the tanh node knows Equation (32.9). Calling `L.backward()` walks the graph from L back to every leaf and multiplies the local derivatives together, which is the chain rule of Equation (32.6), and adds the result into the leaf's `.grad` attribute:

$$\text{W.grad} \mathrel{+}= \frac{\partial L}{\partial W} \tag{33.4}$$

Note the $+=$ in Equation (33.4): gradients *accumulate*. If you call `backward` twice without clearing, the second gradient is added to the first. That is useful for some advanced tricks, and it is the reason every training loop begins by zeroing the gradients.

33.3.4 Optimizers

An optimizer holds a list of parameters and, when `step()` is called, updates each one using its `.grad`. `torch.optim.SGD` with momentum μ implements

$$\mathbf{v} \leftarrow \mu \mathbf{v} + \frac{\partial L}{\partial \theta}, \qquad \theta \leftarrow \theta - \eta \mathbf{v} \tag{33.5}$$

which is Equation (32.13) of Chapter 32 written with the learning rate outside the velocity; the two forms produce the same steps when η is fixed [6].

Adam (adaptive moment estimation), by Kingma and Ba [7], keeps two running averages per weight: $\mathbf{m}$, the average gradient (a momentum), and $\mathbf{s}$, the average *squared* gradient (a measure

of how large and noisy the gradients of that weight usually are). With $\mathbf{g} = \partial L / \partial \theta$ and step number t,

$$\mathbf{m} \leftarrow \beta_1 \mathbf{m} + (1-\beta_1)\,\mathbf{g}, \qquad \mathbf{s} \leftarrow \beta_2 \mathbf{s} + (1-\beta_2)\,\mathbf{g} \odot \mathbf{g}$$
$$\theta \leftarrow \theta - \eta \,\frac{\mathbf{m}/(1-\beta_1^t)}{\sqrt{\mathbf{s}/(1-\beta_2^t)} + \epsilon} \tag{33.6}$$

The division by the square root makes the step size roughly the same for every weight, whether its gradients are large or tiny. The factors $1-\beta^t$ correct the fact that both averages start at zero. The usual constants are $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$ and $\eta = 0.001$, and they work well on a remarkable range of problems, which is why Adam is often the first optimizer people try.

33.3.5 Accuracy, validation and early stopping

The *accuracy* on a set of N examples is the fraction of correct answers,

$$\text{acc} = \frac{1}{N}\sum_{i=1}^{N} [\hat{y}_i = y_i] \tag{33.7}$$

where $\hat{y}_i$ is the digit with the highest score. Training loss keeps falling as long as we train, because the network can always fit the training images a little better. Validation accuracy usually rises, levels off, and may then fall as the network starts fitting peculiarities of the training images that do not generalize: *overfitting*. *Early stopping* keeps the weights of the epoch with the best validation accuracy [8].

33.3.6 Dropout

Dropout, by Srivastava and colleagues [9], is a way to make overfitting harder. During training, each hidden value is independently set to zero with probability p, and the survivors are scaled up so that the expected total stays the same:

$$\tilde{h}_k = \frac{r_k\, h_k}{1-p}, \qquad r_k = \begin{cases} 1 & \text{with probability } 1-p \\ 0 & \text{with probability } p \end{cases} \tag{33.8}$$

Because any unit may vanish at any moment, no unit can rely on one particular partner; the network is pushed toward redundant, robust features. At evaluation time dropout is switched off and every unit is used. PyTorch switches between the two behaviors with `model.train()` and `model.eval()`.

33.4 Building It Step by Step

The code is in `Chapter033`. It needs PyTorch 2.14 (CPU is enough), scikit-learn 1.9.1 and NumPy 2.4.6. The official installation selector at pytorch.org gives the right command for each system; for a CPU-only installation on Windows, macOS or Linux, `pip install torch` from PyPI works, and on Linux the smaller CPU-only wheel is available with `pip install torch --index-url https://download.pytorch.org/whl/cpu` [10].

Every program calls `torch.set_num_threads(1)`. PyTorch normally splits large operations over all CPU cores, and adding numbers in a different order changes the last digits of floating-point

results. With one thread the runs in this chapter are exactly reproducible, and on networks this small it costs almost nothing. On your own projects you can remove that line.

33.4.1 Autograd, checked against Chapter 32

Before trusting autograd with a real network, let us check it on the example we worked by hand in Section 32.3.6. **Listing 33.1** builds the same one-input, one-hidden-unit, two-output network from tensors, computes the loss, and calls `backward()`.

Listing 33.1 `autograd_demo.py`: the hand-worked example of Chapter 32, differentiated by PyTorch.

```
"""Tensors and autograd: Chapter 32's hand-worked example, done by PyTorch."""
import torch

x = torch.tensor([[1.0]])
W1 = torch.tensor([[0.5]], requires_grad=True)    # track operations on W1
b1 = torch.tensor([0.0], requires_grad=True)
W2 = torch.tensor([[1.0, -1.0]], requires_grad=True)
b2 = torch.tensor([0.0, 0.0], requires_grad=True)
y = torch.tensor([1])

h = torch.tanh(x @ W1 + b1)
scores = h @ W2 + b2
loss = torch.nn.functional.cross_entropy(scores, y)   # softmax + -log p_y
loss.backward()                                       # backpropagation, automatic

print(f"h = {h.item():.4f}, loss = {loss.item():.4f}")
print(f"dL/dW1 = {W1.grad.item():.4f}   dL/db1 = {b1.grad.item():.4f}")
print(f"dL/dW2 = {W2.grad.tolist()[0]}")
print(f"dL/db2 = {b2.grad.tolist()}")
```

```
python autograd_demo.py
```

```
h = 0.4621, loss = 1.2584
dL/dW1 = 1.1260   dL/db1 = 1.1260
dL/dW2 = [0.3308315873146057, -0.3308315873146057]
dL/db2 = [0.7159041166305542, -0.7159041166305542]
```

Every number matches Chapter 32: $h = 0.4621$, $L = 1.2584$, $\partial L/\partial W_2 = (0.3308, -0.3308)$ and $\partial L/\partial \mathbf{b}_2 = (0.7159, -0.7159)$. The hidden gradient is printed as 1.1260, where we wrote 1.1261 by hand. Both are right: by hand we multiplied the *rounded* values 1.4318×0.7865; the exact product is 1.12604 ..., which rounds to 1.1260. Rounding intermediate results is a classic source of small disagreements, and PyTorch does not round until it prints.

33.4.2 The data

Listing 33.2 loads the digits and prepares them for PyTorch.

Listing 33.2 `digits_data.py`: loading the digits, splitting 60/20/20, and wrapping them in tensors and a `DataLoader`.

```
"""The 8x8 handwritten digits bundled with scikit-learn, as PyTorch tensors."""
import torch
from sklearn.datasets import load_digits
from sklearn.model_selection import train_test_split
from torch.utils.data import DataLoader, TensorDataset

def load_splits(seed=0):
    """Return (X, y) tensors for training, validation and test (60/20/20)."""
    digits = load_digits()
    X = digits.data / 16.0                      # pixel values 0..16 -> 0..1
    y = digits.target
    X_tmp, X_test, y_tmp, y_test = train_test_split(
        X, y, test_size=0.2, random_state=seed, stratify=y)
    X_train, X_val, y_train, y_val = train_test_split(
        X_tmp, y_tmp, test_size=0.25, random_state=seed, stratify=y_tmp)
    as_t = lambda X, y: (torch.tensor(X, dtype=torch.float32),
                         torch.tensor(y, dtype=torch.long))
    return as_t(X_train, y_train), as_t(X_val, y_val), as_t(X_test, y_test)

def loader(X, y, batch_size=32, shuffle=True, seed=0):
    g = torch.Generator().manual_seed(seed)     # reproducible shuffling
    return DataLoader(TensorDataset(X, y), batch_size=batch_size,
                      shuffle=shuffle, generator=g)
```

- `load_digits()` returns the 1,797 images flattened into rows of 64 pixel values. Dividing by 16 brings every pixel into [0,1], a scaling with the same purpose as Equation (31.7) of Chapter 31.
- Two calls to `train_test_split` make the three sets: first 20% is set aside for testing, then a quarter of the remaining 80% (20% of the total) becomes the validation set. `stratify` keeps all ten digits equally represented in each set.
- The images become `float32` tensors and the labels `long` (64-bit integer) tensors, which is what `CrossEntropyLoss` expects.
- `loader` wraps a pair of tensors in a `TensorDataset` and a `DataLoader`, which hands out shuffled mini-batches of 32. The `Generator` with a fixed seed makes the shuffling reproducible.

33.4.3 The model and the training loop

Listing 33.3 defines the network and the two functions that every PyTorch project needs in some form: one that measures accuracy and one that trains.

Listing 33.3 `model.py`: the `DigitNet` module, an accuracy function and a training loop.

```
"""The digit network: 64 pixels -> hidden layer -> 10 scores (Chapter 33)."""
import torch
from torch import nn
from digits_data import loader

class DigitNet(nn.Module):
    def __init__(self, hidden=32, activation=nn.Tanh, dropout=0.0):
        super().__init__()
        self.layers = nn.Sequential(
            nn.Linear(64, hidden),              # W1, b1
            activation(),
            nn.Dropout(dropout),                # does nothing when dropout=0
            nn.Linear(hidden, 10),              # W2, b2
        )

    def forward(self, x):
        return self.layers(x)                   # raw scores (logits)

def accuracy(model, X, y):
    model.eval()                                # evaluation mode (no dropout)
    with torch.no_grad():                       # no graph needed for testing
        return (model(X).argmax(dim=1) == y).float().mean().item()

def fit(model, train_data, val_data, epochs, optimizer, batch_size=32,
        log_every=0, seed=0):
    """Train with cross-entropy; return per-epoch (train loss, val accuracy)."""
    loss_fn = nn.CrossEntropyLoss()
    batches = loader(*train_data, batch_size=batch_size, seed=seed)
    history = []
    for epoch in range(1, epochs + 1):
        model.train()
        total, count = 0.0, 0
        for xb, yb in batches:
            optimizer.zero_grad()               # forget the previous gradients
            loss = loss_fn(model(xb), yb)
            loss.backward()                     # fill .grad of every parameter
            optimizer.step()                    # update every parameter
            total += loss.item() * len(xb)
            count += len(xb)
        val_acc = accuracy(model, *val_data)
        history.append((total / count, val_acc))
        if log_every and (epoch == 1 or epoch % log_every == 0):
            print(f"epoch {epoch:3d}  train loss {total / count:.4f}  "
                  f"val acc {val_acc:.3f}")
    return history
```

Listing 33.3 (Continued) *model.py: the DigitNet module, an accuracy function and a training loop.*

- `DigitNet` subclasses `nn.Module`, the base class of every PyTorch model. The constructor must call `super().__init__()`, and every layer assigned to an attribute (here the `nn.Sequential` container) is registered automatically, so `model.parameters()` finds all its weights. `nn.Sequential` simply applies its layers one after another: linear (Equation (33.1)), activation, dropout (Equation (33.8)), linear. The activation class and the dropout rate are constructor arguments, so Section 33.6 can try variants without new code.
- `forward` returns raw scores, as Equation (33.3) requires. We never call `forward` directly; we call the model like a function, `model(x)`, and PyTorch calls `forward` for us.

- `accuracy` implements Equation (33.7). `model.eval()` switches dropout off, and `torch.no_grad()` tells autograd not to record a graph, which saves memory and time when we only evaluate.
- `fit` is the training loop. Its inner five lines are shown in **Figure 33.2** and are the same in almost every PyTorch program: zero the gradients (because of Equation (33.4)), run the model, compute the loss, backpropagate, and let the optimizer update the weights. After each epoch it records the average training loss and the validation accuracy.

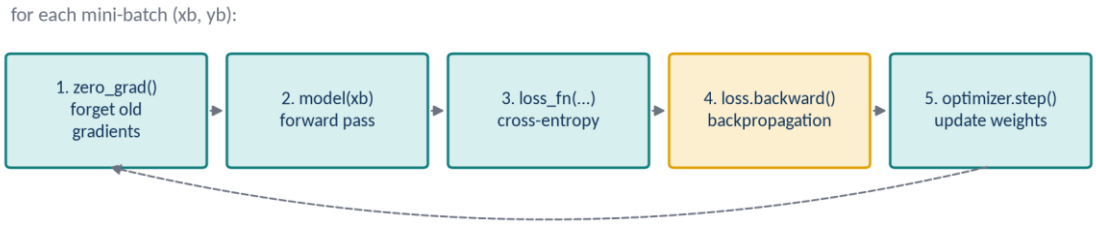

Figure 33.2 The five steps that `fit` performs for every mini-batch. Step 4 is where autograd replaces the hand-written backward pass of Chapter 32.

33.4.4 Training and saving

Listing 33.4 trains the 64-32-10 network for 30 epochs with SGD, learning rate 0.1 and momentum 0.9, reports the test accuracy once, saves the weights, and prints the confusion matrix.

Listing 33.4 `train.py`: training, testing and saving the digit recognizer.

```
"""Train the digit recognizer and save it to digit_net.pt (Chapter 33)."""
import time
import torch
from digits_data import load_splits
from model import DigitNet, accuracy, fit

torch.manual_seed(0)
torch.set_num_threads(1)                        # same numbers on every run
train_data, val_data, test_data = load_splits()
print(f"images: train {len(train_data[0])}, validation {len(val_data[0])}, "
      f"test {len(test_data[0])}")

model = DigitNet(hidden=32)
n_params = sum(p.numel() for p in model.parameters())
print(f"parameters: {n_params}")
optimizer = torch.optim.SGD(model.parameters(), lr=0.1, momentum=0.9)
start = time.perf_counter()
fit(model, train_data, val_data, epochs=30, optimizer=optimizer, log_every=5)
print(f"training time: {time.perf_counter() - start:.1f} s")

test_acc = accuracy(model, *test_data)
print(f"test accuracy: {test_acc:.3f}")
torch.save(model.state_dict(), "digit_net.pt")
print("saved digit_net.pt")

pred = model(test_data[0]).argmax(dim=1)
confusion = torch.zeros(10, 10, dtype=torch.long)
for t, p in zip(test_data[1], pred):
    confusion[t, p] += 1
print("confusion matrix (rows = true digit, columns = predicted):")
print("     " + " ".join(f"{d:3d}" for d in range(10)))
for d in range(10):
    print(f"{d:3d} " + " ".join(f"{v:3d}" for v in confusion[d].tolist()))
```

`model.state_dict()` is an ordered dictionary from parameter names (`layers.0.weight`, `layers.0.bias`, and so on) to tensors. Saving the state dictionary rather than the whole model object is the recommended practice: the file contains only numbers, and the code that gives them meaning stays in `model.py`, where you can read it [11]. The confusion matrix counts, for every true digit (row) and every predicted digit (column), how many test images fell into that cell; a perfect model would have numbers only on the diagonal.

33.4.5 The application

Listing 33.5 is the program a user runs. It rebuilds an empty `DigitNet`, loads the saved weights into it, takes test images by index, prints each image as text art, and lists the model's three most likely digits with their probabilities.

Listing 33.5 `predict.py`: the digit recognizer application, using the saved model.

```
"""Digit recognizer app: show a test image and what the saved model sees.

usage: python predict.py [index ...]      (indexes into the test set)
"""
import sys
import torch
from digits_data import load_splits
from model import DigitNet

SHADES = " .:-=+*#%@"                          # 10 shades, light to dark

def show(image):
    for row in image.view(8, 8):
        print("    " + "".join(SHADES[min(int(v * 10), 9)] * 2 for v in row))

model = DigitNet(hidden=32)
model.load_state_dict(torch.load("digit_net.pt", weights_only=True))
model.eval()
_, _, (X_test, y_test) = load_splits()
for index in [int(a) for a in sys.argv[1:]] or [0]:
    image, label = X_test[index], y_test[index].item()
    with torch.no_grad():
        probs = torch.softmax(model(image.unsqueeze(0)), dim=1)[0]
    top = torch.topk(probs, 3)
    show(image)
    guesses = ", ".join(f"{d.item()} ({p.item():.3f})"
                        for p, d in zip(top.values, top.indices))
    print(f"test image {index}: true digit {label}; model says {guesses}")
```

`torch.load(..., weights_only=True)` loads only tensors and refuses to run any other code stored in the file. Since PyTorch 2.6 this is the default, because loading an arbitrary pickled object from an untrusted file can execute arbitrary code [12]; writing it explicitly documents the intent. `image.unsqueeze(0)` adds a batch dimension, turning one image of shape (64) into a batch of shape (1,64), since layers always expect batches. `torch.topk` returns the three largest probabilities and their positions, which are the digits.

33.4.6 Tests

Listing 33.6 checks that the three sets together contain all 1,797 images with pixels in range, that the model maps a batch of 5 images to 5 rows of 10 scores, and that three epochs of training already beat random guessing by far.

Listing 33.6 `test_digits.py`: unit tests for the data, the model and a short training run.

```
"""Unit tests for the digit recognizer (run: python -m unittest)."""
import unittest
import torch
from digits_data import load_splits
from model import DigitNet, accuracy, fit

class DigitTest(unittest.TestCase):
    def test_splits_are_disjoint_and_complete(self):
        (a, _), (b, _), (c, _) = load_splits()
        self.assertEqual(len(a) + len(b) + len(c), 1797)
        self.assertEqual(a.shape[1], 64)
        self.assertLessEqual(a.max().item(), 1.0)

    def test_output_shape(self):
        out = DigitNet()(torch.zeros(5, 64))
        self.assertEqual(tuple(out.shape), (5, 10))

    def test_short_training_beats_chance(self):
        torch.manual_seed(0)
        tr, va, te = load_splits()
        model = DigitNet()
        opt = torch.optim.SGD(model.parameters(), lr=0.1, momentum=0.9)
        fit(model, tr, va, epochs=3, optimizer=opt)
        self.assertGreater(accuracy(model, *te), 0.8)   # chance is 0.1

if __name__ == "__main__":
    unittest.main()
```

33.5 Running It

Train the model first:

```
python train.py
```

```
images: train 1077, validation 360, test 360
parameters: 2410
epoch   1  train loss 1.4690  val acc 0.894
epoch   5  train loss 0.1112  val acc 0.961
epoch  10  train loss 0.0410  val acc 0.967
epoch  15  train loss 0.0221  val acc 0.961
epoch  20  train loss 0.0133  val acc 0.972
epoch  25  train loss 0.0099  val acc 0.964
epoch  30  train loss 0.0076  val acc 0.961
training time: 1.3 s
test accuracy: 0.967
saved digit_net.pt
confusion matrix (rows = true digit, columns = predicted):
      0   1   2   3   4   5   6   7   8   9
  0  35   0   0   0   1   0   0   0   0   0
  1   0  35   0   0   0   0   0   0   1   0
  2   0   1  34   0   0   0   0   0   0   0
  3   0   0   0  36   0   0   0   0   1   0
  4   0   1   0   0  34   0   0   0   1   0
  5   0   0   0   1   0  36   0   0   0   0
  6   0   1   0   0   0   0  35   0   0   0
  7   0   0   0   0   0   0   0  36   0   0
  8   0   2   0   0   0   1   0   0  32   0
  9   0   0   0   0   0   1   0   0   0  35
```

The first epoch already brings validation accuracy to 89%. By epoch 5 it is 96%, and after that it wanders between 96% and 97% while the training loss keeps falling toward zero: the network is fitting the training images ever more perfectly, but that no longer helps on new images.

Figure 33.3 shows both curves. The test accuracy, measured once at the end, is 96.7%: 348 of the 360 test digits are right. The training took under three seconds on one core (your time will differ; everything else in the output should match exactly).

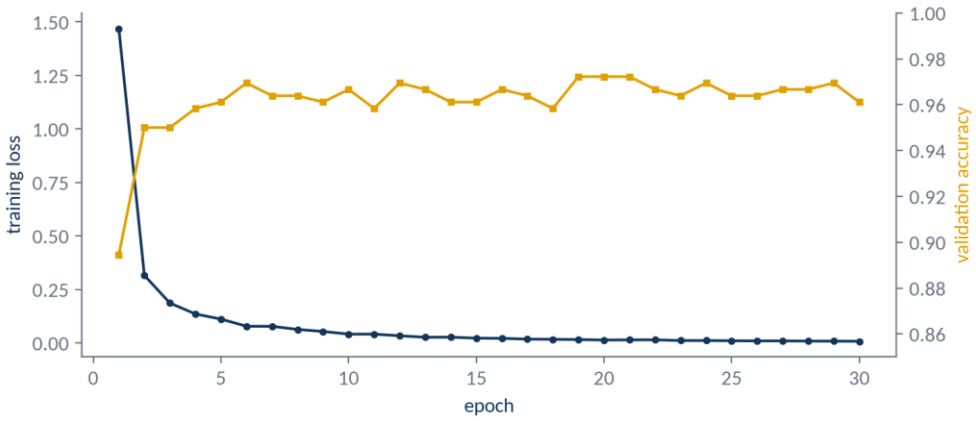

Figure 33.3 Training loss (left axis) and validation accuracy (right axis) after each of the 30 epochs of **Listing 33.4**.

The confusion matrix shows *which* mistakes. **Figure 33.4** draws it with the correct answers in teal on the diagonal and the mistakes in red. The busiest wrong column is 1: two 8s, a 2, a 4 and a 6 were all read as 1. The column for 8 also collects three mistakes. At 8 × 8 pixels a thin, slanted 8 and a thick 1 really are close.

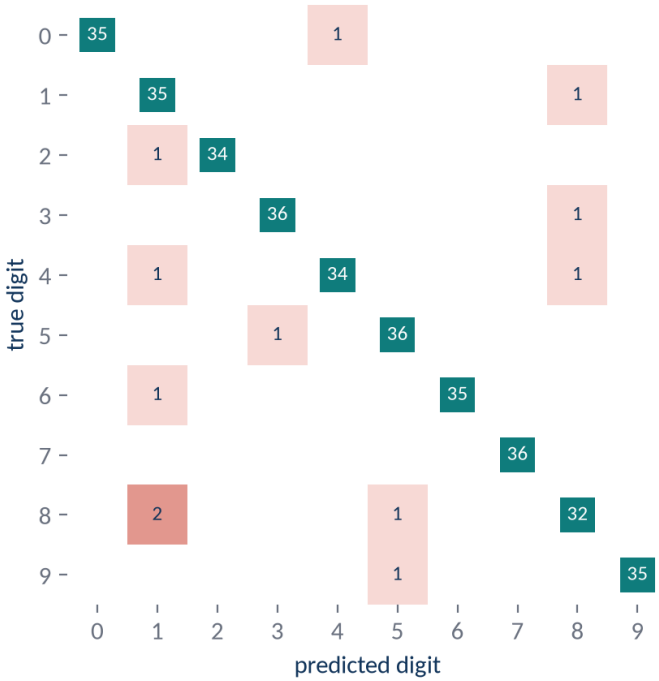

Figure 33.4 The confusion matrix of the trained model on the 360 test images. Diagonal cells (teal) are correct answers; off-diagonal cells (red) are mistakes.

Now use the application on two test images, number 0 and number 15:

```
python predict.py 0 15
```

```
       ..%%@@++
       ####==@@..
       %%..  @@::
         ::**@@--
         %%@@@@++
         --%%
         **++
         @@::
test image 0: true digit 7; model says 7 (0.972), 9 (0.028), 8 (0.000)
       ..++==
       --@@@@..
     --@@**@@::
     --@@**@@
     ..@@@@%%
       ..@@##++..
       ::%%  ##%%
         ##**==
test image 15: true digit 8; model says 1 (0.989), 8 (0.010), 6 (0.000)
```

Image 0 is a 7, recognized with probability 0.972; the runner-up, 9, is a sensible second guess for a 7 with a closed top. Image 15 is an 8 that the model reads as 1 with probability 0.989. Look at the text art and you can see why: the loops of this 8 are squeezed into a thick vertical stroke. A confident mistake like this is a warning that a probability of 0.99 is not a guarantee. **Figure 33.5** shows all twelve test images the model gets wrong, with the model's answer and its probability.

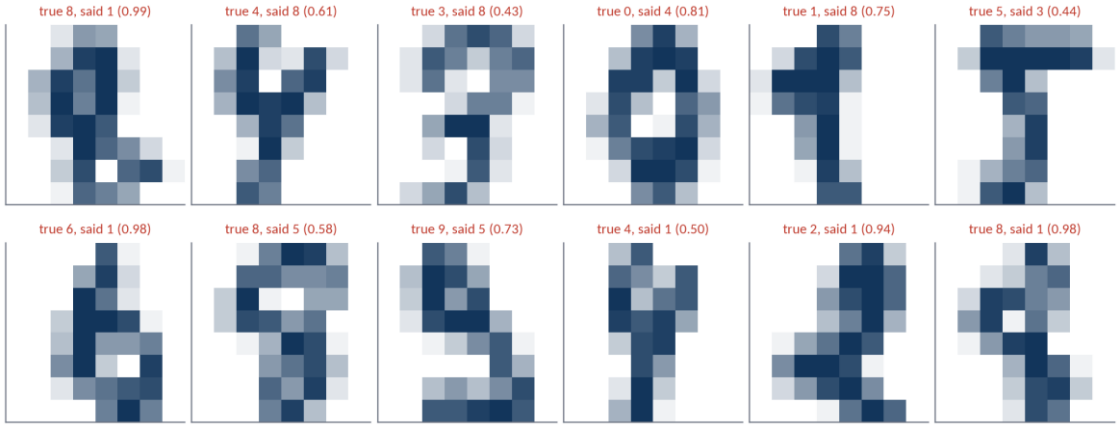

Figure 33.5 The twelve test images the model misreads, each with the true digit, the model's answer and the probability it gave that answer.

Some of these a person would also hesitate over; others, like the 0 read as 4, are genuine failures of a network that looks at 64 independent pixels and knows nothing about shapes. Chapter 35 gives the network that knowledge with convolutions.

Finally, the tests:

```
python -m unittest
```

```
...
----------------------------------------------------------------------
Ran 3 tests in 4.161s

OK
```

33.6 Improving It

Listing 33.7 compares five configurations fairly. Each one starts from the same seed, trains for up to 40 epochs, keeps the weights of the epoch with the best *validation* accuracy (early stopping, done by hand with `state_dict` copies), and only then measures the test accuracy once.

Listing 33.7 `improve.py`: five configurations with early stopping on the validation set.

```
"""Improving the digit recognizer: activation, width, optimizer, dropout."""
import torch
from torch import nn
from digits_data import load_splits
from model import DigitNet, accuracy, fit

torch.set_num_threads(1)
train_data, val_data, test_data = load_splits()
configs = [
    ("tanh 32, SGD+momentum", dict(hidden=32), "sgd"),
    ("ReLU 32, SGD+momentum", dict(hidden=32, activation=nn.ReLU), "sgd"),
    ("ReLU 128, SGD+momentum", dict(hidden=128, activation=nn.ReLU), "sgd"),
    ("ReLU 128, Adam", dict(hidden=128, activation=nn.ReLU), "adam"),
    ("ReLU 128, Adam, dropout 0.2",
     dict(hidden=128, activation=nn.ReLU, dropout=0.2), "adam"),
]
print(f"{'model':30s} {'best val':>8s} {'at epoch':>8s} {'test':>6s}")
for name, kwargs, opt in configs:
    torch.manual_seed(0)
    model = DigitNet(**kwargs)
    if opt == "sgd":
        optimizer = torch.optim.SGD(model.parameters(), lr=0.1, momentum=0.9)
    else:
        optimizer = torch.optim.Adam(model.parameters(), lr=0.001)
    best_acc, best_epoch, best_state = -1.0, 0, None
    for epoch in range(1, 41):                  # early stopping by hand
        fit(model, train_data, val_data, 1, optimizer, seed=epoch)
        val_acc = accuracy(model, *val_data)
        if val_acc > best_acc:
            best_acc, best_epoch = val_acc, epoch
            best_state = {k: v.clone() for k, v in model.state_dict().items()}
    model.load_state_dict(best_state)           # go back to the best epoch
    print(f"{name:30s} {best_acc:8.3f} {best_epoch:8d} "
          f"{accuracy(model, *test_data):6.3f}")
```

```
python improve.py
```

```
model                          best val at epoch   test
tanh 32, SGD+momentum             0.972       11  0.969
ReLU 32, SGD+momentum             0.972       28  0.967
ReLU 128, SGD+momentum            0.972       17  0.972
ReLU 128, Adam                    0.978       35  0.969
ReLU 128, Adam, dropout 0.2       0.978       37  0.972
```

The whole comparison takes about 25 seconds. The honest conclusion is that on this small, clean data set all five configurations land within half a percentage point of each other: 96.7% to 97.2% on the test set. Four times more hidden units, ReLU instead of tanh, Adam instead of SGD and dropout each change the result by at most one or two test images out of 360, which is within the noise of a different random seed. The best validation score (0.978) belongs to the two Adam models, which needed the most epochs to reach it.

This is a valuable lesson, not a disappointment. Techniques that are indispensable for large networks on large data sets, such as Adam and dropout, do not automatically help a 2,410-parameter model on 1,077 training images; the simple model is already about as good as a network that looks at independent pixels can be. When changes to the training recipe stop

helping, the next step is usually a change to the *architecture* that builds in knowledge about the data. For images that means convolutions, which is the subject of Chapter 35. Meanwhile, the procedure of **Listing 33.7**, same seed, validation set for every decision, test set once, is the part to keep.

33.7 Common Mistakes, and How to Avoid Them

Forgetting `optimizer.zero_grad()`. Gradients accumulate (Equation (33.4)), so without zeroing, each step uses the sum of all previous gradients, and training goes haywire. Keep the five lines of **Figure 33.2** together.

Adding softmax before `CrossEntropyLoss`. The loss applies softmax itself (Equation (33.3)). Return raw scores from `forward`, and apply `torch.softmax` only when you want to show probabilities, as `predict.py` does.

Wrong label type or shape. `CrossEntropyLoss` wants class indices as a `long` tensor of shape (m), not floats and not one-hot rows. A `float` label tensor gives an error, and an $(m, 1)$ tensor gives a confusing one.

Forgetting `model.eval()` and `torch.no_grad()`. Without `eval()`, dropout keeps dropping units during testing and the accuracy looks worse and random. Without `no_grad()`, PyTorch builds graphs nobody will use, wasting memory; on large models this can exhaust it.

Choosing settings with the test set. If you pick the best of five configurations by their *test* accuracy, the winning number is optimistic. Decide with the validation set, report with the test set.

Unscaled inputs. Feeding raw pixel values 0 to 16 instead of 0 to 1 makes the first-layer sums sixteen times larger and pushes tanh units into their flat regions, where gradients vanish. Exercise 33.3 shows the damage.

Loading untrusted model files with `weights_only=False`. A pickled model file can contain code. Keep the default `weights_only=True`, and save state dictionaries.

33.8 Chapter Summary

- PyTorch tensors record the operations applied to them; `loss.backward()` applies the chain rule through that record and fills `.grad` for every parameter, reproducing Chapter 32's hand-computed gradients.
- A model is an `nn.Module` whose `forward` returns raw scores; `nn.Linear` computes Equation (33.1), and `CrossEntropyLoss` fuses softmax with cross-entropy (Equation (33.3)).
- The training loop is five lines: zero the gradients (they accumulate, Equation (33.4)), forward, loss, backward, optimizer step (Equation (33.5) or Equation (33.6)).
- Split the data into training, validation and test sets; measure accuracy (Equation (33.7)) on validation to choose epochs and settings, and on test once.
- The 64-32-10 network (Equation (33.2): 2,410 parameters) reaches 96.7% on the test digits; Adam, ReLU, width and dropout (Equation (33.8)) change little on this small data set.
- Save `state_dict()` and load it with `weights_only=True` in the application.

33.9 Exercises

1. Explain what would go wrong in `accuracy` if `model.eval()` were removed but the model had dropout 0.5. And what would go wrong if `torch.no_grad()` were removed?
2. Use Equation (33.2) to count the parameters of the 64-128-10 network of **Listing 33.7**. Then count those of a network with two hidden layers of 64 units each.
3. Train the model for 10 epochs on the raw pixel values 0 to 16 instead of 0 to 1 and compare the loss curve and test accuracy with the scaled version. Explain the result.
4. Train for 10 epochs with batch sizes 1, 32 and 1,077 (the whole training set) with the same learning rate 0.01 and momentum 0.9. Report the number of update steps, the time and the test accuracy, and explain the differences.
5. In Equation (33.6), suppose one weight always receives the gradient $g = 0.002$ and another always receives $g = 200$. After many steps, what size of step does Adam take for each of them? Compare with SGD without momentum.
6. The confusion matrix of **Figure 33.4** has 12 off-diagonal counts. How can you compute the test accuracy from the matrix alone? Which digit has the lowest *recall* (fraction of its images recognized)?

33.10 Solutions to the Exercises

Solution 1. Without `model.eval()` the dropout layer stays in training mode, so during testing half of the hidden units are zeroed at random and the rest are doubled (Equation (33.8)). The accuracy would be lower than the model really deserves, and different on every call. Without `torch.no_grad()` the answers would be the same, but PyTorch would record a computation graph for every test image and keep all intermediate tensors in memory, which wastes time and, on large models, memory. (In `accuracy` the graph is thrown away at once, so on our tiny model the waste is invisible, but the habit matters.)

Solution 2. For 64-128-10, $N = (64 \cdot 128 + 128) + (128 \cdot 10 + 10) = 8192 + 128 + 1280 + 10 = 9610$. For two hidden layers of 64: $(64 \cdot 64 + 64) + (64 \cdot 64 + 64) + (64 \cdot 10 + 10) = 4160 + 4160 + 650 = 8970$. Each extra `nn.Linear` layer adds its own $n_{\text{in}} n_{\text{out}} + n_{\text{out}}$.

Solution 3. **Listing 33.8** trains both versions from the same seed.

Listing 33.8 `sol_no_scaling.py`: scaled versus raw pixel values.

```
"""Exercise 33.3: training on raw pixel values 0..16 instead of 0..1."""
import torch
from digits_data import load_splits
from model import DigitNet, accuracy, fit

torch.set_num_threads(1)
train_data, val_data, test_data = load_splits()
for name, factor in [("scaled 0..1", 1.0), ("raw 0..16", 16.0)]:
    torch.manual_seed(0)
    model = DigitNet(hidden=32)
    opt = torch.optim.SGD(model.parameters(), lr=0.1, momentum=0.9)
    tr = (train_data[0] * factor, train_data[1])
    va = (val_data[0] * factor, val_data[1])
    history = fit(model, tr, va, epochs=10, optimizer=opt)
    losses = " ".join(f"{loss:.3f}" for loss, _ in history[::3])
    test_acc = accuracy(model, test_data[0] * factor, test_data[1])
    print(f"{name:12s} loss (epochs 1,4,7,10): {losses}  test {test_acc:.3f}")
```

```
scaled 0..1  loss (epochs 1,4,7,10): 1.469 0.135 0.077 0.041  test 0.967
raw 0..16    loss (epochs 1,4,7,10): 1.191 1.348 1.296 2.008  test 0.292
```

With raw pixels the loss after 10 epochs is *higher* than after the first, and the test accuracy is 29%. The first-layer sums are sixteen times larger, so most tanh units sit at ± 1, where the slope of tanh, Equation (32.9), is almost zero; the gradients that do get through are large and erratic, and with a learning rate chosen for scaled inputs the weights jump around instead of converging. Scaling the inputs costs one division and is almost always worth it.

Solution 4. **Listing 33.9** passes the batch size to `fit`.

Listing 33.9 `sol_batch_size.py`: ten epochs with three batch sizes.

```
"""Exercise 33.4: the same number of epochs with different batch sizes."""
import time
import torch
from digits_data import load_splits
from model import DigitNet, accuracy, fit

torch.set_num_threads(1)
train_data, val_data, test_data = load_splits()
n_train = len(train_data[0])
for batch in (1, 32, n_train):
    torch.manual_seed(0)
    model = DigitNet(hidden=32)
    opt = torch.optim.SGD(model.parameters(), lr=0.01, momentum=0.9)
    steps = -(-n_train // batch) * 10            # ceiling division, 10 epochs
    start = time.perf_counter()
    fit(model, train_data, val_data, 10, opt, batch_size=batch)
    print(f"batch {batch:5d}: {steps:6d} steps, "
          f"{time.perf_counter() - start:5.1f} s, "
          f"test accuracy {accuracy(model, *test_data):.3f}")
```

```
batch     1:  10770 steps,   7.2 s, test accuracy 0.953
batch    32:    340 steps,   0.5 s, test accuracy 0.922
batch  1077:     10 steps,   0.6 s, test accuracy 0.106
```

With batch size 1 the model takes 10,770 small, noisy steps and reaches 95.3%, but it is by far the slowest, because each step processes a single image and cannot use the computer's ability to multiply whole matrices at once. With batches of 32 it takes 340 steps and reaches 92.2% in half a second; with a larger learning rate (0.1, as in **Listing 33.4**) it would do much better. With the whole training set as one batch the model takes only 10 steps in 10 epochs, far too few with this learning rate, and it is still barely better than guessing (10.6%). The number of *steps*, not only the number of epochs, determines how far training gets; mini-batches are the compromise between the noisy but numerous steps of batch size 1 and the accurate but rare steps of the full batch. Your times will differ from the ones printed here.

Solution 5. After many steps the bias corrections are close to 1, and with a constant gradient $\mathbf{m} \approx g$ and $\mathbf{s} \approx g^2$. The step is then $\eta \cdot g/\left(\sqrt{g^2} + \epsilon\right) \approx \eta \cdot g/|g| = \pm\eta$. So both weights move by about $\eta = 0.001$ per step, although their gradients differ by a factor of 100,000. SGD without momentum would move them by ηg, that is $0.1 \times 0.002 = 0.0002$ and $0.1 \times 200 = 20$ with $\eta = 0.1$: one would barely move and the other would jump wildly. Adam's per-weight normalization is why a single learning rate works for layers whose gradients have very different sizes.

Solution 6. The accuracy is the sum of the diagonal divided by the sum of all cells: $(35 + 35 + 34 + 36 + 34 + 36 + 35 + 36 + 32 + 35)/360 = 348/360 = 0.967$, the number `train.py` printed. The recall of a digit is its diagonal cell divided by its row sum. Digit 8 has $32/35 = 0.914$, the lowest; digit 4 follows with $34/36 = 0.944$. Digit 7 is perfect, $36/36$.

Chapter 34

Autoencoder That Compresses and Denoises

Every network so far has learned from labeled examples: this image is a 7, this flower is a versicolor. This chapter builds a network that learns from the images alone, with no labels at all, by setting itself a strange-sounding task: reproduce your own input. The trick is that the network must squeeze each image through a narrow middle layer, so it cannot simply copy; it has to discover a compact description. Such a network is an *autoencoder*. By the end of the chapter you will be able to explain the encoder, the code and the decoder in plain words, write the reconstruction loss and the denoising loss as equations, build and train an autoencoder in PyTorch that stores each 8×8 digit as just 8 numbers and rebuilds it with an error of about 0.12 per pixel, turn it into a *denoising* autoencoder that cleans up noisy images, compare it honestly with PCA, the classic linear method of Chapter 17, and use the reconstruction error as an alarm for images that do not look like anything the network has seen. Training takes about six seconds per model.

34.1 Why Learn to Copy?

Imagine you had to describe a handwritten digit over a crackly telephone line using only eight numbers. Sending all 64 pixel values is not allowed. What would you send? Perhaps: how tall the stroke is, how much it leans, whether there is a loop at the top, a loop at the bottom, a horizontal bar, how thick the pen was. A listener who knows what digits look like could then redraw something close to the original from those eight numbers.

An autoencoder learns such a description by itself. Its first half, the *encoder*, reads the 64 pixels and writes down a short *code*, here 8 numbers. Its second half, the *decoder*, reads only the code and tries to redraw the 64 pixels. We train the two halves together, rewarding them only for how close the redrawing is to the original. Nobody tells the network what the 8 numbers should mean; whatever description lets the decoder redraw best is what the encoder learns to write [1], [2].

What is that good for, if the output is only a blurry copy of the input? More than you might expect.

- **Compression.** The code is 8 times smaller than the image. For images, sound and sensor data, learned codes are a building block of modern compression.
- **Denoising.** If we feed the encoder a *noisy* image but still ask the decoder for the *clean* one, the network learns to remove noise. Scanned laundry receipts, photos taken in bad light and crackly recordings are all targets for this [3].
- **Anomaly detection.** An autoencoder trained on normal data redraws normal data well and strange data badly. A large reconstruction error is therefore an alarm: a damaged sensor reading, a fraudulent transaction, a scan of something that is not a digit. Part 7 of the book builds anomaly detectors, and Exercise 34.4 gives a first taste.
- **Features and generation.** The codes are a compact description that other models can use, and generating new data by decoding new codes is the idea behind variational autoencoders and, further along, today's image generators.

And the setting matters: all of this is learned *without labels*. Labeling data costs money and time; raw images are cheap. Methods that learn from unlabeled data, *unsupervised* or *self-supervised* learning, are how most of today's large models get most of their knowledge.

34.2 The Idea in Plain Words

Figure 34.1 shows the shape of an autoencoder: an hourglass. On the left, 64 pixels go in. The encoder narrows them down, layer by layer, to the code **z** in the middle, the *bottleneck*. The decoder widens the code back out to 64 pixels. The output is compared with the input, pixel by pixel, and the differences are the loss.

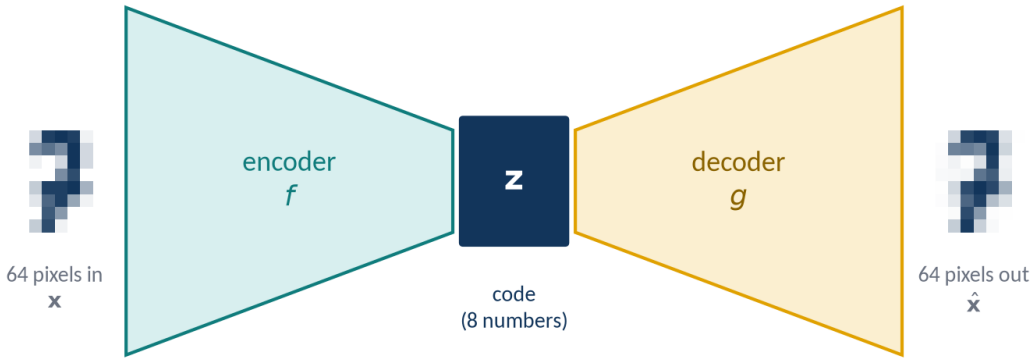

Figure 34.1 An autoencoder is an hourglass. The encoder f squeezes 64 pixels into an 8-number code **z**; the decoder g rebuilds 64 pixels from the code. The digit on the right is the real reconstruction of the digit on the left.

Why does the narrow middle matter? If the code had 64 numbers, the network could learn to pass every pixel straight through, and it would learn nothing interesting. With 8 numbers it is forced to find what the 64 pixels have in common. Handwritten digits are not random collections of pixels: neighboring pixels tend to be alike, strokes are continuous, and there are only ten basic shapes with variations. That regularity is what the encoder exploits. The same trick would fail on pure noise, which has no regularity; you will see in Exercise 34.4 that the autoencoder redraws random pixels very badly, and that this failure is useful.

The denoising version adds one twist. During training we spoil each input image by adding random noise, but the target stays the clean image. The network cannot learn to copy the noise, because the noise is different every time and is not in the target. It learns instead to recognize the digit behind the noise and to draw it cleanly.

> **KEY INSIGHT.** An autoencoder turns an unsupervised problem into a supervised one: the input is its own label. The bottleneck (or the noise) is what makes the task hard enough to be worth learning.

34.3 The Mathematics, Gently

34.3.1 Encoder, code and decoder

Let $\mathbf{x}$ be an image, a vector of $n = 64$ pixel values between 0 and 1. The encoder is a function f, a small neural network with weights of its own, that produces the code

$$\mathbf{z} = f(\mathbf{x}), \qquad \mathbf{z} \in \mathbb{R}^k \tag{34.1}$$

where $\mathbb{R}^k$ means "a list of k real numbers" and k is the *code size*, here $k = 8$. The decoder is a second network g that maps the code back to an image:

$$\hat{\mathbf{x}} = g(\mathbf{z}) = g(f(\mathbf{x})) \tag{34.2}$$

In our program, f is `Linear(64, 32)`, ReLU, `Linear(32, 8)`, and g is `Linear(8, 32)`, ReLU, `Linear(32, 64)`, sigmoid. There is no activation after the last encoder layer: the code may be any real numbers, positive or negative. The final sigmoid,

$$\sigma(a) = \frac{1}{1 + e^{-a}} \tag{34.3}$$

squashes every output into (0,1), the range of the pixels. A worked value: $\sigma(0) = \frac{1}{2}$, $\sigma(2) = 1/(1 + 0.1353) = 0.881$, $\sigma(-2) = 0.119$.

34.3.2 The reconstruction loss

How far is $\hat{\mathbf{x}}$ from $\mathbf{x}$? For images we measure the *mean squared error* (MSE), the average of the squared pixel differences. For a batch of m images of n pixels,

$$L = \frac{1}{m\,n} \sum_{i=1}^{m} \sum_{j=1}^{n} (\hat{x}_{ij} - x_{ij})^2 \tag{34.4}$$

Squaring makes every difference positive and punishes large differences more than small ones. If a pixel should be 1.0 (black) and the network draws 0.8, that pixel contributes $0.2^2 = 0.04$. An MSE of 0.0151 per pixel, which is what our model reaches, corresponds to a typical error of $\sqrt{0.0151} \approx 0.12$, that is 12% of the black-to-white range, or about two of the 17 gray levels.

A worked example shows why a bottleneck can work at all. Take a tiny "image" of two neighboring pixels, $\mathbf{x} = (0.8, 0.6)$, and squeeze it into a one-number code with the encoder $z = 0.5x_1 + 0.5x_2 = 0.5 \cdot 0.8 + 0.5 \cdot 0.6 = 0.7$. A decoder that knows neighboring pixels are usually alike can simply copy the code into both pixels: $\hat{\mathbf{x}} = (z, z) = (0.7, 0.7)$. By Equation (34.4), with $m = 1$ and $n = 2$, the error is $\frac{1}{2}((0.7 - 0.8)^2 + (0.7 - 0.6)^2) = \frac{1}{2}(0.01 + 0.01) = 0.01$. Half the numbers, and the picture is only a little off. For two unrelated pixels such as (1.0,0.0) the same code gives $z = 0.5$ and an error of $\frac{1}{2}(0.25 + 0.25) = 0.25$, twenty-five times worse. The encoder and decoder are only as good as the regularity of the data, and learning that regularity is exactly what training does.

Training follows Chapter 33 exactly: minimize Equation (34.4) over the weights of f and g together with Adam. The labels of the digits are never used.

34.3.3 How much is saved

If an image has n values and its code has k, the *compression ratio* is

$$\text{ratio} = \frac{n}{k} \tag{34.5}$$

so $64/8 = 8$. This counts only the per-image data. The decoder's weights must also be stored once, and they are shared by all images; Exercise 34.1 works out when the saving becomes real.

34.3.4 The denoising objective

Let $\boldsymbol{\epsilon}$ be random noise, each pixel drawn independently from a normal distribution with mean 0 and standard deviation s (we use $s = 0.3$). The corrupted image is the clean image plus noise, clipped back into [0,1]:

$$\tilde{\mathbf{x}} = \text{clip}(\mathbf{x} + \boldsymbol{\epsilon},\, 0,\, 1), \qquad \epsilon_j \sim \mathcal{N}(0, s^2) \tag{34.6}$$

The denoising autoencoder of Vincent and colleagues [3] is trained to rebuild the *clean* image from the corrupted one:

$$L_{\text{denoise}} = \frac{1}{m\,n} \sum_{i=1}^{m} \| \, g(f(\tilde{\mathbf{x}}_i)) - \mathbf{x}_i \, \|^2 \tag{34.7}$$

where $\| \, \mathbf{v} \, \|^2$ is the sum of the squares of the entries of $\mathbf{v}$. The only difference from Equation (34.4) is that the input is $\tilde{\mathbf{x}}$ while the target is still $\mathbf{x}$. Because fresh noise is drawn for every batch, the network sees each digit spoiled in many different ways and must learn what stays the same underneath.

How noisy is $s = 0.3$? Before clipping, each pixel is off by 0.3 on average in size, so the MSE of the noisy image itself is at most $0.3^2 = 0.09$; clipping pulls it down, and the measured value on our test digits is 0.0524. **Figure 34.2** shows what that looks like: plainly readable, but speckled.

34.3.5 The linear cousin: PCA

Chapter 17 met *principal component analysis* (PCA). PCA also compresses: it finds the k directions in pixel space along which the images vary most, collected as the columns of a matrix V_k ($n \times k$), and describes each image by its coordinates along them. Reconstructing from those coordinates gives

$$\hat{\mathbf{x}} = \boldsymbol{\mu} + V_k V_k^{\top} (\mathbf{x} - \boldsymbol{\mu}) \tag{34.8}$$

where $\boldsymbol{\mu}$ is the average image. Read Equation (34.8) as an autoencoder: the encoder is $\mathbf{z} = V_k^{\top}(\mathbf{x} - \boldsymbol{\mu})$ and the decoder is $\boldsymbol{\mu} + V_k \mathbf{z}$, both *linear*. Baldi and Hornik proved in 1989 that a linear autoencoder trained with Equation (34.4) learns exactly the subspace that PCA finds [4]. So PCA is the best *linear* autoencoder, and the only way a neural autoencoder can beat it is through its nonlinear activations. Whether it does is an experimental question, and Section 34.6 answers it.

34.4 Building It Step by Step

The code is in `Chapter034` and uses PyTorch 2.14, scikit-learn 1.9.1 and NumPy 2.4.6, as in Chapter 33. This time we split the 1,797 digits only into training (80%) and test (20%) images: we will not tune many settings, and the labels are only used to label pictures.

34.4.1 The model

Listing 34.1 holds everything the other programs share.

Listing 34.1 `ae_model.py`: data loading, the `Autoencoder` module, noise, training and the error measure.

```
"""An autoencoder for 8x8 digits: 64 pixels -> small code -> 64 pixels."""
import torch
from torch import nn
from sklearn.datasets import load_digits
from sklearn.model_selection import train_test_split

def load_images(seed=0):
    """Training and test images as float tensors with pixels in [0, 1]."""
    digits = load_digits()
    X = torch.tensor(digits.data / 16.0, dtype=torch.float32)
    y = torch.tensor(digits.target)
    X_tr, X_te, y_tr, y_te = train_test_split(X, y, test_size=0.2,
                                              random_state=seed, stratify=y)
    return X_tr, X_te, y_tr, y_te

class Autoencoder(nn.Module):
    def __init__(self, code_size=8, hidden=32):
        super().__init__()
        self.encoder = nn.Sequential(nn.Linear(64, hidden), nn.ReLU(),
                                     nn.Linear(hidden, code_size))
        self.decoder = nn.Sequential(nn.Linear(code_size, hidden), nn.ReLU(),
                                     nn.Linear(hidden, 64), nn.Sigmoid())

    def forward(self, x):
        return self.decoder(self.encoder(x))   # squeeze, then rebuild

def add_noise(x, std, generator=None):
    """Gaussian noise, clipped so that pixels stay between 0 and 1."""
    noise = torch.randn(x.shape, generator=generator) * std
    return (x + noise).clamp(0.0, 1.0)

def train_autoencoder(X, code_size=8, noise_std=0.0, epochs=200, seed=0):
    """Train on X; with noise_std > 0 the input is corrupted (denoising)."""
    torch.manual_seed(seed)
    gen = torch.Generator().manual_seed(seed)
    model = Autoencoder(code_size)
    opt = torch.optim.Adam(model.parameters(), lr=0.003)
    loss_fn = nn.MSELoss()
    history = []
    for epoch in range(epochs):
        order = torch.randperm(len(X), generator=gen)
        for start in range(0, len(X), 64):
```

Listing 34.1 (Continued) *ae_model.py: data loading, the Autoencoder module, noise, training and the error measure.*

```
            clean = X[order[start:start + 64]]
            noisy = add_noise(clean, noise_std, gen) if noise_std else clean
            opt.zero_grad()
            loss = loss_fn(model(noisy), clean)  # target: the clean image
            loss.backward()
            opt.step()
        with torch.no_grad():
            history.append(loss_fn(model(X), X).item())
    return model, history

def mse(model, X_in, X_target):
    """Mean squared error per pixel between the output and the target."""
    model.eval()
    with torch.no_grad():
        return ((model(X_in) - X_target) ** 2).mean().item()
```

- `load_images` returns training and test images as tensors with pixels in [0,1], and the labels, which only the pictures and the app use.
- `Autoencoder` keeps the encoder and decoder as two separate `nn.Sequential` blocks, so that we can call `model.encoder(x)` to get codes, as Equation (34.1) describes, or `model(x)` to get the reconstruction of Equation (34.2).
- `add_noise` implements Equation (34.6): `torch.randn` draws standard normal numbers, which we scale by the noise level, and `clamp` clips to [0,1]. It takes an optional random `generator` so that the test noise can be made identical on every run.
- `train_autoencoder` is the training loop of Chapter 33, adapted in three places. It shuffles the training images itself with `torch.randperm`, in batches of 64. When `noise_std` is positive it spoils each batch with fresh noise, but the loss always compares the output with the `clean` batch; this single line is the difference between Equation (34.4) and Equation (34.7). And `nn.MSELoss` [5] replaces the cross-entropy loss. After each epoch it records the error on the clean training images.
- `mse` measures Equation (34.4) between the model's output for one set of inputs and a set of targets, so we can ask both "how well does it rebuild clean images?" and "how close to the clean image is its output for a noisy one?".

34.4.2 Training both models

Listing 34.2 trains a plain autoencoder and a denoising one, both with 8-number codes and 200 epochs, compares four errors on the test images, and saves both models.

Listing 34.2 `train_ae.py`: training and comparing the plain and denoising autoencoders.

```
"""Train a plain and a denoising autoencoder and save both (Chapter 34)."""
import time
import torch
from ae_model import add_noise, load_images, mse, train_autoencoder

torch.set_num_threads(1)
X_tr, X_te, _, _ = load_images()
print(f"training images {len(X_tr)}, test images {len(X_te)}")

start = time.perf_counter()
plain, h_plain = train_autoencoder(X_tr, code_size=8)
denoiser, h_den = train_autoencoder(X_tr, code_size=8, noise_std=0.3)
print(f"training time for both: {time.perf_counter() - start:.1f} s")
for epoch in (1, 10, 50, 100, 200):
    print(f"epoch {epoch:3d}  plain loss {h_plain[epoch - 1]:.4f}  "
          f"denoising (clean-input) loss {h_den[epoch - 1]:.4f}")

noisy_te = add_noise(X_te, 0.3, torch.Generator().manual_seed(123))
print("test error per pixel (MSE):")
print(f"  plain AE,     clean input -> clean: {mse(plain, X_te, X_te):.4f}")
print(f"  noisy input itself        vs clean: "
      f"{((noisy_te - X_te) ** 2).mean().item():.4f}")
print(f"  plain AE,     noisy input -> clean: {mse(plain, noisy_te, X_te):.4f}")
print(f"  denoising AE, noisy input -> clean: {mse(denoiser, noisy_te, X_te):.4f}")
torch.save(plain.state_dict(), "ae_plain.pt")
torch.save(denoiser.state_dict(), "ae_denoise.pt")
print("saved ae_plain.pt and ae_denoise.pt")
```

The test noise uses its own generator with seed 123, separate from the training noise, so that every run sees exactly the same noisy test images and every model is judged on the same ones.

34.4.3 The application

Listing 34.3 is the program you run to see the models at work. For each requested test image it prints the 8-number code, then four pictures side by side as text art, the original, the plain model's reconstruction, the noisy version and the denoising model's output, and finally the error of each against the original.

Listing 34.3 `ae_app.py`: compressing and denoising test digits with the saved models.

```
"""Compress and denoise digits with the saved autoencoders (Chapter 34).

usage: python ae_app.py [index ...]     (indexes into the test set)
"""
import sys
import torch
from ae_model import Autoencoder, add_noise, load_images

SHADES = " .:-=+*#%@"

def rows(image):
    return ["".join(SHADES[min(int(v * 10), 9)] * 2 for v in r)
            for r in image.view(8, 8)]

plain, denoiser = Autoencoder(8), Autoencoder(8)
plain.load_state_dict(torch.load("ae_plain.pt", weights_only=True))
denoiser.load_state_dict(torch.load("ae_denoise.pt", weights_only=True))
plain.eval()
denoiser.eval()
_, X_te, _, y_te = load_images()
noisy_te = add_noise(X_te, 0.3, torch.Generator().manual_seed(123))

for index in [int(a) for a in sys.argv[1:]] or [0]:
    clean, noisy = X_te[index:index + 1], noisy_te[index:index + 1]
    with torch.no_grad():
        code = plain.encoder(clean)[0]
        rebuilt = plain(clean)[0]
        cleaned = denoiser(noisy)[0]
    print(f"test image {index} (digit {y_te[index].item()})")
    print("code (8 numbers instead of 64):",
          " ".join(f"{v:+.2f}" for v in code.tolist()))
    titles = ["original", "rebuilt from code", "noisy", "denoised"]
    print("   ".join(f"{t:16s}" for t in titles))
    for parts in zip(*(rows(im) for im in (clean[0], rebuilt, noisy[0], cleaned))):
        print("   ".join(parts))
    for name, im in [("rebuilt", rebuilt), ("noisy", noisy[0]),
                     ("denoised", cleaned)]:
        err = ((im - clean[0]) ** 2).mean().item()
        print(f"  {name:8s} error per pixel {err:.4f}")
```

`plain.encoder(clean)` runs only the first half of the hourglass. The function `rows` turns an image into eight lines of text art, as in Chapter 33, and `zip(*...)` walks through the four images row by row so they appear side by side.

34.4.4 Tests

Listing 34.4 checks the shapes of the code and the output, that noisy pixels stay in range, and that a short training run on 300 images already halves the error of an untrained model.

Listing 34.4 `test_ae.py`: unit tests for the autoencoder.

```
"""Unit tests for the autoencoder (run: python -m unittest)."""
import unittest
import torch
from ae_model import Autoencoder, add_noise, load_images, mse, train_autoencoder

class AutoencoderTest(unittest.TestCase):
    def test_shapes(self):
        model = Autoencoder(code_size=5)
        x = torch.rand(3, 64)
        self.assertEqual(tuple(model.encoder(x).shape), (3, 5))
        self.assertEqual(tuple(model(x).shape), (3, 64))

    def test_noise_stays_in_range(self):
        x = add_noise(torch.rand(10, 64), 0.5, torch.Generator().manual_seed(0))
        self.assertGreaterEqual(x.min().item(), 0.0)
        self.assertLessEqual(x.max().item(), 1.0)

    def test_training_reduces_error(self):
        X_tr, X_te, _, _ = load_images()
        before = mse(Autoencoder(8), X_te, X_te)
        model, _ = train_autoencoder(X_tr[:300], code_size=8, epochs=20)
        self.assertLess(mse(model, X_te, X_te), before / 2)

if __name__ == "__main__":
    unittest.main()
```

34.5 Running It

Train both models (about 13 seconds on one core):

```
python train_ae.py
```

```
training images 1437, test images 360
training time for both: 12.7 s
epoch   1  plain loss 0.0990  denoising (clean-input) loss 0.0984
epoch  10  plain loss 0.0303  denoising (clean-input) loss 0.0348
epoch  50  plain loss 0.0167  denoising (clean-input) loss 0.0201
epoch 100  plain loss 0.0145  denoising (clean-input) loss 0.0175
epoch 200  plain loss 0.0126  denoising (clean-input) loss 0.0162
test error per pixel (MSE):
  plain AE,     clean input -> clean: 0.0151
  noisy input itself        vs clean: 0.0524
  plain AE,     noisy input -> clean: 0.0536
  denoising AE, noisy input -> clean: 0.0240
saved ae_plain.pt and ae_denoise.pt
```

The loss of the plain model falls from 0.099 after the first epoch to 0.0126 after 200. On the test images it reaches 0.0151: an unseen digit, squeezed into 8 numbers, comes back with a typical error of 0.12 per pixel. The denoising model's loss on clean inputs is a little higher, 0.0162: it has spent some of its capacity learning to ignore noise.

The four test errors tell the main story. The noisy test images differ from the clean ones by 0.0524. The plain autoencoder, given those noisy images, produces outputs that are just as far from the clean images, 0.0536: it never saw noise during training and faithfully tries to redraw it. The denoising autoencoder cuts the error to 0.0240, less than half. **Figure 34.2** shows eight test digits in all four versions.

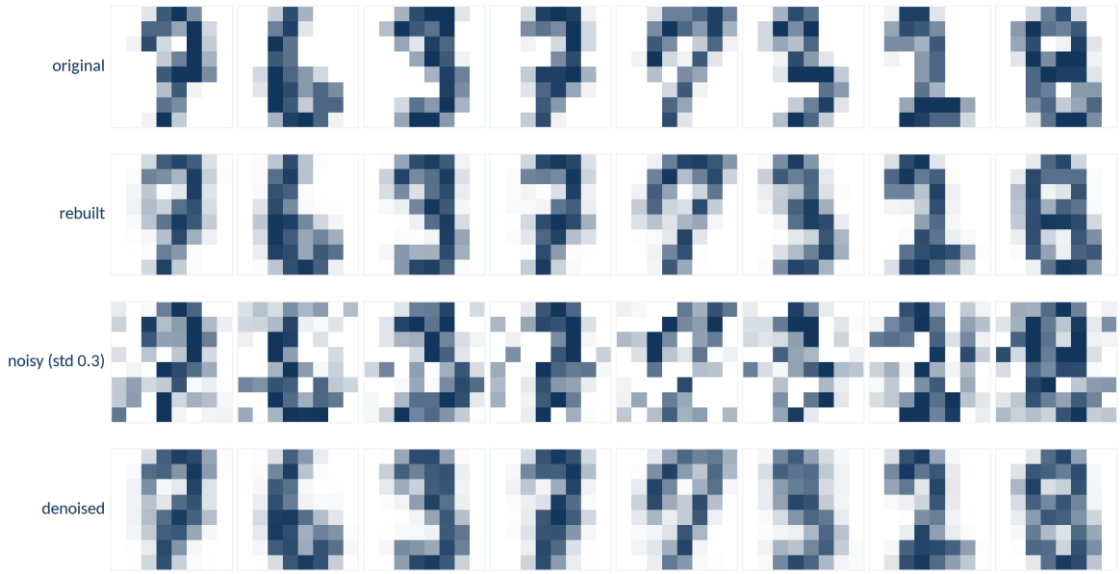

Figure 34.2 Eight test digits: the original, the plain autoencoder's reconstruction from 8 numbers, the same digit with noise of standard deviation 0.3, and the denoising autoencoder's output for the noisy input.

The reconstructions are slightly blurred, and fine details such as the exact end of a stroke are lost, but every digit is recognizable. The denoised row is cleaner than the noisy row: the speckles in the background are gone and the strokes are solid again.

Now the application on test image 3:

```
python ae_app.py 3
```

```
test image 3 (digit 7)
code (8 numbers instead of 64): +0.42 -0.07 -1.23 -3.13 +3.98 +1.42 -3.99 -5.51
original           rebuilt from code   noisy               denoised
    ..@@@@@@           ::@@@@@@..          ..%%@@##           ..%%@@%%..
    ++**++@@..         ****++@@::      --  ==@@%%@@..         ++#####@@--
        ..@@..             ..@@               ++@@           ::  ==@@
        ++%%               **##         ++    %%@@  ::          ..@@##
    ::@@@@@@--         ..%%@@%%--      ==    @@##****           %%@@%%..
    ..##@@==           ..##@@---.      --  ..%%++==            ..%%%%++
      %%++               %%==          --    %%@@**              @@##..
    ::%%               ::@@::                @@  ==            ::%%==
  rebuilt  error per pixel 0.0024
  noisy    error per pixel 0.0432
  denoised error per pixel 0.0135
```

Eight numbers describe this 7. The reconstruction's error is only 0.0024 per pixel, an easy digit. The noise raises the error to 0.0432 and the denoiser brings it back to 0.0135. In the text art you can see how the denoiser removed the stray marks on the left while keeping the bar and the stem of the 7.

What do the 8 numbers mean? No single one has a simple meaning, but we can get a feeling for the codes by training an autoencoder with only $k = 2$ and plotting every test digit as a point. The right panel of **Figure 34.3** does that, with each digit's median position marked. The left panel shows the first two PCA coordinates for comparison.

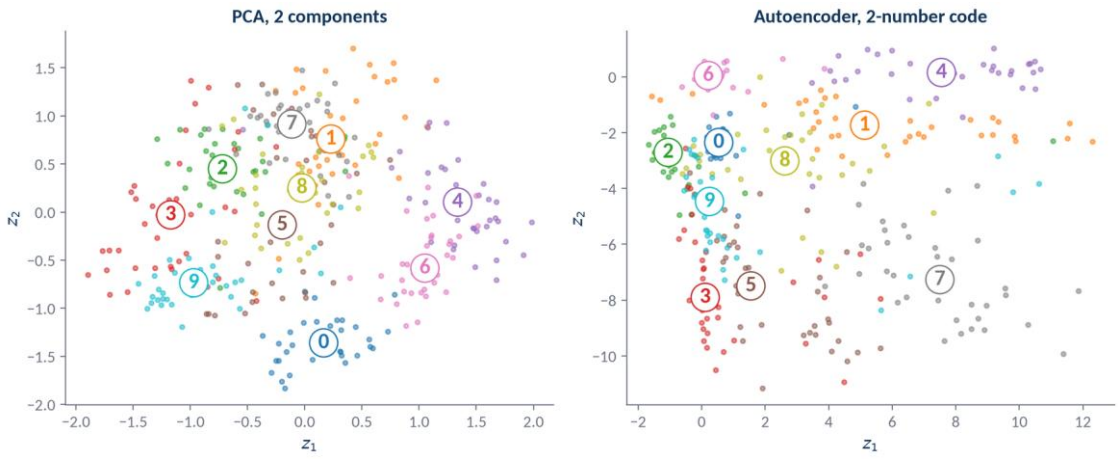

Figure 34.3 The 360 test digits described by two numbers each. Left: the first two principal components. Right: the code of an autoencoder with $k = 2$. Circled numbers mark the median position of each digit. Labels were not used by either method.

Neither method was told which image is which digit, yet both place similar digits near each other. The autoencoder's layout separates several digits more clearly: the 7s, 4s and 1s occupy their own regions, while 3, 5 and 9, which share a curved right-hand side, are neighbors. The structure of the data has emerged from the images alone.

Finally, the tests:

```
python -m unittest
```

```
...
----------------------------------------------------------------------
Ran 3 tests in 5.377s

OK
```

34.6 Improving It

How small can the code be, and is the neural network worth its trouble compared with PCA? **Listing 34.5** answers both questions by training autoencoders with codes of 2, 4, 8, 16 and 32 numbers and fitting scikit-learn's `PCA` [6] with the same number of components.

Listing 34.5 `compare_sizes.py`: test error for five code sizes, PCA versus autoencoder.

```
"""How small can the code be? Autoencoder versus PCA (Chapter 34)."""
import torch
from sklearn.decomposition import PCA
from ae_model import load_images, mse, train_autoencoder

torch.set_num_threads(1)
X_tr, X_te, _, _ = load_images()
print("code size | ratio | PCA test MSE | autoencoder test MSE")
for k in (2, 4, 8, 16, 32):
    pca = PCA(n_components=k).fit(X_tr.numpy())
    rebuilt = pca.inverse_transform(pca.transform(X_te.numpy()))
    pca_mse = ((torch.tensor(rebuilt) - X_te) ** 2).mean().item()
    model, _ = train_autoencoder(X_tr, code_size=k)
    print(f"{k:9d} | {64 // k:4d}x | {pca_mse:12.4f} | "
          f"{mse(model, X_te, X_te):20.4f}")
```

```
python compare_sizes.py
```

```
code size | ratio | PCA test MSE | autoencoder test MSE
        2 |   32x |       0.0532 |               0.0401
        4 |   16x |       0.0379 |               0.0263
        8 |    8x |       0.0246 |               0.0151
       16 |    4x |       0.0116 |               0.0077
       32 |    2x |       0.0026 |               0.0059
```

Figure 34.4 plots the two columns. For small codes the autoencoder wins clearly: with 8 numbers its error is 0.0151 against PCA's 0.0246, about 40% lower, and with 2 numbers it is 0.0401 against 0.0532. The nonlinear activations let it describe curved families of shapes that a flat PCA subspace can only approximate.

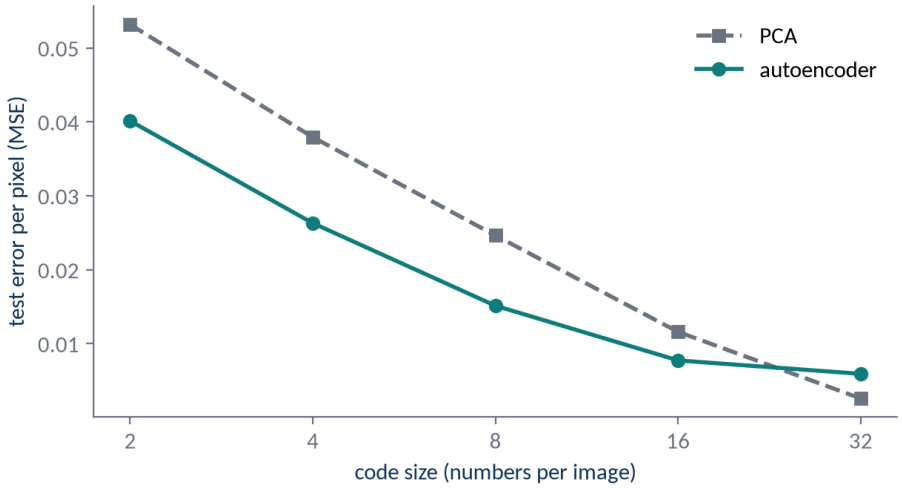

Figure 34.4 Test reconstruction error for codes of 2 to 32 numbers, from the run of **Listing 34.5**. The autoencoder wins for small codes; PCA wins at 32.

But at 32 numbers, PCA wins, 0.0026 against 0.0059. Why? Look at our architecture: every path through the network passes through hidden layers of 32 units, so a code of 32 numbers is not really the narrowest point any more, and the network has only 200 epochs to learn a nearly perfect copy. PCA with 32 components simply keeps half the dimensions of the data exactly, and digits have most of their variation in far fewer than 32 directions. The lesson is general: a neural network is not automatically better than a classical method. It pays off where the structure is nonlinear and the budget is tight, and a wider network or more training would be needed to win at the easy end. Always run the simple baseline.

Three further improvements are worth knowing about, even though we do not build them here.

- **Convolutional autoencoders** replace the linear layers with the convolutions of Chapter 35, which know that neighboring pixels belong together. They are the standard for real images.
- **Variational autoencoders** (VAEs), introduced by Kingma and Welling [7], make the code a probability distribution and push it toward a standard shape, so that decoding a *random* code gives a plausible new image. That turns the autoencoder into a generator, a theme that Chapter 40 continues with GANs.
- **Choosing the noise.** The denoiser was trained on noise of strength 0.3. Exercise 34.3 shows how it behaves on weaker and stronger noise, with a surprise at the weak end.

34.7 Common Mistakes, and How to Avoid Them

A bottleneck that is not narrow. If the code is as large as the input, or if any path around the bottleneck exists, the network can learn the identity and the code means nothing. Keep k well below n.

Comparing the output with the noisy input. In a denoising autoencoder the loss must use the clean image as the target, as in Equation (34.7). Compare with the noisy input and you have trained a very expensive copier of noise.

Forgetting the output range. Pixels are in [0,1]; without the closing sigmoid the decoder can output -0.3 or 1.4, and the MSE spends effort on impossible values. Match the output activation to the data.

Judging on training images. A reconstruction error measured on the images the network was trained on is optimistic. The test errors in this chapter all use images the network never saw.

Skipping the baseline. Without the PCA column of **Listing 34.5** you would not know that the autoencoder's result at $k = 32$ is poor. A classical baseline takes three lines and often surprises.

Expecting the codes to be readable. The individual numbers of a code rarely have a human meaning such as "slant". Neighborhoods in code space are meaningful; single coordinates usually are not.

34.8 Chapter Summary

- An autoencoder is an encoder $\mathbf{z} = f(\mathbf{x})$ (Equation (34.1)) and a decoder $\hat{\mathbf{x}} = g(\mathbf{z})$ (Equation (34.2)) trained together to make $\hat{\mathbf{x}}$ close to $\mathbf{x}$, measured by the mean squared error (Equation (34.4)); a sigmoid (Equation (34.3)) keeps outputs in the pixel range.
- The narrow code forces the network to learn what the data have in common; the compression ratio is n/k (Equation (34.5)), 8 for our digits.
- A denoising autoencoder corrupts the input (Equation (34.6)) but keeps the clean target (Equation (34.7)); ours halves the error of noisy digits, from 0.0524 to 0.0240.
- PCA is the best linear autoencoder (Equation (34.8)); our nonlinear autoencoder beats it for codes of 2 to 16 numbers and loses at 32.
- Codes learned without labels still group similar digits together, and a large reconstruction error signals unusual inputs.

34.9 Exercises

1. Our decoder has $8 \cdot 32 + 32 + 32 \cdot 64 + 64 = 2400$ parameters. If every number is stored as a 4-byte float, how many images must be compressed before storing the codes plus the decoder takes less space than storing the images as 64 floats each? And if the images were stored as 64 bytes each (one byte per pixel)?
2. The plain autoencoder's test error is 0.0151 per pixel. Convert this into a typical error measured in the original gray levels 0 to 16. Is it visible?
3. Test the saved plain and denoising autoencoders on noise of standard deviation 0.1, 0.3 and 0.5 (without retraining). For each level, compare the error of the noisy image itself with the errors of the two models' outputs, and explain the result at 0.1.

4. Use the plain autoencoder as an alarm. Compute the reconstruction error of every test digit and take the 99th percentile as the alarm limit. Then compute the errors of five images of random pixels, five inverted digits ($1 - \mathbf{x}$) and five blank images. How many of them set off the alarm?
5. Explain why an autoencoder with $k = 64$ and no hidden layers, $\hat{\mathbf{x}} = \sigma(W_2(W_1\mathbf{x} + \mathbf{b}_1) + \mathbf{b}_2)$, can learn to reproduce its input almost perfectly and why its code is then useless.
6. In **Figure 34.3**, which pairs of digits overlap most in the autoencoder's two-number code? Look back at the confusion matrix of Section 33.5 and compare with the digits that the classifier confused.

34.10 Solutions to the Exercises

Solution 1. With 4-byte floats, N images cost $64 \cdot 4N = 256N$ bytes raw, and $8 \cdot 4N + 2400 \cdot 4 = 32N + 9600$ bytes as codes plus decoder. The codes win when $32N + 9600 < 256N$, that is $N > 9600/224 \approx 42.9$, so from 43 images on. With one byte per pixel the raw images cost $64N$ bytes, and codes stored as 4-byte floats cost $32N + 9600$; they win when $32N + 9600 < 64N$, that is $N > 300$. (Storing the codes as bytes too would help further; real compressors also quantize their codes.) The general point: a learned decoder is a fixed cost that pays off only over many images.

Solution 2. The typical error is $\sqrt{0.0151} = 0.123$ on the 0 to 1 scale. Multiplying by 16 gives 1.97, so about two gray levels out of 17. Next to the original the blur is visible, as **Figure 34.2** shows, but the digit's identity is intact.

Solution 3. **Listing 34.6** loads both saved models and applies them to three noise levels.

Listing 34.6 `sol_noise_levels.py`: both models on three noise levels.

```
"""Exercise 34.3: the saved autoencoders on weaker and stronger noise."""
import torch
from ae_model import Autoencoder, add_noise, load_images, mse

models = {}
for name in ("plain", "denoise"):
    models[name] = Autoencoder(8)
    models[name].load_state_dict(torch.load(f"ae_{name}.pt", weights_only=True))
_, X_te, _, _ = load_images()
print("noise std | noisy vs clean | plain AE | denoising AE")
for std in (0.1, 0.3, 0.5):
    noisy = add_noise(X_te, std, torch.Generator().manual_seed(123))
    raw = ((noisy - X_te) ** 2).mean().item()
    print(f"{std:9.1f} | {raw:14.4f} | {mse(models['plain'], noisy, X_te):8.4f} | "
          f"{mse(models['denoise'], noisy, X_te):12.4f}")
```

```
noise std | noisy vs clean | plain AE | denoising AE
      0.1 |         0.0068 |   0.0211 |       0.0177
      0.3 |         0.0524 |   0.0536 |       0.0240
      0.5 |         0.1182 |   0.0883 |       0.0379
```

At 0.3, the level it was trained on, the denoiser more than halves the error. At 0.5 it still helps a lot (0.1182 → 0.0379), and even the plain model helps a little, because anything it draws looks like a digit. The surprise is at 0.1: the noisy image itself is already very close to the original (0.0068), closer than *any* reconstruction from an 8-number code can be, since even clean inputs come back with an error of 0.0151. Passing a lightly noisy image through the bottleneck makes it worse. A denoiser's own blur sets a floor on its error, and for inputs that are already cleaner than that floor, doing nothing is best.

Solution 4. **Listing 34.7** computes one error per image and compares with the limit.

Listing 34.7 `sol_anomaly.py`: reconstruction error as an anomaly alarm.

```
"""Exercise 34.4: reconstruction error as an alarm for unusual images."""
import torch
from ae_model import Autoencoder, load_images

model = Autoencoder(8)
model.load_state_dict(torch.load("ae_plain.pt", weights_only=True))
model.eval()
_, X_te, _, _ = load_images()

def errors(X):
    with torch.no_grad():
        return ((model(X) - X) ** 2).mean(dim=1)   # one error per image

normal = errors(X_te)
limit = torch.quantile(normal, 0.99).item()
print(f"test digits: mean error {normal.mean().item():.4f}, "
      f"99th percentile {limit:.4f} (alarm limit)")
g = torch.Generator().manual_seed(0)
odd = {"random pixels": torch.rand(5, 64, generator=g),
       "inverted digits": 1.0 - X_te[:5],
       "blank images": torch.zeros(5, 64)}
for name, X in odd.items():
    e = errors(X)
    alarms = int((e > limit).sum())
    print(f"{name:15s}: errors {' '.join(f'{v:.3f}' for v in e.tolist())}"
          f"  -> {alarms}/5 alarms")
```

```
test digits: mean error 0.0151, 99th percentile 0.0408 (alarm limit)
random pixels  : errors 0.207 0.221 0.246 0.217 0.217  -> 5/5 alarms
inverted digits: errors 0.521 0.515 0.506 0.541 0.434  -> 5/5 alarms
blank images   : errors 0.073 0.073 0.073 0.073 0.073  -> 5/5 alarms
```

All fifteen unusual images set off the alarm. Random pixels have errors around 0.22, five times the limit of 0.041; the decoder can only draw digit-like shapes, and noise is not one. Inverted digits, black background with white strokes, are the worst, around 0.5. Even blank images are caught (0.073): the decoder has never had to draw "nothing" and puts faint strokes there. On the other side of the coin, by construction about 1% of genuine test digits (the 99th percentile) also exceed the limit; choosing the limit trades missed anomalies against false alarms, a trade-off Part 7 studies in detail.

Solution 5. With $k = 64$ the code has as many numbers as the image, so there is no bottleneck. The network can choose W_1 to be any invertible matrix and W_2 its inverse, scaled so that the sigmoid is in its nearly linear middle, and then $\hat{\mathbf{x}} \approx \mathbf{x}$ for *every* input, digit or not. The code is just the image in other coordinates: it has learned nothing about digits, it does not compress, and it cannot denoise or detect anomalies, because noise and anomalies pass through as faithfully as digits do.

Solution 6. In the autoencoder's panel, 3 and 5 sit side by side at the lower left, 9 lies between 0 and 3, and 8 sits in the crowded middle between 1 and 2. In Chapter 33's confusion matrix a 5 was read as 3 and a 9 as 5, and the 8s were confused with 1 and 5. The overlaps are similar because both models see the same fact about these digits: at 8×8 pixels their shapes share many pixels. An unsupervised method and a supervised one found the same hard cases.

Chapter 35

Convolutional Network for Images

The digit recognizer of Chapter 33 read about 97% of its test digits correctly, and it would be easy to call the job done. This chapter starts by breaking it: move each test digit by a single pixel, and the same network falls to 39%. The reason is that a fully connected network treats the 64 pixels as 64 unrelated numbers; it has no idea that pixel 10 is the right-hand neighbor of pixel 9, so a stroke that moves one step to the right looks to it like a completely different input. The cure is the *convolutional network* (CNN), which moves a small window of weights across the image and uses the same weights everywhere. By the end of the chapter you will be able to compute a convolution by hand and check it with PyTorch, work out the size of every layer's output and the number of its weights, explain max pooling and why a convolution *shifts along* when its input shifts, build a small CNN in PyTorch that has fewer weights than Chapter 33's network, and combine it with *data augmentation* so that it reads digits moved by a pixel with 97.5% accuracy. Every model trains in a few seconds.

35.1 Why Convolutions?

Think about how you would recognize a handwritten 7 if someone slid the laundry tag it was written on one centimeter to the left. You would not notice the difference. The 7 is made of the same pieces, a horizontal bar and a slanted stroke, joined in the same way; only their position on the paper has changed. Our eyes, and the parts of the brain that process them, look for local patterns wherever they happen to appear. In the late 1950s and 1960s David Hubel and Torsten Wiesel found cells in the visual cortex of cats that respond to an edge of a particular orientation in a small patch of the visual field, with many such cells covering the whole field [1].

Neural networks borrowed this idea twice. Kunihiko Fukushima's *Neocognitron* of 1980 stacked layers of local pattern detectors [2], and Yann LeCun and colleagues trained such a network with backpropagation to read handwritten postal codes in 1989, and refined it into the LeNet networks that read bank checks in the 1990s [3]. In 2012 a much larger CNN, AlexNet, won the ImageNet image recognition competition by a wide margin and started the deep-learning boom [4]. Today convolutions are part of almost every system that processes images: phone cameras, medical scans, the object counters and document readers of Part 5.

The two ideas that make a convolution work are simple.

- **Local connections.** Each unit of a convolutional layer looks only at a small patch of its input, say 3×3 pixels, not at the whole image. A stroke is a local thing, so a local detector is enough to find it.
- **Shared weights.** The same small set of weights, the *kernel* or *filter*, is used at every position. A detector for "a vertical edge" that works in the top-left corner works in the bottom-right corner too, and it has to be learned only once.

Together they give the property we are after: if the input moves, the detected patterns move with it, and the network no longer has to learn the same stroke separately at every position.

35.2 The Idea in Plain Words

Picture a small square of stiff card with a 3 × 3 grid of numbers written on it, the kernel. Lay it on the top-left corner of the image, so that each of its nine numbers covers one pixel. Multiply every kernel number by the pixel under it and add up the nine products. Write the total down: that is the first number of the output. Move the card one pixel to the right and repeat. When you reach the right edge, go back to the left and one row down. The table of totals you have written is the *feature map*, and the whole procedure is a *convolution*.

What does a feature map show? That depends on the kernel. **Figure 35.1** shows a kernel whose left column is −1, middle column 0 and right column +1. Wherever the image is darker on the right of the window than on the left, the products add up to a large positive number; where it is lighter on the right, to a large negative number; where the window is uniform, to zero. So this kernel is a detector for vertical edges that go from light to dark. In a CNN the kernels are not written by hand; they are weights, learned by backpropagation like any others, and the network discovers which local patterns are useful [5].

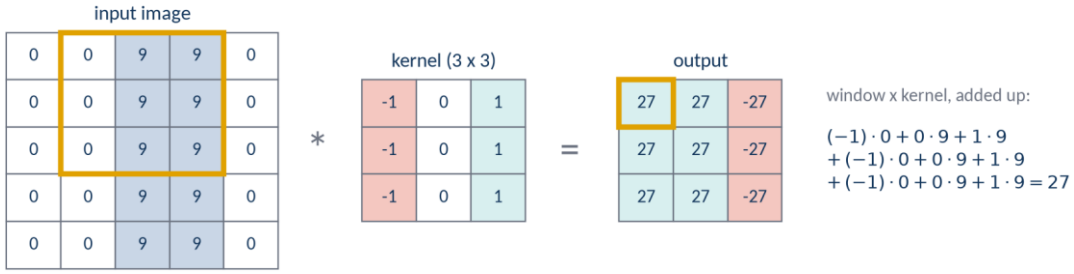

Figure 35.1 A convolution. The 3 × 3 window (amber) of the input is multiplied cell by cell with the kernel and added up, giving one output number; moving the window gives the whole 3 × 3 output. This kernel responds to a rise in darkness from left to right.

A CNN layer uses several kernels at once, each producing its own feature map; ours has 8 in the first layer. Then comes *max pooling*: cut each feature map into 2 × 2 blocks and keep only the largest number of each block. The map shrinks to a quarter of its size, and a pattern that moved by a pixel inside a block gives the same result. A second convolution layer then looks for patterns *of patterns*, for instance “a horizontal edge above a slanted one”, and a second pooling shrinks again. Finally the small maps are flattened into a list and a linear layer turns the list into ten scores, exactly as in Chapter 33. **Figure 35.2** shows the whole network.

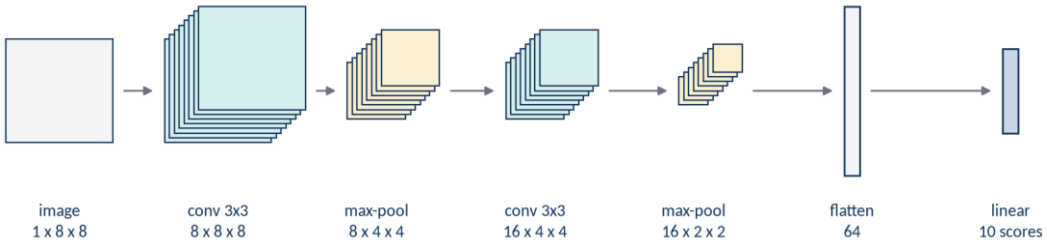

Figure 35.2 The network of this chapter. Two rounds of 3 × 3 convolution and 2 × 2 max pooling turn the 8 × 8 image into 16 maps of 2 × 2; these 64 numbers feed a linear layer with 10 outputs.

> **KEY INSIGHT.** A convolutional layer is a fully connected layer with two restrictions: each output sees only a small neighborhood, and all outputs share the same weights. The restrictions remove parameters and add knowledge: that images are made of local patterns that can appear anywhere.

35.3 The Mathematics, Gently

35.3.1 One convolution

Let X be an image with pixels $X[i, j]$, where i counts rows and j counts columns, both from 0. Let K be a $k \times k$ kernel and b a bias. The output of the convolution at position (i, j) is

$$Y[i,j] = b + \sum_{u=0}^{k-1} \sum_{v=0}^{k-1} X\,[i+u,\, j+v]\; K[u,v] \tag{35.1}$$

In words: put the kernel's top-left corner on pixel (i, j), multiply what overlaps, and add. Mathematicians would call Equation (35.1) a *cross-correlation*; a true convolution flips the kernel first. Deep-learning libraries compute Equation (35.1) and call it convolution, and since the kernels are learned, the flip makes no difference [6].

Let us compute one output of **Figure 35.1** by hand. The image has columns 0,0,9,9,0 in every row, the kernel has columns -1,0,1, and $b = 0$. At $(i, j) = (0,0)$ the window covers columns 0 to 2, whose values are 0,0,9 in each of the three rows. Each row contributes $(-1) \cdot 0 + 0 \cdot 0 + 1 \cdot 9 = 9$, and three rows give $Y[0,0] = 27$. At $(0,2)$ the window covers columns 2 to 4, values 9,9,0, and each row gives $(-1) \cdot 9 + 0 \cdot 9 + 1 \cdot 0 = -9$, so $Y[0,2] = -27$: the edge from dark to light is detected with the opposite sign.

35.3.2 Many channels in, many maps out

A color image has three *channels* (red, green, blue), and the output of a convolutional layer with 8 kernels has 8 channels. A layer that reads c_{in} channels and writes c_{out} maps has one kernel of size $c_{\text{in}} \times k \times k$ for every output map c, and adds up over all input channels d:

$$Y_c[i,j] = b_c + \sum_{d=1}^{c_{\text{in}}} \sum_{u=0}^{k-1} \sum_{v=0}^{k-1} X_d\,[i+u,\, j+v]\; K_{c,d}[u,v] \tag{35.2}$$

So a kernel of the second layer, which reads the 8 maps of the first, looks at a 3×3 patch of all 8 maps at once, 72 numbers, and can combine "an edge here in map 2" with "a corner there in map 5".

35.3.3 Output size and padding

A $k \times k$ window fits into an $n \times n$ image in $n - k + 1$ positions along each direction: our 5×5 image and 3×3 kernel give a 3×3 output. To keep the size, we can add a border of p zeros around the image, called *padding*. We can also move the window s pixels at a time instead of one, the *stride*. The general rule for the output size is

$$n_{\text{out}} = \left\lfloor \frac{n + 2p - k}{s} \right\rfloor + 1 \tag{35.3}$$

where $\lfloor \cdot \rfloor$ means "round down". With $n = 8$, $k = 3$, $p = 1$, $s = 1$ we get $\lfloor 7/1 \rfloor + 1 = 8$: padding 1 keeps an 8×8 image 8×8, which is why our layers use `padding=1`. A 2×2 max pooling with stride 2 is Equation (35.3) with $k = 2$, $p = 0$, $s = 2$: $\lfloor 6/2 \rfloor + 1 = 4$. The guide by Dumoulin and Visin works through every combination with pictures [7].

35.3.4 Counting parameters

A convolutional layer has c_{out} kernels of $c_{\text{in}} \cdot k^2$ weights each, plus one bias per kernel:

$$N_{\text{conv}} = (c_{\text{in}}\, k^2 + 1) c_{\text{out}} \tag{35.4}$$

Crucially, the image size does not appear: the same weights are reused at every position. For our network, the first layer has $(1 \cdot 9 + 1) \cdot 8 = 80$ parameters, the second $(8 \cdot 9 + 1) \cdot 16 = 1168$, and the last linear layer $64 \cdot 10 + 10 = 650$, in total 1898. Chapter 33's fully connected network had 2,410. The CNN does more with less.

35.3.5 Max pooling

A 2×2 max pooling with stride 2 replaces each non-overlapping 2×2 block by its largest value:

$$P[i, j] = \max(Y[2i, 2j],\ Y[2i, 2j+1],\ Y[2i+1, 2j],\ Y[2i+1, 2j+1]) \tag{35.5}$$

It has no weights. It halves the height and the width, so the next layer's 3×3 window covers a patch twice as wide in the original image, and it makes the answer insensitive to where exactly inside the block a pattern was found.

35.3.6 Shifting along

Let S be the operation "shift the image one pixel to the right" (filling the new column with zeros). Because Equation (35.1) uses the same kernel at every position, shifting the input and then convolving gives the same result as convolving and then shifting, apart from the border columns:

$$\text{conv}(S(X)) = S(\text{conv}(X)) \tag{35.6}$$

This property is called *translation equivariance*. A fully connected layer has no such property: its weight for pixel 9 and its weight for pixel 10 are unrelated. Exercise 35.4 checks Equation (35.6) numerically on our trained network. Note that equivariance is not yet *invariance*: the feature maps move, they do not stay the same. Pooling adds a little invariance for small moves inside a block, and training on shifted images, Section 35.6, adds the rest.

35.4 Building It Step by Step

The code is in `Chapter035`, with the same requirements as Chapter 33: PyTorch 2.14, scikit-learn 1.9.1 and NumPy 2.4.6.

35.4.1 A convolution by hand

Listing 35.1 computes the example of **Figure 35.1** with two nested loops that implement Equation (35.1) literally, then asks PyTorch's `conv2d` for the same thing.

Listing 35.1 `conv_by_hand.py`: Equation (35.1) with loops, compared with `torch.nn.functional.conv2d`.

```
"""One convolution computed by hand and by PyTorch (Chapter 35)."""
import numpy as np
import torch
import torch.nn.functional as F

image = np.array([[0, 0, 9, 9, 0],
                  [0, 0, 9, 9, 0],
                  [0, 0, 9, 9, 0],
                  [0, 0, 9, 9, 0],
                  [0, 0, 9, 9, 0]], dtype=float)
kernel = np.array([[-1, 0, 1],
                   [-1, 0, 1],
                   [-1, 0, 1]], dtype=float)  # responds to left-to-right rises

out = np.zeros((3, 3))
for i in range(3):                            # slide the 3x3 window down
    for j in range(3):                        # ... and across
        window = image[i:i + 3, j:j + 3]
        out[i, j] = (window * kernel).sum()   # multiply and add up
print("by hand:")
print(out)

t_img = torch.tensor(image, dtype=torch.float32).view(1, 1, 5, 5)
t_ker = torch.tensor(kernel, dtype=torch.float32).view(1, 1, 3, 3)
print("torch.nn.functional.conv2d:")
print(F.conv2d(t_img, t_ker)[0, 0])
print("with padding=1 the output keeps the 5x5 size:",
      tuple(F.conv2d(t_img, t_ker, padding=1).shape))
```

```
python conv_by_hand.py
```

```
by hand:
[[ 27.  27. -27.]
 [ 27.  27. -27.]
 [ 27.  27. -27.]]
torch.nn.functional.conv2d:
tensor([[ 27.,  27., -27.],
        [ 27.,  27., -27.],
        [ 27.,  27., -27.]])
with padding=1 the output keeps the 5x5 size: (1, 1, 5, 5)
```

The two agree, confirming that PyTorch's "convolution" is Equation (35.1) without a flip. PyTorch wants 4-dimensional tensors of shape (batch, channels, height, width), hence `view(1, 1, 5, 5)`. With `padding=1` the output is 5×5, as Equation (35.3) predicts.

35.4.2 The models and the data

Listing 35.2 defines the data, the image-shifting helpers, the CNN, the fully connected network of Chapter 33 for comparison, and the training and evaluation functions.

Listing 35.2 `cnn_model.py`: data, shifting, the CNN, the MLP baseline, training and accuracy.

```

    return sum(p.numel() for p in model.parameters())
```

- `load_images` keeps the images as 8×8 grids (`d.images`, not the flattened `d.data`) and adds a channel dimension with `unsqueeze(1)`, giving the shape $(N, 1, 8, 8)$ that convolution layers expect.
- `shift` moves a batch of images `dx` pixels right and `dy` pixels down, filling the uncovered border with zeros (white) and dropping what falls off the other side. It works by copying a slice of the source into a slice of an empty tensor; the `max(0, ...)` expressions choose the slices for positive and negative moves. `random_shifts` gives every image its own random move of -1, 0 or $+1$ in each direction, 9 possibilities, one of which is "no move".
- `DigitCNN` follows **Figure 35.2**: `Conv2d(1, 8, 3, padding=1)` is Equation (35.2) with 1 input channel and 8 output maps; `MaxPool2d(2)` is Equation (35.5). The comments give each stage's output shape, which you can verify with Equation (35.3). `flatten(1)` turns the $(N, 16, 2, 2)$ tensor into $(N, 64)$, keeping the batch dimension.
- `DigitMLP` is Chapter 33's 64-32-10 network, with an `nn.Flatten` in front so that it reads the same image tensors.
- `train` is Chapter 33's loop with one addition: when `augment` is true, every mini-batch is randomly shifted before it is shown to the model. We come back to this in Section 35.6.

35.4.3 Training and the shift test

Listing 35.3 trains both networks for 30 epochs from the same seed, measures their accuracy on the normal test images and on a copy of the test set in which every image has been randomly moved by up to one pixel, and saves both models.

Listing 35.3 `train_cnn.py`: training the MLP and the CNN and testing them on plain and shifted digits.

```
"""Train the CNN and the MLP, test them on plain and shifted digits."""
import time
import torch
from cnn_model import (DigitCNN, DigitMLP, accuracy, count_params,
                       load_images, random_shifts, train)

torch.set_num_threads(1)
X_tr, X_te, y_tr, y_te = load_images()
X_moved = random_shifts(X_te, torch.Generator().manual_seed(99))
print(f"training images {len(X_tr)}, test images {len(X_te)}")
print(f"{'model':5s} {'params':>6s} {'time':>6s} {'test':>6s} {'shifted':>8s}")
for name, cls in [("MLP", DigitMLP), ("CNN", DigitCNN)]:
    torch.manual_seed(0)                          # same start for every run
    model = cls()
    start = time.perf_counter()
    train(model, X_tr, y_tr)
    seconds = time.perf_counter() - start
    print(f"{name:5s} {count_params(model):6d} {seconds:5.1f}s "
          f"{accuracy(model, X_te, y_te):6.3f} "
          f"{accuracy(model, X_moved, y_te):8.3f}")
    torch.save(model.state_dict(), f"{name.lower()}.pt")
print("saved mlp.pt and cnn.pt")
```

`torch.manual_seed(0)` right before each model is built gives both models the same kind of start on every run. The shifted test set uses its own generator (seed 99) and is the same for every model.

35.4.4 The application

Listing 35.4 lets you move a test digit by hand and see what three saved models make of it: the MLP, the CNN, and the CNN trained on shifted images from Section 35.6 (run `improve.py` once to create `cnn_aug.pt`).

Listing 35.4 `cnn_app.py`: shifting a test digit and asking three models.

```
"""Move a test digit around and ask three saved models what they see.

usage: python cnn_app.py index [dx dy]     (run train_cnn.py and improve.py first)
"""
import sys
import torch
from cnn_model import DigitCNN, DigitMLP, load_images, shift

SHADES = " .:-=+*#%@"
models = {"MLP": DigitMLP(), "CNN": DigitCNN(), "CNN + shifts": DigitCNN()}
for (name, model), file in zip(models.items(), ["mlp.pt", "cnn.pt", "cnn_aug.pt"]):
    model.load_state_dict(torch.load(file, weights_only=True))
    model.eval()

_, X_te, _, y_te = load_images()
index = int(sys.argv[1]) if len(sys.argv) > 1 else 0
dx, dy = (int(sys.argv[2]), int(sys.argv[3])) if len(sys.argv) > 3 else (0, 0)
image = shift(X_te[index:index + 1], dx, dy)
for row in image[0, 0]:
    print("   " + "".join(SHADES[min(int(v * 10), 9)] * 2 for v in row))
print(f"test image {index}, true digit {y_te[index].item()}, moved by "
      f"({dx}, {dy})")
for name, model in models.items():
    with torch.no_grad():
        p = torch.softmax(model(image), dim=1)[0]
    print(f"  {name:13s} says {p.argmax().item()} (probability {p.max():.3f})")
```

35.4.5 Tests

Listing 35.5 checks the output shape and the parameter count of Equation (35.4), and that `shift` moves a single pixel to the right place and loses what falls off the edge.

Listing 35.5 `test_cnn.py`: unit tests for the CNN and the shift helper.

```
"""Unit tests for the convolutional network (run: python -m unittest)."""
import unittest
import torch
from cnn_model import DigitCNN, count_params, shift

class CNNTest(unittest.TestCase):
    def test_output_shape_and_size(self):
        model = DigitCNN()
        self.assertEqual(tuple(model(torch.zeros(4, 1, 8, 8)).shape), (4, 10))
        self.assertEqual(count_params(model), 80 + 1168 + 650)

    def test_shift_moves_pixels(self):
        img = torch.zeros(1, 1, 8, 8)
        img[0, 0, 3, 4] = 1.0
        moved = shift(img, 2, -1)                # right 2, up 1
        self.assertEqual(moved[0, 0, 2, 6].item(), 1.0)
        self.assertEqual(moved.sum().item(), 1.0)

    def test_shift_off_the_edge_is_lost(self):
        img = torch.ones(1, 1, 8, 8)
        self.assertEqual(shift(img, 1, 0).sum().item(), 56.0)   # one column gone

if __name__ == "__main__":
    unittest.main()
```

35.5 Running It

```
python train_cnn.py
```

```
training images 1437, test images 360
model params   time   test  shifted
MLP     2410   6.0s  0.975    0.389
CNN     1898   6.3s  0.975    0.539
saved mlp.pt and cnn.pt
```

On the ordinary test digits the two networks tie at 97.5%, and the CNN gets there with 1,898 parameters instead of 2,410. The difference appears on the shifted digits: the MLP collapses to 38.9%, the CNN keeps 53.9%. Both numbers are low, which is worth understanding. An 8×8 digit moved by one pixel has moved by one eighth of its width, and our digits almost touch the border, so part of a stroke often falls off. Moreover, the CNN has seen only centered digits during training, and its final linear layer has learned *where* in the 2×2 maps each pattern should be. Equivariance moves the patterns; the last layer is not equivariant. The CNN is more robust, but not yet robust enough.

What has the CNN learned? **Figure 35.3** shows the 8 kernels of the first layer, teal for positive weights and red for negative, and the 8 feature maps they produce for a test digit 7. Several kernels look like edge detectors, a band of red weights beside a band of teal ones, facing in different directions. Each feature map lights up where the digit has an edge of its kernel's orientation: some along the bar of the 7, others along its slanted stem.

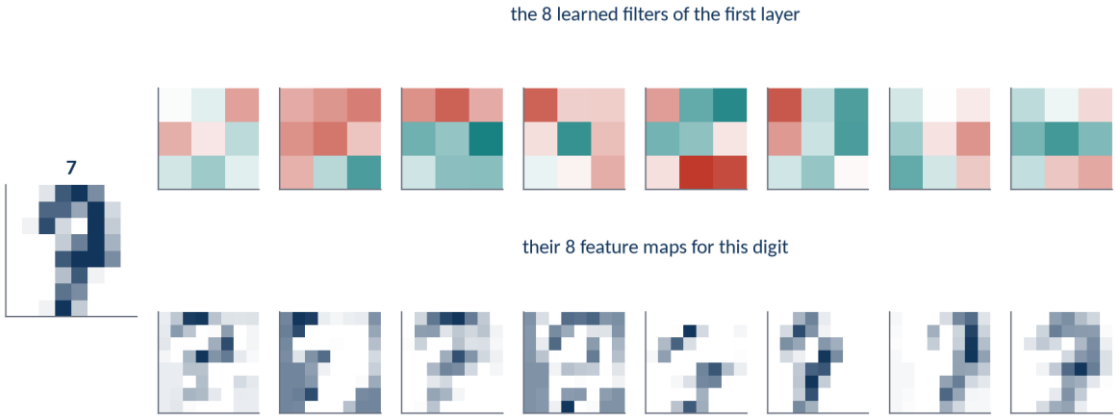

Figure 35.3 Top: the eight 3×3 kernels learned by the first convolution layer (teal positive, red negative). Bottom: the feature maps they produce for the test digit on the left, after ReLU; dark means strong response.

The application makes the shift problem concrete. Test image 5 is a 3; move it one pixel right and one pixel down:

```
python cnn_app.py 5 1 1
```

```
         --%%**
       ..@@++@@
       ..==--##
           %%++..
         ..@@@@@::
               **++
           ::**@@..
test image 5, true digit 3, moved by (1, 1)
  MLP           says 1 (probability 0.872)
  CNN           says 1 (probability 0.831)
  CNN + shifts  says 3 (probability 0.999)
```

The moved 3 has lost its right-most column and its bottom row, and gained an empty top row. The MLP and the plain CNN both read it as 1, confidently. The CNN trained on shifted digits reads it correctly with probability 0.999. How that model was made is the subject of the next section.

The tests pass:

```
python -m unittest
```

```
...
----------------------------------------------------------------------
Ran 3 tests in 0.114s

OK
```

35.6 Improving It: Data Augmentation

If we want a model that does not care about one-pixel moves, the most direct way is to show it moved digits during training. *Data augmentation* creates new training examples by transforming the old ones in ways that do not change the answer: a 3 moved one pixel is still a 3. Each epoch, every training image appears with a fresh random shift, so over 30 epochs the network sees each digit in many positions. Simard, Steinkraus and Platt showed in 2003 that such distortions were among the most effective improvements for handwritten digit recognition [8], and augmentation remains standard practice in image work. **Listing 35.6** trains both networks with and without it.

Listing 35.6 `improve.py`: both networks with and without shifted training images.

```
"""Data augmentation: train on randomly shifted digits (Chapter 35)."""
import torch
from cnn_model import (DigitCNN, DigitMLP, accuracy, load_images,
                       random_shifts, train)

torch.set_num_threads(1)
X_tr, X_te, y_tr, y_te = load_images()
X_moved = random_shifts(X_te, torch.Generator().manual_seed(99))
print(f"{'model':22s} {'test':>6s} {'shifted':>8s}")
for name, cls in [("MLP", DigitMLP), ("CNN", DigitCNN)]:
    for augment in (False, True):
        torch.manual_seed(0)
        model = train(cls(), X_tr, y_tr, epochs=30, augment=augment)
        label = f"{name} {'+ shifted training' if augment else ''}"
        print(f"{label:22s} {accuracy(model, X_te, y_te):6.3f} "
              f"{accuracy(model, X_moved, y_te):8.3f}")
        if name == "CNN" and augment:
            torch.save(model.state_dict(), "cnn_aug.pt")
```

```
python improve.py
```

```
model                    test  shifted
MLP                     0.975    0.389
MLP + shifted training  0.911    0.875
CNN                     0.975    0.539
CNN + shifted training  0.956    0.925
```

Figure 35.4 draws the table. With augmentation, the MLP's accuracy on shifted digits jumps from 38.9% to 87.5%, but its accuracy on ordinary digits drops to 91.1%: with only 32 hidden units and no notion of neighborhood, it must learn every stroke at nine positions, and its capacity is spread thin. The CNN learns the shifted digits much better, 92.5%, and loses much less on ordinary ones, 95.6%. Built-in knowledge (convolutions) and taught knowledge (augmentation) work best together.

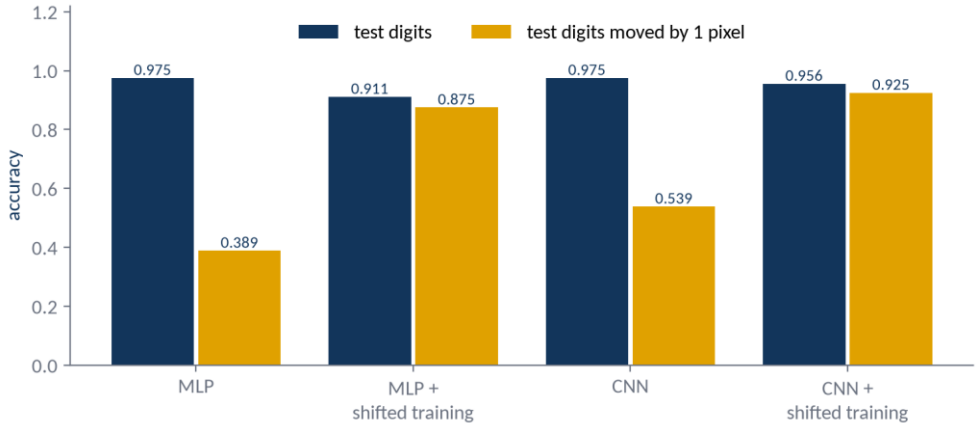

Figure 35.4 Test accuracy on ordinary digits (navy) and on digits moved by up to one pixel (amber) for the four models of **Listing 35.6**.

Exercise 35.5 adds a revealing detail: on digits moved exactly one pixel to the right, the augmented CNN scores 97.5%, as high as the original model does on unmoved digits, while the MLP manages 44.4%.

Other improvements, which later chapters and your own experiments can explore:

- **More augmentation.** Small rotations, scaling, thickening or thinning of strokes, all of which leave the digit's identity unchanged. Chapter 49 builds a whole data augmentation lab.
- **Global average pooling.** Replacing the last linear layer over positions by an average over each whole feature map removes the last position-dependent part of the network.
- **Bigger images, deeper networks.** At 28×28 (MNIST) or real photographs, several convolution blocks and a few million weights are normal, and a graphics card becomes worthwhile. Chapter 50 reuses a trained CNN for a new task.

35.7 Common Mistakes, and How to Avoid Them

Wrong tensor shape. `Conv2d` expects (batch, channels, height, width). A batch of 8×8 grayscale images must be $(N, 1, 8, 8)$, not $(N, 8, 8)$ or $(N, 64)$. The error message mentions "expected input … to have 1 channels"; add the channel dimension with `unsqueeze(1)`.

Losing track of sizes. When you change a kernel size, padding or pooling, the size of the flattened features changes, and the last `nn.Linear` no longer fits. Compute every stage with Equation (35.3), write the shapes in comments as in **Listing 35.2**, or pass a dummy tensor through `features` and print its shape.

Expecting convolutions to give shift invariance for free. Convolutions are equivariant (Equation (35.6)), and pooling adds only a little invariance. As the shifted-digit test shows, a CNN trained on centered images can still fail on moved ones. Test on the variations you care about, and train on them.

Augmenting the test set. Augmentation is for training. The test set must show the model data as it will really arrive; our shifted test set is a separate, deliberate stress test, not an augmented copy used for training.

Transformations that change the answer. Flipping a digit left to right turns a 3 into something that is not a 3, and rotating a 6 by 180 degrees makes a 9. Only use augmentations that keep the label true.

35.8 Chapter Summary

- A convolution moves a small kernel over the image, multiplying and adding at every position (Equation (35.1)); with several channels it sums over all of them (Equation (35.2)).
- Output sizes follow $\lfloor (n + 2p - k)/s \rfloor + 1$ (Equation (35.3)); a layer has $(c_{\text{in}}k^2 + 1)c_{\text{out}}$ parameters regardless of the image size (Equation (35.4)); max pooling keeps the largest value of each block (Equation (35.5)).
- Shared weights make convolutions translation equivariant (Equation (35.6)): moving the input moves the feature maps.
- Our CNN (1,898 parameters) matches the MLP (2,410) on ordinary digits, 97.5%, and is more robust to one-pixel moves, 53.9% against 38.9%.
- Data augmentation with random shifts raises the CNN to 92.5% on shifted digits, and to 97.5% on digits moved one pixel right; the MLP benefits less and loses more on ordinary digits.

35.9 Exercises

1. MNIST images are 28×28. Using Equation (35.3), give the output size after a 5×5 convolution without padding, then a 2×2 max pooling with stride 2, then another 5×5 convolution without padding and another pooling. (This is the layout of LeNet-5.)
2. Verify the parameter counts 80, 1168 and 650 of our network with Equation (35.4). How many parameters would a fully connected layer need to map a $1 \times 8 \times 8$ image to $8 \times 8 \times 8$ outputs?
3. Compute by hand the convolution of the 4×4 image with rows (0,0,0,0), (0,0,0,0), (5,5,5,5), (5,5,5,5) with the kernel whose rows are $(-1, -1, -1)$, (0,0,0), (1,1,1), without padding. What does this kernel detect?
4. Check Equation (35.6) on the trained CNN: pass a test image and its one-pixel shift through the first convolution layer and compare the shifted feature maps with the feature maps of the shifted image, away from the borders.
5. Using the three saved models, measure the test accuracy when every digit is moved exactly 0, 1 and 2 pixels to the right. Explain the pattern, especially the augmented CNN's result for a move of 1.
6. Explain why max pooling makes a model slightly insensitive to small moves, using Equation (35.5) and a 2×2 block in which the largest value moves from one corner to another.

35.10 Solutions to the Exercises

Solution 1. Convolution: $\lfloor (28-5)/1 \rfloor + 1 = 24$. Pooling: $\lfloor (24-2)/2 \rfloor + 1 = 12$. Convolution: $\lfloor (12-5)/1 \rfloor + 1 = 8$. Pooling: $\lfloor (8-2)/2 \rfloor + 1 = 4$. The final maps are 4×4, and with 16 of them LeNet-5's classifier reads $16 \cdot 4 \cdot 4 = 256$ numbers [3].

Solution 2. First layer: $(1 \cdot 3^2 + 1) \cdot 8 = 10 \cdot 8 = 80$. Second: $(8 \cdot 9 + 1) \cdot 16 = 73 \cdot 16 = 1168$. Linear: $64 \cdot 10 + 10 = 650$. The unit test in **Listing 35.5** checks the total, 1898. A fully connected layer from 64 inputs to $8 \cdot 8 \cdot 8 = 512$ outputs would need $64 \cdot 512 + 512 = 33{,}280$ parameters, 416 times as many as the first convolution layer, for the same output shape.

Solution 3. By Equation (35.3) the output is 2×2. In output row 0 the window covers image rows 0 to 2, which hold (0,0,0), (0,0,0) and (5,5,5) under the kernel; the sum is $-1 \cdot (0+0+0) + 0 \cdot (0+0+0) + 1 \cdot (5+5+5) = 15$, at both column positions. In output row 1 the window covers image rows 1 to 3, holding (0,0,0), (5,5,5) and (5,5,5); the sum is $-1 \cdot 0 + 0 \cdot 15 + 1 \cdot 15 = 15$. The output is 15 everywhere. The kernel is the vertical-edge kernel of **Figure 35.1** turned on its side: it detects *horizontal* edges where the image becomes darker going down, like the top of the bar of a 7.

Solution 4. **Listing 35.7** compares the two orders of operations inside the image.

Listing 35.7 `sol_equivariance.py`: checking translation equivariance on the first layer.

```
"""Exercise 35.4: shifting the input shifts the feature maps (Chapter 35)."""
import torch
from cnn_model import DigitCNN, load_images, shift

model = DigitCNN()
model.load_state_dict(torch.load("cnn.pt", weights_only=True))
conv1 = model.features[0]                       # the first convolution layer
_, X_te, _, _ = load_images()
image = X_te[:1]
with torch.no_grad():
    maps_of_moved = conv1(shift(image, 1, 0))   # move first, then convolve
    moved_maps = shift(conv1(image), 1, 0)      # convolve first, then move
inside = (slice(None), slice(None), slice(1, 7), slice(2, 7))   # away from edges
diff = (maps_of_moved - moved_maps)[inside].abs().max().item()
print(f"feature maps: {tuple(maps_of_moved.shape)}")
print(f"largest difference away from the borders: {diff:.2e}")
```

```
feature maps: (1, 8, 8, 8)
largest difference away from the borders: 0.00e+00
```

Away from the borders the two results are identical: every multiplication and addition of Equation (35.1) happens in the same order, only at a different position. At the borders they differ, because shifting first drops a column of pixels and adds a column of zeros, which the padding then sees differently; that is why the check skips the outermost columns and rows.

Solution 5. **Listing 35.8** moves every test digit right by 0, 1 or 2 pixels.

Listing 35.8 `sol_shift_sizes.py`: accuracy for moves of 0, 1 and 2 pixels.

```
"""Exercise 35.5: accuracy of the saved models as the digits move further."""
import torch
from cnn_model import DigitCNN, DigitMLP, accuracy, load_images, shift

models = {"MLP": DigitMLP(), "CNN": DigitCNN(), "CNN + shifts": DigitCNN()}
for (name, model), file in zip(models.items(), ["mlp.pt", "cnn.pt", "cnn_aug.pt"]):
    model.load_state_dict(torch.load(file, weights_only=True))
_, X_te, _, y_te = load_images()
print(f"{'move':>6s} " + " ".join(f"{n:>13s}" for n in models))
for d in (0, 1, 2):
    row = [accuracy(m, shift(X_te, d, 0), y_te) for m in models.values()]
    print(f"right {d} " + " ".join(f"{a:13.3f}" for a in row))
```

```
  move           MLP           CNN  CNN + shifts
right 0         0.975         0.975         0.956
right 1         0.444         0.631         0.975
right 2         0.067         0.425         0.664
```

All three models do well on unmoved digits. For a move of one pixel, the MLP falls to 44.4%, the plain CNN holds 63.1%, and the augmented CNN scores 97.5%, even higher than on unmoved digits (95.6%): during training it saw moves of -1, 0 and $+1$ equally often, so one pixel to the right is as familiar as the center. For two pixels, a move it never saw, the augmented CNN still reaches 66.4%, while the others collapse (6.7% and 42.5%). Models are robust to the variations they are built for or trained on, and much less to others.

Solution 6. In a 2×2 block, the pooled value is the maximum of four numbers, whichever of the four positions holds it. If a strong edge response moves from the top-left to the bottom-right cell of the same block, because the stroke moved by one pixel, the maximum is unchanged, and so is every later layer's input. Only moves that carry the response into a *neighboring* block change the pooled map. So pooling gives invariance to small moves within blocks, on average about half of all one-pixel moves, which is some but not all of what we need.

Chapter 36

Next-Word Prediction for a Phone Keyboard

You type “tolong belikan” and the phone offers *sayur*, *deterjen*, *obat*; you type “ob” and it offers *obat* alone. That strip of three words above the keyboard is one of the most used pieces of AI in the world, and it runs on the phone itself, within a few milliseconds of every key. This chapter builds one for a single person’s Indonesian messages, twice: once by counting word triples, and once with a recurrent neural network that reads the text one character at a time. By the end of it you will be able to explain how a recurrent network carries a memory of what it has read in a hidden state; why plain recurrent networks forget and how a GRU fixes it; train a character-level GRU language model in PyTorch; turn its character probabilities into word suggestions that respect what has already been typed; measure a keyboard by top-k accuracy and by keystrokes saved; and judge a model the way a phone must, by its latency and its size as well as its accuracy.

36.1 Who Uses Next-Word Prediction Today

Everyone with a smartphone. Google’s Gboard runs more than 30 on-device language models, in more than seven languages and more than 15 countries, and uses them for next-word prediction, Smart Compose, completion, glide typing and proofreading [1]. The models run on the phone, not in the cloud, for two reasons that shape this whole chapter. The first is speed: people expect the keyboard to respond within about 20 milliseconds of a key press [2]. The second is privacy: what people type is among the most personal data there is, so the model should learn and predict without sending keystrokes to a server. Gboard’s production next-word model of 2018 was a recurrent network with 1.4 million weights, stored in 1.4 megabytes, and it predicted the next word correctly as its first suggestion 16.4% of the time, against 13.0% for the n-gram model it replaced [2].

What does it save? Every correct suggestion replaces the letters of a word, and its space, by a single tap. On a phone, where typing is slow and error-prone, that adds up to a large share of all key presses, and for people who type with difficulty, with one finger, a pointer or an eye tracker, word prediction can be the difference between writing a message and giving up. The measure that captures this is the share of keystrokes saved, and Section 36.6 finds that on the messages of this chapter, suggestions save about three keystrokes in four.

Chapter 27 predicted a whole reply from a list; here we predict the next word of free text. We will build the counting baseline first, the same kind of n-gram model as Chapter 27, and then ask whether a neural network does better, at what cost in speed and memory, and what a phone would actually ship.

36.2 The Idea in Plain Words

An n-gram keyboard remembers, for every pair of words, which words followed it: after “tolong belikan” came *sayur* 40 times, *deterjen* 30 times, and so on. It is fast and small, but it sees only two words back, and it knows nothing about a pair of words it has never seen.

A **recurrent neural network** (RNN) reads the text one character at a time, like a person reading along a line with a finger, and keeps a small list of numbers, its **hidden state**, as a running summary of everything so far. At each character it mixes the new character into the summary, and from the summary it guesses the next character. **Figure 36.1** shows it reading "aku o". The same weights are used at every step; that is what "recurrent" means. Nothing forces the summary to forget "aku" after two words, and because the network works with letters, it can make sense of a word it has never seen, such as *ketinggalannya*, from its pieces.

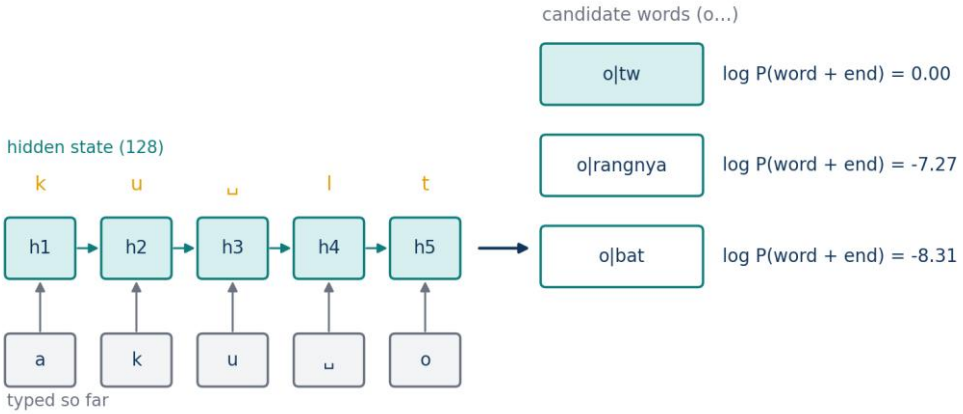

Figure 36.1 The trained character GRU reading "aku o": each character updates the hidden state $\mathbf{h}_t$ of 128 numbers, whose most probable next character is shown in amber. To suggest words, every lexicon word that begins with the typed prefix "o" is scored by the log-probability of its remaining characters followed by an end character.

A keyboard needs *words*, not characters. So we keep a **lexicon**, the words the person has typed before, and score each candidate word by the probability the network gives to its remaining letters followed by a space or punctuation mark. If the person has already typed "o", only words beginning with "o" are candidates. The three best candidates are the suggestions.

36.3 The Mathematics, Gently

36.3.1 Characters as vectors

The network cannot compute with letters, so each character c of the vocabulary of V characters is given its own vector of E numbers, $\mathbf{e}(c)$, stored as one row of an **embedding** table. At first the rows are random; training moves them so that characters that behave alike get similar vectors. Our vocabulary has $V = 41$ characters (letters, digits, space, punctuation and the line break that ends a message) and $E = 32$.

36.3.2 The recurrence

Let $\mathbf{x}_t = \mathbf{e}(c_t)$ be the vector of the character read at step t and $\mathbf{h}_{t-1}$ the hidden state before it, a vector of $H = 128$ numbers that starts at zero. A plain RNN computes the new state and a score for every possible next character:

$$\mathbf{h}_t = \tanh(W_x \mathbf{x}_t + W_h \mathbf{h}_{t-1} + \mathbf{b}), \qquad \mathbf{o}_t = W_o \mathbf{h}_t + \mathbf{b}_o \tag{36.1}$$

W_x $(H \times E)$, W_h $(H \times H)$ and W_o $(V \times H)$ are weight matrices, the $\mathbf{b}$s are bias vectors, and tanh squeezes each number into $(-1,1)$. The **softmax** turns the V scores into probabilities for the next character:

$$P(c_{t+1} = k \mid c_1, \ldots, c_t) = \frac{e^{o_{t,k}}}{\sum_{j=1}^{V} e^{o_{t,j}}} \tag{36.2}$$

36.3.3 Why plain RNNs forget, and the GRU

Training adjusts the weights by gradient descent, and the gradient of a prediction at step t with respect to a state k steps earlier is, by the chain rule, a product of k factors, one per step:

$$\frac{\partial \mathbf{h}_t}{\partial \mathbf{h}_{t-k}} = \prod_{s=t-k+1}^{t} \operatorname{diag}\left(1 - \mathbf{h}_s^2\right) W_h \tag{36.3}$$

Each factor usually shrinks vectors (the tanh slope $1 - h^2$ is at most one), so after a few dozen characters the product is nearly zero: the network cannot learn that a character long ago mattered. This is the **vanishing gradient** problem. The **gated recurrent unit** (GRU) of Cho et al. [3] adds two gates, numbers between 0 and 1 computed by the sigmoid σ, that decide how much of the old state to keep:

$$\begin{aligned} \mathbf{z}_t &= \sigma(W_z \mathbf{x}_t + U_z \mathbf{h}_{t-1} + \mathbf{b}_z), \qquad \mathbf{r}_t = \sigma(W_r \mathbf{x}_t + U_r \mathbf{h}_{t-1} + \mathbf{b}_r) \\ \tilde{\mathbf{h}}_t &= \tanh(W_h \mathbf{x}_t + U_h(\mathbf{r}_t \odot \mathbf{h}_{t-1}) + \mathbf{b}_h), \qquad \mathbf{h}_t = (1 - \mathbf{z}_t) \odot \tilde{\mathbf{h}}_t + \mathbf{z}_t \odot \mathbf{h}_{t-} \end{aligned} \tag{36.4}$$

Here $\odot$ multiplies two vectors number by number. When the update gate $\mathbf{z}_t$ is close to 1, the state is copied almost unchanged, $\mathbf{h}_t \approx \mathbf{h}_{t-1}$, and so is the gradient: information can travel many steps without fading. The reset gate $\mathbf{r}_t$ lets the network ignore the old state when a new word starts. Gboard's model used a close relative, the LSTM with coupled gates [2].

36.3.4 Training by predicting the next character

We train on the person's messages joined into one long text, each message ending with a line break. At every position the network predicts the next character, and the loss is the average negative log-probability of the character that really came, the **cross-entropy**:

$$L = -\frac{1}{N} \sum_{t=1}^{N} \ln P(c_{t+1} \mid c_1, \ldots, c_t) \tag{36.5}$$

A network that knows nothing gives every character probability $1/V$ and has loss $\ln 41 \approx 3.71$; a loss of 0.18 means that the right next character gets, on average, probability $e^{-0.18} \approx 0.84$ in the geometric mean. PyTorch computes the gradient of Equation (36.5) through all steps of a window automatically; this is called **backpropagation through time**.

36.3.5 From characters to a word

Suppose the text typed so far is s, ending in a partial word p (possibly empty), and $w = p\,a_1 a_2 \ldots a_m$ is a lexicon word that begins with p. After reading s, the network gives the probability that the next characters are exactly $a_1, \ldots, a_m$ followed by an end character (space, comma, full stop, question mark, exclamation mark or line break), by the chain rule:

$$\log P(w \mid s) = \sum_{i=1}^{m} \log P(a_i \mid s\, a_1 \cdots a_{i-1}) + \log \sum_{e \in \mathrm{END}} P\,(e \mid s\, a_1 \cdots a_m) \tag{36.6}$$

Without the end term, "ob" would score *obat* no higher than every longer word that starts with *obat*. Different words are different futures of the same text, so their probabilities can never add up to more than one; a test in Section 36.4.6 checks this.

36.3.6 The n-gram keyboard

The baseline predicts word w from the two words u, v before it with the interpolated trigram estimate of Chapter 27:

$$P(w \mid u, v) = \lambda_3 \frac{c(u,v,w)}{c(u,v)} + \lambda_2 \frac{c(v,w)}{c(v)} + \lambda_1 \frac{c(w)+1}{N + |L|} \tag{36.7}$$

where the c are counts in the training messages, N is the number of training words, $|L|$ the size of the lexicon, and a term is left out when its context was never seen. At the start of a message, u and v are start symbols.

36.3.7 Temperature

To let the network write a continuation instead of scoring given words, we draw characters one at a time. A **temperature** τ reshapes the softmax of Equation (36.2) before drawing:

$$P_\tau(c_{t+1} = k) = \frac{e^{o_{t,k}/\tau}}{\sum_j e^{o_{t,j}/\tau}} \tag{36.8}$$

With $\tau < 1$ the likely characters become likelier and the text safer and more repetitive; with $\tau > 1$ the distribution flattens and the text becomes more varied and more error-prone; $\tau = 1$ is the model's own distribution.

36.3.8 Measuring a keyboard

Two measures matter. **Top-k accuracy** is the share of word positions at which the word the person really typed next is among the k suggestions shown before they type any letter of it. **Keystroke savings** simulates the person typing each test message: before each letter of a word, if the word is among the three suggestions, the person taps it (one key press, which also inserts the space); otherwise they type the next letter. With K the key presses needed this way and C the number of characters of the messages,

$$\text{keystrokes saved} = 1 - \frac{K}{C} \tag{36.9}$$

Top-1 is the number the Gboard paper reports [2]; keystroke savings is what the person feels.

36.4 Building It Step by Step

The programs are in `Chapter036/`. They need PyTorch (the CPU version is enough), and every program calls `torch.set_num_threads(1)` so that its numbers, apart from timings, are exactly those printed here.

36.4.1 One person's messages

A keyboard learns from its owner. Our owner is Bu Wulan, who runs a laundry in Surabaya and, like everyone, writes to her family, her staff, her friends and her customers. We wrote 37 kinds of her messages as templates with slots, in `data/templates.json`, each with a weight for how often she sends it:

```
[6, "{hon} nanti aku pulang {time}"],
[6, "tolong belikan {buy} ya"],
[4, "maaf baru balas, tadi lagi {activity}"],
[3, "stok deterjen tinggal {n} bungkus, tolong pesan lagi"],
```

The slot `{buy}` is filled with an item *and the shop where it is sold* ("obat batuk di apotek", "telur di warung"), so the word after "di" depends on a word further back. **Listing 36.1** draws 6,000 messages and, a quarter of the time, uses the short forms people type (*udah*, *gak*, *tlg*, *blm*).

Listing 36.1 `make_corpus.py`: one person's messages, drawn from templates.

```
"""make_corpus.py - write one person's chat messages from data/templates.json."""
import json
import random

SHORT = {"sudah": "udah", "tidak": "gak", "terima kasih": "makasih",
         "sebentar": "bentar", "tolong": "tlg", "belum": "blm"}

def fill(rng, template, slots):
    values = {k: rng.choice(v) for k, v in slots.items() if k != "buy"}
    item, shop = rng.choice(slots["buy"])        # an item and where it is sold
    values["buy"] = f"{item} di {shop}"
    return template.format(**values)

def main(n=6000, seed=36):
    spec = json.load(open("data/templates.json", encoding="utf-8"))
    rng = random.Random(seed)
    weights = [w for w, _ in spec["templates"]]
    texts = [t for _, t in spec["templates"]]
    lines = []
    for _ in range(n):
        line = fill(rng, rng.choices(texts, weights)[0], spec["slots"])
        for long, short in SHORT.items():        # the way people really type
            if long in line and rng.random() < 0.25:
                line = line.replace(long, short)
        lines.append(line)
    with open("data/messages.txt", "w", encoding="utf-8") as f:
        f.write("\n".join(lines) + "\n")
    words = sum(len(s.split()) for s in lines)
    print(f"wrote data/messages.txt: {len(lines)} messages, {words} words, "
          f"{sum(map(len, lines))} characters")

if __name__ == "__main__":
    main()
```

```
python make_corpus.py
```

```
wrote data/messages.txt: 6000 messages, 39971 words, 213504 characters
```

Like real messages, many are repeated word for word ("oke siap, nanti aku kabari lagi"): the 6,000 messages contain only 870 different ones. A personal keyboard sees exactly this, and it is one reason why keyboards work so well.

36.4.2 The data split and the n-gram keyboard

Listing 36.2 holds the shared helpers and the baseline.

Listing 36.2 `ngram_kb.py`: splitting the messages, separating the typed text into context and partial word, and the trigram keyboard.

```
"""ngram_kb.py - the data, and a word trigram keyboard to compare against."""
import math
import random
import re
from collections import Counter, defaultdict

BOS = "<s>"

def words(text):
    """The words of a message: letters, digits and hyphens, lowercase."""
    return re.findall(r"[a-z0-9-]+", text.lower())

def load_split(path="data/messages.txt", seed=36):
    """80% training, 10% development, 10% test messages."""
    lines = open(path, encoding="utf-8").read().split("\n")
    lines = [s for s in lines if s]
    random.Random(seed).shuffle(lines)
    a, b = int(0.8 * len(lines)), int(0.9 * len(lines))
    return lines[:a], lines[a:b], lines[b:]

def split_typed(typed):
    """'tolong belikan ob' -> (['tolong', 'belikan'], 'ob')."""
    ws = words(typed)
    if typed and typed[-1].isalnum() and ws:
        return ws[:-1], ws[-1]
    return ws, ""

class NgramKeyboard:
    """P(w | u, v) = l3 P_ML(w | u, v) + l2 P_ML(w | v) + l1 P_add1(w)."""

    def __init__(self, lambdas=(0.6, 0.3, 0.1)):
        self.l3, self.l2, self.l1 = lambdas
```

Listing 36.2 (Continued) *ngram_kb.py: splitting the messages, separating the typed text into context and partial word, and the trigram keyboard.*

```
    def fit(self, messages):
        self.tri = defaultdict(Counter)            # tri[(u, v)][w]
        self.bi = defaultdict(Counter)             # bi[v][w]
        self.uni = Counter()
        for m in messages:
            ws = [BOS, BOS] + words(m)
            for u, v, w in zip(ws, ws[1:], ws[2:]):
                self.tri[(u, v)][w] += 1
                self.bi[v][w] += 1
                self.uni[w] += 1
        self.n = sum(self.uni.values())
        self.lexicon = sorted(self.uni)
        return self

    def prob(self, u, v, w):
        p = self.l1 * (self.uni[w] + 1) / (self.n + len(self.lexicon))
        c2 = self.bi.get(v)
        if c2:
            p += self.l2 * c2[w] / sum(c2.values())
        c3 = self.tri.get((u, v))
        if c3:
            p += self.l3 * c3[w] / sum(c3.values())
        return p

    def scores(self, typed):
        """Every lexicon word that starts with what is being typed, and its
        log-probability given the two words before it."""
        context, prefix = split_typed(typed)
        u, v = ([BOS, BOS] + context)[-2:]
        cands = [w for w in self.lexicon if w.startswith(prefix)]
        return cands, [math.log(self.prob(u, v, w)) for w in cands]

    def suggest(self, typed, k=3):
        """The k most probable words that start with what is being typed."""
        cands, logp = self.scores(typed)
        order = sorted(range(len(cands)), key=lambda i: (-logp[i], cands[i]))
        return [cands[i] for i in order[:k]]

    def entries(self):
        """How many numbers the model stores: one count per n-gram."""
        return (len(self.uni) + sum(map(len, self.bi.values()))
                + sum(map(len, self.tri.values())))
```

- `load_split` shuffles the messages once and cuts 80% for training, 10% for development and 10% for testing.
- `split_typed` separates what has been typed into the finished words and the word being typed: “tolong belikan ob” becomes `["tolong", "belikan"]` and `"ob"`; “tolong” (ending in a space) has an empty partial word.
- `NgramKeyboard.fit` counts every triple, pair and single word; `prob` is Equation (36.7). `scores` returns every lexicon word that starts with the partial word, with its log-probability, and `suggest` keeps the best k. `entries` counts the numbers the model stores, for the size comparison.

36.4.3 The character GRU and its keyboard

Listing 36.3 is the neural model.

```

- `CharGRU` is Equation (36.4) with the embedding of Section 36.3.1 in front and the output layer of Equation (36.1) behind: `nn.GRU` implements the gates, and `head` turns each hidden state into 41 character scores. `encode` maps an unknown character to a space.
- `batches` cuts 32 random windows of 65 characters from the training text: the first 64 are the input, and the same window shifted by one is the target, so every position is a training example of Equation (36.5).
- `train` runs Adam with a learning rate of 0.004, clips gradients to length 1 (a standard guard against the opposite of vanishing, exploding gradients), and every 250 steps measures the loss on the development text with `loss_on`, keeping the weights of the best measurement. This is **early stopping**.
- `CharKeyboard.scores` is Equation (36.6), vectorized. It reads the typed text once, prefixed by a line break so that the network knows a message has started, and takes the probabilities `first` of the next character. Then it runs the network on all candidate words at once, as one batch that starts from the same hidden state, and adds up the log-probabilities of each word's own characters; `mask` ignores the padding of shorter words, and `end` adds the log-probability of any end character after the word.

36.4.4 Training

Listing 36.4 trains the network for 2,000 steps and saves it.

Listing 36.4 `train_rnn.py`: training the character GRU and saving it with its vocabulary.

```
"""train_rnn.py - train the character GRU on the messages; write char_gru.pt."""
import json
import time

import torch

from charlm import train
from ngram_kb import load_split

step  2000  train loss 0.246  dev loss 0.183
68809 parameters, 41 characters, trained in 63 s
```

Training took about a minute on one CPU thread; the loss per character fell from $\ln 41 \approx 3.71$ at the start to 0.18 on the development messages. **Figure 36.2** shows the development loss flattening after about 1,000 steps. The printed training loss is measured on one random batch and is noisier; it is also higher, because the first characters of a random window are predicted with no context at all, whereas `loss_on` reads the development text in order.

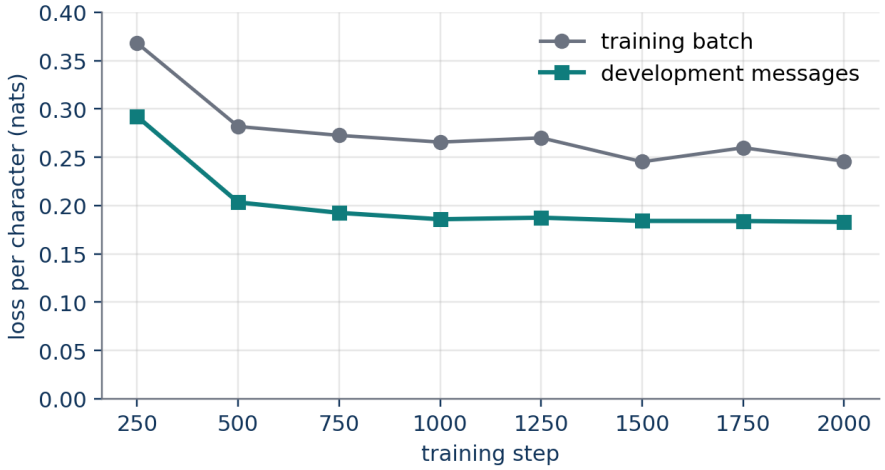

Figure 36.2 Loss per character during training: one random training batch every 250 steps, and the whole development text. The weights with the lowest development loss are kept.

The network has 68,809 weights: $41 \times 32 = 1{,}312$ in the embedding, $3 \times (32 \times 128 + 128 \times 128 + 2 \times 128) = 62{,}208$ in the GRU (three sets of weights, for $\mathbf{z}$, $\mathbf{r}$ and $\tilde{\mathbf{h}}$) and $128 \times 41 + 41 = 5{,}289$ in the output layer.

36.4.5 The application

Listing 36.5 shows what each keyboard suggests for a piece of typed text. With `--words` it keeps tapping the first suggestion, as bored phone users sometimes do, and with `--temperature` it lets the network write three endings by drawing characters with Equation (36.8).

Listing 36.5 `keyboard.py`: suggestions from the three keyboards, greedy phrase completion, and sampling with a temperature.

```
"""keyboard.py - word suggestions for a message being typed, and phrases."""
import argparse

import torch

from charlm import lexicon_of
from evaluate import load_rnn
from mixed import MixedKeyboard
from ngram_kb import NgramKeyboard, load_split, split_typed

torch.set_num_threads(1)

@torch.no_grad()
def sample(model, typed, gen, temperature=1.0, max_chars=40):
    """Continue the text one character at a time, drawn with a temperature."""
    scores, h = model(torch.tensor([model.encode("\n" + typed)]))
    out = ""
    for _ in range(max_chars):
        p = (scores[0, -1] / temperature).softmax(-1)
        c = model.vocab[torch.multinomial(p, 1, generator=gen).item()]
        if c == "\n":
            break
        out += c
        scores, h = model(torch.tensor([[model.index[c]]]), h)
    return out

def main():
    ap = argparse.ArgumentParser(description=__doc__)
    ap.add_argument("text", help="what has been typed so far")
    ap.add_argument("--words", type=int, default=0,
                    help="complete this many words by always taking the first")
    ap.add_argument("--temperature", type=float, default=0.0,
                    help="also draw three endings at this temperature")
    args = ap.parse_args()
    train, _, _ = load_split()
    ngram = NgramKeyboard((0.8, 0.15, 0.05)).fit(train)
    rnn = load_rnn(lexicon_of(train))
    both = MixedKeyboard(ngram, rnn, 0.7)
    for name, kb in (("trigram", ngram), ("char GRU", rnn), ("mixed", both)):
        print(f"{name:<9} {kb.suggest(args.text)}")
    text = args.text
    for _ in range(args.words):
        best = both.suggest(text, k=1)
        if not best:
```

Listing 36.5 (Continued) *keyboard.py: suggestions from the three keyboards, greedy phrase completion, and sampling with a temperature.*

```
            break
        _, prefix = split_typed(text)
        text = text[:len(text) - len(prefix)] + best[0] + " "
    if args.words:
        print(f"tapping the first suggestion {args.words} times: {text!r}")
    if args.temperature:
        gen = torch.Generator().manual_seed(36)
        for _ in range(3):
            ending = sample(rnn.m, args.text, gen, args.temperature)
            print(f"T={args.temperature}: {args.text}{ending}")

if __name__ == "__main__":
    main()
```

It uses `MixedKeyboard` from Section 36.7, which combines the two models.

36.4.6 Tests

Listing 36.6 checks the pieces that are easy to get subtly wrong: that the trigram probabilities add up to one over the lexicon, that an untrained network is close to the uniform loss $\ln V$, that the word probabilities of Equation (36.6) never add up to more than one, that mixing gives a distribution, and that the keystroke counter charges exactly one tap per word to a keyboard that always knows the answer.

Listing 36.6 `tests/test_keyboard.py`: unit tests for both keyboards, the mixture and the keystroke counter.

```
"""Run with:  python -m unittest discover -s tests"""

```

36.5 Running It

```
python keyboard.py "tolong belikan "
```

```
trigram   ['sayur', 'deterjen', 'hanger']
char GRU  ['sayur', 'deterjen', 'plester']
mixed     ['sayur', 'deterjen', 'hanger']
```

All the answers are things Bu Wulan asks for. The models agree on the first two and differ on the third, because in her messages fourteen items are about equally common after “tolong belikan”. One letter settles it:

```
python keyboard.py "tolong belikan ob"
```

```
trigram   ['obat']
char GRU  ['obat']
mixed     ['obat']
```

Now the word that depends on something further back:

```
python keyboard.py "tolong belikan obat batuk di "
```

```
trigram   ['apotek', 'jalan', 'rumah']
char GRU  ['apotek', 'rumah', 'warung']
mixed     ['apotek', 'jalan', 'rumah']
```

Both models know that cough medicine is bought at the pharmacy (*apotek*). For the trigram, the two words “batuk di” happen to be enough; the GRU, which reads characters, has to carry *obat batuk* across the space and the word *di* in its hidden state. Tapping the first suggestion again and again:

```
python keyboard.py "hari ini" --words 6
```

```
trigram   ['ini']
char GRU  ['ini']
mixed     ['ini']
tapping the first suggestion 6 times: 'hari ini ada 10 kilo cucian masuk '
```

and letting the network write, at a low and a high temperature:

```
python keyboard.py "nanti sore" --temperature 0.5
python keyboard.py "nanti sore" --temperature 1.5
```

```
trigram   ['sore']
char GRU  ['sore']
mixed     ['sore']
T=0.5: nanti sore jadi ketemu di taman bungkul?
T=0.5: nanti sore jadi ketemu di taman bungkul?
T=0.5: nanti sore jadi ketemu di warung pojok?
trigram   ['sore']
char GRU  ['sore']
mixed     ['sore']
T=1.5: nanti sore jadi ketemu di taman buntum ya
T=1.5: nanti sore jadi ketemu kakir gitu
T=1.5: nanti sore jadi ketemu di warung potw ya, tunggu s
```

At $\tau = 0.5$ the endings are safe, fluent and similar; at $\tau = 1.5$ the network takes risks, and some of its words are no longer words. Chapter 39 uses the same knob to generate text with a Transformer.

36.6 Measuring It

Listing 36.7 measures both keyboards on test messages they never saw: top-1 and top-3 accuracy over every word of the first 300 test messages, keystroke savings on the first 100, the average time per suggestion, and the size. The trigram's weights λ are chosen on the development messages first.

Listing 36.7 `evaluate.py`: accuracy, keystroke savings, latency and size of the trigram and the character GRU.

```python
"""evaluate.py - n-gram versus GRU keyboard: accuracy, keystrokes, speed, size."""
import re
import time

import torch

from charlm import CharGRU, CharKeyboard, lexicon_of
from ngram_kb import NgramKeyboard, load_split, words

torch.set_num_threads(1)
GRID = [(0.6, 0.3, 0.1), (0.8, 0.15, 0.05), (0.4, 0.4, 0.2), (0.2, 0.5, 0.3)]

def load_rnn(lexicon, path="char_gru.pt"):
    saved = torch.load(path)
    model = CharGRU(saved["vocab"])
    model.load_state_dict(saved["state"])
    return CharKeyboard(model, lexicon)

def next_word(kb, messages):
    """Top-1 and top-3 accuracy of the next word, before any letter is typed."""
    hit1 = hit3 = total = 0
    for m in messages:
        ws = words(m)
        for i, w in enumerate(ws):
            top = kb.suggest(" ".join(ws[:i]) + (" " if i else ""))
            hit1 += top[:1] == [w]
            hit3 += w in top
            total += 1
    return hit1 / total, hit3 / total

def keystrokes(kb, message):
    """Keys pressed when a tap on a suggestion (word + space) replaces typing."""
    keys, typed = 0, ""
    for word, tail in re.findall(r"([a-z0-9-]+)([^a-z0-9-]*)", message):
        for j in range(len(word) + 1):
            if word in kb.suggest(typed + word[:j]):
                keys += 1 + len(tail.strip())        # one tap, then punctuation
                break
            if j < len(word):
                keys += 1
        else:
            keys += len(tail)                        # typed in full, plus space
        typed += word + tail
```

Listing 36.7 (Continued) *evaluate.py: accuracy, keystroke savings, latency and size of the trigram and the character GRU.*

```
    return keys

def main():
    tr, dv, te = load_split()
    lam = max(GRID, key=lambda g: next_word(NgramKeyboard(g).fit(tr), dv)[1])
    models = {"trigram": NgramKeyboard(lam).fit(tr),
              "char GRU": load_rnn(lexicon_of(tr))}
    print(f"trigram weights chosen on development data: {lam}")
    print(f"{'model':<10}{'top-1':>7}{'top-3':>7}{'keys saved':>12}"
          f"{'ms/suggestion':>15}")
    for name, kb in models.items():
        top1, top3 = next_word(kb, te[:300])        # 300 test messages
        sample = te[:100]
        keys = sum(keystrokes(kb, m) for m in sample)
        saved = 1 - keys / sum(map(len, sample))
        start = time.perf_counter()
        for m in te[:100]:
            kb.suggest(" ".join(words(m)[:2]) + " ")
        ms = (time.perf_counter() - start) * 10
        print(f"{name:<10}{top1:>7.3f}{top3:>7.3f}{saved:>12.1%}{ms:>15.2f}")
    ng, rnn = models["trigram"], models["char GRU"].m
    n_rnn = sum(p.numel() for p in rnn.parameters())
    print(f"trigram: {ng.entries()} stored counts; "
          f"char GRU: {n_rnn} weights = {4 * n_rnn / 1024:.0f} KB as float32")

if __name__ == "__main__":
    main()
```

```
python evaluate.py
```

```
trigram weights chosen on development data: (0.8, 0.15, 0.05)
model       top-1  top-3  keys saved  ms/suggestion
trigram     0.658  0.802       75.7%           0.27
char GRU    0.597  0.726       75.9%          10.21
trigram: 1979 stored counts; char GRU: 68809 weights = 269 KB as float32
```

The result is not the one the neural network's reputation would suggest.

- **Accuracy.** The trigram is right with its first suggestion 65.8% of the time and within three suggestions 80.2%; the GRU reaches 59.7% and 72.6%. Both are far above Gboard's 16% top-1 [2], because one person's messages are much more predictable than everybody's. But the counting model wins.
- **Keystrokes.** Both save about 76% of the key presses. Once the first letter or two has been typed, both keyboards nearly always offer the right word, so their differences at the very start of a word matter little to the person typing.
- **Speed.** The trigram answers in about a quarter of a millisecond, the GRU in about 10 milliseconds: it must read the whole typed text and then run a batch of hundreds of candidate words through the network. That is inside the 20-millisecond budget of [2] on a laptop, but a phone's processor is slower, and the budget covers much more than the language model.
- **Size.** The trigram stores 1,979 counts, the GRU 68,809 weights, 269 KB as 32-bit numbers.

Why does the network lose? Because of the data, not the architecture. Our 4,800 training messages contain about 32,000 words, and most of what is predictable in them is predictable from the last two words, which a trigram memorizes perfectly. A neural network earns its keep when there is far more text than any table can store and when useful context lies further back than two words; Gboard trained on the typing of millions of phones [2]. With little data, the

honest verdict is that the model is limited by the data. **Figure 36.3** places the keyboards, including the mixture of the next section, on the two axes a phone cares about.

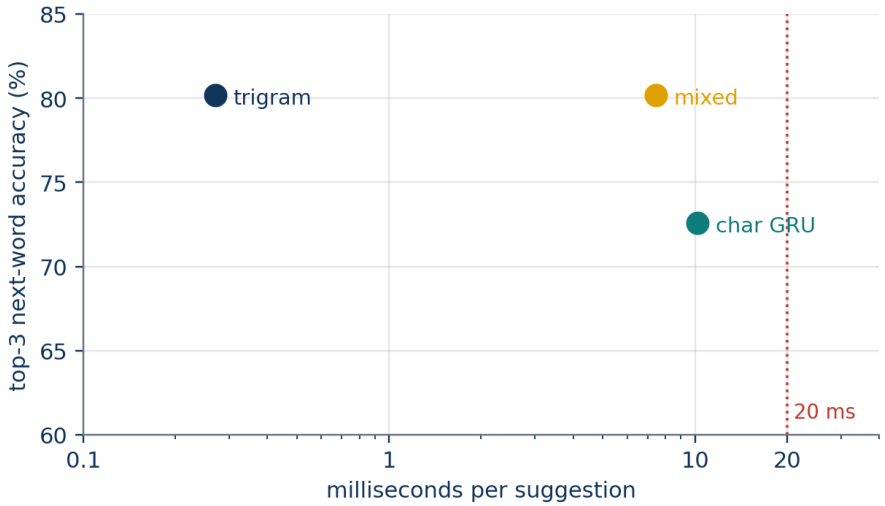

Figure 36.3 Top-3 next-word accuracy against the time per suggestion on a laptop CPU (logarithmic axis) for the three keyboards; the dotted line marks the 20 ms response time users expect.

36.7 Improving It

36.7.1 Two models are better than one

The two models make different mistakes: the trigram knows exact phrases, the GRU knows spelling and longer context. **Listing 36.8** turns each model's scores for the candidate words into probabilities with a softmax and mixes them, $P = \alpha P_{\text{trigram}} + (1 - \alpha) P_{\text{GRU}}$.

Listing 36.8 `mixed.py`: mixing the probabilities of the two keyboards.

```
"""mixed.py - a keyboard that mixes the trigram's and the GRU's probabilities."""
import math

def normalize(logp):
    """Log-scores -> probabilities that sum to one (a softmax)."""
    top = max(logp)
    z = top + math.log(sum(math.exp(x - top) for x in logp))
    return [math.exp(x - z) for x in logp]

def mix(scored_a, scored_b, alpha):
    """alpha * P_a + (1 - alpha) * P_b over the same candidate words."""
    (cands, la), (_, lb) = scored_a, scored_b
    pa, pb = normalize(la), normalize(lb)
    return cands, [alpha * x + (1 - alpha) * y for x, y in zip(pa, pb)]

class MixedKeyboard:
    def __init__(self, ngram, rnn, alpha=0.7):
        self.ngram, self.rnn, self.alpha = ngram, rnn, alpha

    def suggest(self, typed, k=3):
        cands, p = mix(self.ngram.scores(typed), self.rnn.scores(typed),
                       self.alpha)
        order = sorted(range(len(cands)), key=lambda i: (-p[i], cands[i]))
        return [cands[i] for i in order[:k]]
```

Listing 36.9 chooses α on the development messages, measures the mixture, and tries a way to make the network smaller.

Listing 36.9 `improve.py`: choosing the mixing weight, measuring the mixed keyboard, and rounding the GRU's weights to 8 bits.

```
"""improve.py - mixing the two keyboards, and shrinking the GRU to 8 bits."""
import copy

            p.copy_(torch.round(p / scale).clamp(-127, 127) * scale)
    return q
```

Listing 36.9 (Continued) *improve.py: choosing the mixing weight, measuring the mixed keyboard, and rounding the GRU's weights to 8 bits.*

```
def main():
    tr, dv, te = load_split()
    ngram = NgramKeyboard((0.8, 0.15, 0.05)).fit(tr)
    rnn = load_rnn(lexicon_of(tr))
    dev = cached(ngram, rnn, dv[:200])
    alpha = max((0.3, 0.5, 0.7, 0.9), key=lambda a: accuracy(dev, a))
    both = MixedKeyboard(ngram, rnn, alpha)
    top1, top3 = accuracy(cached(ngram, rnn, te[:300]), alpha)
    keys = sum(keystrokes(both, m) for m in te[:100])
    saved = 1 - keys / sum(map(len, te[:100]))
    start = time.perf_counter()
    for m in te[:100]:
        both.suggest(" ".join(words(m)[:2]) + " ")
    ms = (time.perf_counter() - start) * 10
    print(f"mixed, alpha={alpha}: top-1 {top1:.3f}  top-3 {top3:.3f}  "
          f"keys saved {saved:.1%}  {ms:.2f} ms/suggestion")
    rnn.m = quantize(rnn.m)
    top1, top3 = next_word(rnn, te[:300])
    n = sum(p.numel() for p in rnn.m.parameters())
    tensors = len(list(rnn.m.parameters()))
    print(f"char GRU, 8-bit weights: top-1 {top1:.3f}  top-3 {top3:.3f}  "
          f"size {(n + 4 * tensors) / 1024:.0f} KB")

if __name__ == "__main__":
    main()
```

```
python improve.py
```

```
mixed, alpha=0.7: top-1 0.683  top-3 0.802  keys saved 75.8%  7.45 ms/suggestion
char GRU, 8-bit weights: top-1 0.596  top-3 0.724  size 67 KB
```

The mixture raises the accuracy of the first suggestion from 65.8% to 68.3%, with the same top-3 accuracy (80.2%) and keystroke savings (75.8%) as the trigram. It costs what the GRU costs: its time per suggestion includes the GRU's, and the printed 7.45 ms against the 10.21 ms of `evaluate.py` only shows that timings on a laptop vary by a few milliseconds from run to run. This is how production keyboards work too: a neural model is combined with other signals, and each is weighted by what it is good at.

36.7.2 Eight bits are enough

A phone stores and multiplies small integers much faster than 32-bit floating-point numbers. **Quantization** replaces every weight w of a matrix by the nearest of 255 levels, $w \approx s \cdot q$ with an integer $q \in \{-127, \dots, 127\}$ and one scale $s = \max|w|/127$ per matrix. `quantize` does exactly that and puts the rounded values back, so that we can measure the effect. The GRU keeps its accuracy (top-1 59.6% and top-3 72.4%, against 59.7% and 72.6%) and shrinks to 67 KB, a quarter of its size. Gboard's model was shipped in the same way: 1.4 million weights in 1.4 megabytes [2].

36.7.3 What else would help

- **More data, on the phone.** The model should keep learning from its owner. **Federated learning** trains on each phone and sends only weight updates, never text, to be averaged on a server; Gboard's model was trained this way, with the same accuracy as server training [2], and later with formal differential-privacy guarantees [1].
- **A word-level model.** With a large vocabulary, a network that reads and predicts whole words (with an embedding per word, as in Chapter 37) is faster at suggestion time: one output layer

gives the probabilities of all words at once, instead of a batch of spellings. Its cost is the size of the embedding table; in Gboard's model it was more than two thirds of all weights [2].

- **Caching.** The hidden state after "tolong belikan" does not change while the person types the next word; keeping it saves reading the whole text again at every key.

36.8 Common Mistakes, and How to Avoid Them

Evaluating on the training messages. A keyboard scored on the messages it learned from looks brilliant. *Avoid it:* keep test messages apart, as `load_split` does, and choose settings on development messages.

Scoring words without the end character. Then every short word is "part of" longer words, and "ob" cannot choose between *obat* and a word that starts with *obat*. *Avoid it:* add the probability of an end character, Equation (36.6).

Believing the bigger model must win. With little data, the trigram beat the GRU. *Avoid it:* always build the counting baseline first and compare on the same test messages.

Forgetting latency and size. A model that is 1% better but misses the 20 ms budget makes the keyboard feel broken. *Avoid it:* measure time per suggestion and model size with every experiment.

Letting the gradient explode. Long windows can make gradients huge and training jump. *Avoid it:* clip the gradient norm, as `train` does.

Learning what must never be suggested. A keyboard that learns everything will one day suggest a password, a card number or a word the owner would never want shown. *Avoid it:* never learn from password fields, drop long digit strings from training text, and keep a blocklist of words that are never suggested.

36.9 Using It for Real

Your own text. Export your own chats (for example WhatsApp's *Export chat*), keep only the lines you wrote, and save them one message per line as `data/messages.txt`. A few thousand messages give a useful personal model; `train_rnn.py` then takes a minute or two on a laptop. If your messages mix languages, both models handle it without change: they learn whatever you type.

On the phone. Train on a computer, then export the GRU for the phone: PyTorch models can be exported with `torch.export` and run on Android and iOS with PyTorch's on-device runtime, or converted to ONNX for other runtimes. Ship the 8-bit weights, the character vocabulary and the lexicon. The trigram is simpler still: its counts are a small table that any language can read.

Privacy. What a person types is personal data in the sense of Indonesia's Personal Data Protection Law (UU No. 27 Tahun 2022) [4], and some of it, such as health or financial details, is specific personal data that needs extra care. A keyboard that learns on the device and never uploads text avoids most of the risk; if a model must learn from many people, use federated learning with differential privacy, as Gboard does [1].

Combining. Use the mixture of Section 36.7: the trigram for exact phrases and speed, the GRU for spelling and unseen words, with the weight chosen on your own development messages.

Measuring in use. Count how often a suggestion is tapped and how many keystrokes it saved. If that share falls, the owner's writing has changed (a new job, a new language), and it is time to retrain.

36.10 Chapter Summary

- A phone keyboard predicts the next word from what has been typed; it must answer within about 20 ms and fit on the phone, and it should learn without uploading what people type ([1], [2]).
- An **RNN** carries a hidden state through the text (Equation (36.1), Equation (36.2), **Figure 36.1**); plain RNNs forget because gradients vanish (Equation (36.3)), and the **GRU**'s gates fix this (Equation (36.4)).
- The character GRU is trained with the cross-entropy of the next character (Equation (36.5), **Listing 36.3**, **Listing 36.4**, **Figure 36.2**) and turned into a word keyboard by scoring lexicon words with their characters and an end character (Equation (36.6)).
- The **trigram** baseline (Equation (36.7), **Listing 36.2**) counts word triples. On one person's 4,800 messages it beat the GRU in accuracy and was about 40 times faster (**Listing 36.7**, **Figure 36.3**); both saved about three keystrokes in four (Equation (36.9)).
- **Mixing** the two (**Listing 36.8**, **Listing 36.9**) gives the best first suggestion, and **8-bit quantization** shrinks the network to a quarter without loss.
- **Temperature** (Equation (36.8)) controls how adventurous generated text is (**Listing 36.5**).

36.11 Exercises

Exercise 36.1. Suppose that after the typed text "aku o" a network gives the next characters these probabilities: $P(\text{t}) = 0.9$; then, after "aku ot", $P(\text{w}) = 0.95$; then, after "aku otw", the end characters together 0.8. Compute $\log P(\text{otw} \mid \text{"aku o"})$ with Equation (36.6), using natural logarithms, and the probability itself.

Exercise 36.2. Bu Wulan types "oke siap" (8 characters). Before she types anything, the suggestions are *oke*, *aku*, *tolong*; after she taps *oke*, they are *siap*, *terima*, *nanti*. How many key presses does she need, and what are the keystrokes saved by Equation (36.9)? Assume a tap inserts the word and a space.

Exercise 36.3. Explain why the GRU's weights number $3 \times (32 \times 128 + 128 \times 128 + 2 \times 128)$, and compute how many weights a GRU with $H = 256$ would have in the recurrent layer.

Exercise 36.4. Write a program that measures the top-3 accuracy of the trigram and the GRU separately for the first word of a message and for later words, on the first 100 test messages. Explain the difference.

Exercise 36.5. Would a 4-gram keyboard beat the trigram? Write a program that adds a 4-gram term to Equation (36.7) and compares top-1 and top-3 accuracy on the first 300 test messages.

Exercise 36.6. A keyboard learned from its owner's messages suggests a word the owner typed only once, in a private message, while a colleague is watching. Name three design rules that prevent embarrassing or harmful suggestions.

36.12 Solutions to the Exercises

Solution 36.1. $\log P = \ln 0.9 + \ln 0.95 + \ln 0.8 = -0.105 - 0.051 - 0.223 = -0.380$, so $P = e^{-0.380} \approx 0.684$: the network thinks there is about a two-in-three chance that the next word is *otw*.

Solution 36.2. The first suggestion bar already offers *oke*: one tap types "oke". Then *siap* is offered: a second tap types "siap". Two key presses instead of 8 characters, so the keystrokes saved are $1 - 2/8 = 0.75$.

Solution 36.3. The GRU of Equation (36.4) computes three vectors, $\mathbf{z}$, $\mathbf{r}$ and $\tilde{\mathbf{h}}$, each with its own input matrix (128×32 weights), recurrent matrix (128×128) and, in PyTorch, two bias vectors of 128 (one added to the input part and one to the recurrent part). With $H = 256$: $3 \times (32 \times 256 + 256 \times 256 + 2 \times 256) = 3 \times (8{,}192 + 65{,}536 + 512) = 222{,}720$ weights, 3.6 times as many, because the recurrent matrix grows with H^2. Its time per step grows about as fast.

Solution 36.4. Listing 36.10 splits the positions.

Listing 36.10 `solutions/by_position.py`: top-3 accuracy for the first word of a message and for later words.

```
"""by_position.py - Exercise 36.4: first word of a message versus later words."""
import os
import sys

import torch

sys.path.insert(0, os.path.dirname(os.path.dirname(os.path.abspath(__file__))))
from charlm import lexicon_of  # noqa: E402

from ngram_kb import NgramKeyboard, load_split, words  # noqa: E402

torch.set_num_threads(1)
train, _, test = load_split()
models = {"trigram": NgramKeyboard((0.8, 0.15, 0.05)).fit(train),
          "char GRU": load_rnn(lexicon_of(train))}
print(f"{'model':<10}{'first word':>12}{'later words':>13}")
for name, kb in models.items():
    hits, totals = [0, 0], [0, 0]
    for m in test[:100]:
        ws = words(m)
        for i, w in enumerate(ws):
            top = kb.suggest(" ".join(ws[:i]) + (" " if i else ""))
            hits[i > 0] += w in top
            totals[i > 0] += 1
    print(f"{name:<10}{hits[0] / totals[0]:>12.3f}{hits[1] / totals[1]:>13.3f}")
```

```
python solutions/by_position.py
```

```
model       first word  later words
trigram          0.290        0.899
char GRU         0.280        0.816
```

For the first word of a message, both keyboards are right within three suggestions only 29% of the time: with no context at all, the best they can do is to offer Bu Wulan's most common first words (*tolong*, *oke*, *aku*). For later words the trigram reaches 89.9% and the GRU 81.6%. The whole difference between the two models lies where there is context, and there the trigram's exact memory of her phrases beats the network's smoother, character-based guess.

Solution 36.5. Listing 36.11 adds a fourth weight for the counts of four-word sequences.

Listing 36.11 `solutions/fourgram.py`: a 4-gram keyboard compared with the trigram.

```

Listing 36.11 (Continued) *solutions/fourgram.py: a 4-gram keyboard compared with the trigram.*

```
train, _, test = load_split()
print(f"{'model':<10}{'top-1':>7}{'top-3':>7}")
for name, kb in (("trigram", NgramKeyboard((0.8, 0.15, 0.05)).fit(train)),
                 ("4-gram", FourgramKeyboard().fit(train))):
    hit1 = hit3 = total = 0
    for m in test[:300]:
        ws = words(m)
        for i, w in enumerate(ws):
            top = kb.suggest(" ".join(ws[:i]) + (" " if i else ""))
            hit1 += top[:1] == [w]
            hit3 += w in top
            total += 1
    print(f"{name:<10}{hit1 / total:>7.3f}{hit3 / total:>7.3f}")
```

```
python solutions/fourgram.py
```

```
model       top-1  top-3
trigram     0.658  0.802
4-gram      0.687  0.802
```

The 4-gram improves the first suggestion from 65.8% to 68.7% and leaves top-3 unchanged at 80.2%. In Bu Wulan's messages a third word back sometimes decides the next word (after "jemput adik di" the next word is a place, after "tolong belikan obat" it is usually *batuk*), and her phrases repeat often enough for four-word counts to be reliable. In more varied text, most four-word contexts would be seen once or never, which is why the lower orders stay in the mixture, exactly the lesson of Chapter 27.

Solution 36.6. First, learn only from ordinary text fields: never from password, card-number or one-time-code fields, which apps mark as such. Second, require that a word has been typed several times, on different days, before it is ever suggested, so that a single private message leaves no trace. Third, keep a blocklist of offensive and sensitive words that are never suggested, whatever the counts say, and let the owner delete a learned word or the whole personal model. Federated learning with differential privacy adds a mathematical version of the second rule: no single message can change the shared model noticeably [1].

Chapter 37

Word Embeddings Trained from Scratch

To a computer, the words *kopi* (coffee) and *teh* (tea) are as different as *kopi* and *kambing* (goat): three unrelated strings of letters, or three unrelated index numbers. Every text program in Part 3 treated words that way, and paid for it: a spam filter that learned "gratis" was suspicious knew nothing about "cuma-cuma". This chapter teaches the computer that some words are alike, without telling it which. We train *word embeddings*, one short vector of numbers per word, arranged so that words used in similar sentences get similar vectors. By the end of the chapter you will be able to state the distributional idea behind embeddings, write the skip-gram model with negative sampling as equations and explain every term, build the training pairs from a corpus, train 16-dimensional embeddings for 89 Indonesian words in about two seconds, find a word's nearest neighbors with cosine similarity, pick the odd one out of a group, try word analogies by vector arithmetic, and compare the neural method honestly with the older count-based method of PPMI and SVD. The corpus is 4,000 Indonesian sentences that a small program in the chapter generates, so everything runs offline.

37.1 Why Words Need Vectors

Imagine a laundry's customer-service chat. One customer writes "sprei saya belum dicuci" (my bed sheet has not been washed yet) and another "selimut saya belum dicuci" (my blanket …). A program that knows *sprei* and *selimut* are both bedding can route both messages to the same answer, even if its training examples only ever mentioned sheets. A program that sees two unrelated strings cannot.

The fix goes back to an observation linguists made long before computers could use it. Zellig Harris noted in 1954 that words that occur in similar contexts tend to have similar meanings [1], and J. R. Firth put it memorably in 1957: "You shall know a word by the company it keeps" [2]. *Kopi* and *teh* both appear after *minum* (drink), before *panas* (hot), near *warung* (food stall); *kambing* appears near *rumput* (grass) and *kandang* (pen). If we describe every word by the company it keeps, words with similar company get similar descriptions.

In 2013 Tomas Mikolov and colleagues at Google turned this into a fast neural method, *word2vec*, that learns a short, dense vector for every word by predicting its neighbors [3], [4]. The vectors, trained on billions of words, captured similarity so well that simple arithmetic such as vec(Paris) − vec(France) + vec(Italy) landed near vec(Rome). Word embeddings became the first layer of almost every language model that followed; the embedding tables in the RNN of Chapter 36 and the Transformer of Chapter 39 are exactly such vectors, learned as a side effect of their own training. This chapter trains them on their own, so that we can look at them.

Our corpus is small and deliberately regular: 4,000 sentences generated from 23 templates about people, food, drinks, cities, animals, laundry items and colors, such as *nenek minum es dingin di warung* (grandmother drinks iced … cold at the stall) or *sprei biru sudah dicuci* (the blue sheet has been washed). A real application would train on millions of real sentences; the generated corpus

has the advantage that we know exactly which words *should* come out similar, so we can check the result.

37.2 The Idea in Plain Words

Play a guessing game with the sentence *nenek minum es dingin di warung*. Point at one word, the *center* word, say *es*, and ask: which words are likely to appear within two positions of it? Here the answers are *nenek*, *minum*, *dingin* and *di*. **Figure 37.1** draws the game. Every (center, neighbor) combination is a training example, and our 4,000 sentences give 56,772 of them.

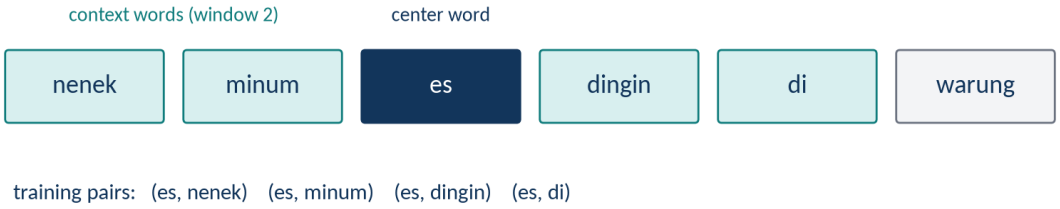

Figure 37.1 The skip-gram game. For the center word *es* and a window of two words on each side, the four surrounding words become its context, giving four training pairs.

We give every word two vectors of 16 numbers, one used when the word is the center and one used when it is a neighbor, and start them at random or zero. The model's guess of how likely a pair is to be real is simply how well the two vectors line up: their dot product. Training pushes the vectors of real pairs, *es* with *dingin*, to line up more, and the vectors of fake pairs, *es* with a randomly drawn word such as *kambing*, to line up less. After enough pairs, *es* and *jus* (juice) end up with similar center vectors, not because they ever appeared together, but because both had to line up with the same neighbors: *minum*, *dingin*, *segar*, *warung*. Similar company, similar vectors.

That is the whole idea. The rest is choosing how to measure "line up", how to draw the fake pairs, and how to read the vectors afterward.

> **KEY INSIGHT.** An embedding is learned from a prediction task that nobody cares about for its own sake (guessing neighbors). The useful product is the vectors that the task forces the model to invent.

37.3 The Mathematics, Gently

37.3.1 From index to vector

Number the V words of the vocabulary from 0 to $V-1$; here $V = 89$. A word can be written as a *one-hot* vector $\mathbf{x}_w$ of length V, all zeros except a 1 at position w. An embedding matrix W with V rows and d columns turns it into a dense vector:

$$\mathbf{v}_w = W^{\top}\mathbf{x}_w = \text{row } w \text{ of } W \tag{37.1}$$

Multiplying by a one-hot vector simply picks one row, so in practice we look the row up directly, which is what `nn.Embedding` does [5]. With $d = 16$ each word is described by 16 learned numbers instead of 89 mostly-zero ones.

37.3.2 The skip-gram model

Skip-gram gives each word w a *center vector* $\mathbf{v}_w$ and a *context vector* $\mathbf{u}_w$. The probability that word o appears near center word c is modeled with a softmax over the whole vocabulary:

$$P(o \mid c) = \frac{e^{\mathbf{u}_o \cdot \mathbf{v}_c}}{\sum_{w=0}^{V-1} e^{\mathbf{u}_w \cdot \mathbf{v}_c}} \tag{37.2}$$

Training would maximize the log of Equation (37.2) over all pairs. The trouble is the denominator: it needs a dot product with every word in the vocabulary, for every pair. With 89 words that is fine; with the three million words of a real vocabulary it is hopeless.

37.3.3 Negative sampling

Mikolov and colleagues replaced the softmax with a cheaper question: is this pair real or fake? Let $\sigma(s) = 1/(1 + e^{-s})$ be the sigmoid, which turns any score into a number between 0 and 1. For a real pair (c, o) and k *negative* words $n_1, \ldots, n_k$ drawn at random, the loss is

$$L = -\log\sigma(\mathbf{u}_o \cdot \mathbf{v}_c) - \sum_{j=1}^{k} \log \sigma(-\mathbf{u}_{n_j} \cdot \mathbf{v}_c) \tag{37.3}$$

The first term is small when $\mathbf{u}_o \cdot \mathbf{v}_c$ is large: the real neighbor should line up with the center. Each other term is small when $\mathbf{u}_{n_j} \cdot \mathbf{v}_c$ is very negative, because $\sigma(-s)$ is close to 1 for large s: random words should *not* line up. Each pair now costs $k + 1$ dot products instead of V. We use $k = 5$.

A worked value. Suppose the real pair has score 2 and two negatives have scores -1 and 0. Then $\sigma(2) = 1/(1 + e^{-2}) = 0.881$, $\sigma(1) = 0.731$ and $\sigma(0) = 0.5$, and $L = -\log 0.881 - \log 0.731 - \log 0.5 = 0.127 + 0.313 + 0.693 = 1.133$. The negative with score 0 contributes most: it is the one the model has not yet learned to push away. At the very start of training all context vectors are zero, every score is 0, and each of the $k + 1$ terms is $\log 2$, so the loss is $(k + 1)\log 2 = 6 \times 0.693 = 4.16$; the unit test in Section 37.4.5 checks exactly that.

37.3.4 Which negatives?

Negatives are drawn from a *noise distribution*. Drawing words in proportion to their frequency $f(w)$ would mostly produce *di* and *ke*; drawing uniformly would over-represent rare words. Word2vec uses a compromise, the frequency raised to the power $\frac{3}{4}$:

$$P_n(w) = \frac{f(w)^{3/4}}{\sum_{w'} f(w')^{3/4}} \tag{37.4}$$

For three words with counts 100, 10 and 1, raw frequencies give probabilities 0.901,0.090,0.009; with the power $\frac{3}{4}$ the counts become 31.6,5.6,1 and the probabilities 0.827,0.147,0.026: common words are still common, but rare ones are drawn about three times as often as before.

37.3.5 Measuring similarity

Two word vectors are compared by the cosine of the angle between them:

$$\cos(\mathbf{a},\mathbf{b}) = \frac{\mathbf{a}\cdot\mathbf{b}}{\|\,\mathbf{a}\,\|\,\|\,\mathbf{b}\,\|} \tag{37.5}$$

It is 1 for vectors pointing the same way, 0 for perpendicular ones and -1 for opposite ones, and it ignores length, which mostly reflects how frequent a word is. For example $\mathbf{a} = (1,2,2)$ and $\mathbf{b} = (2,1,2)$ have $\mathbf{a}\cdot\mathbf{b} = 2+2+4 = 8$ and lengths $\sqrt{9} = 3$ each, so $\cos = 8/9 = 0.89$. If every vector is first scaled to length 1, the cosine is just the dot product, which is how our code computes all similarities at once.

37.3.6 The counting alternative

Before word2vec, embeddings were built by counting. Fill a $V \times V$ table with how often word w appears within the window of word c. Raw counts are dominated by frequent words, so we convert them to *pointwise mutual information*, which asks how much more often the two words meet than they would by chance:

$$\mathrm{PMI}(w,c) = \log\frac{P(w,c)}{P(w)\,P(c)}, \qquad \mathrm{PPMI}(w,c) = \max(0,\mathrm{PMI}(w,c)) \tag{37.6}$$

The positive part (PPMI) keeps only attractions. A truncated singular value decomposition (SVD) then compresses each row of the PPMI table to d numbers, much as PCA did in Chapter 34. Levy and Goldberg showed in 2014 that skip-gram with negative sampling is, in a precise sense, implicitly factorizing a shifted PMI matrix [6], so the two approaches are close relatives. Section 37.6 compares them on our corpus.

37.3.7 Analogies

If the difference between two vectors captures a relation, it can be transferred. To answer "a is to b as c is to ?", compute

$$\mathbf{t} = \mathbf{v}_b - \mathbf{v}_a + \mathbf{v}_c \tag{37.7}$$

and return the word whose vector has the highest cosine with $\mathbf{t}$, excluding a, b and c themselves. Exercise 37.4 tries it.

37.4 Building It Step by Step

The code is in `Chapter037` and uses PyTorch 2.14 only.

37.4.1 The corpus

Listing 37.1 writes `corpus.txt`. The dictionary `GROUPS` lists the words of seven categories, several split into sub-groups: hot drinks (*kopi*, *teh*, *wedang*) and cold drinks (*jus*, *es*, *susu*), soups (*soto*, *rawon*, *bakso*) and dry dishes (*sate*, *pecel*, *nasi*), cities on Java reached by train and cities farther away reached by plane, pets and farm animals, clothes and bedding. The templates use the sub-groups where the meaning differs, *minum {hot} panas* versus *minum {cold} dingin*, and whole categories where it does not.

Listing 37.1 `make_corpus.py`: generating 4,000 template sentences with a fixed seed.

```
"""Write corpus.txt: simple Indonesian sentences from templates (Chapter 37)."""
import random

GROUPS = {                          # category -> sub-group -> words

def normalized(model):
    """Center-word vectors scaled to length 1, so dot product = cosine."""
    E = model.center.weight.detach()
    return E / E.norm(dim=1, keepdim=True)
```

Listing 37.2 (Continued) *word2vec.py: vocabulary, training pairs, the skip-gram model with negative sampling, training and nearest neighbors.*

```
def neighbors(E, vocab, word, k=5):
    sims = E @ E[vocab.index[word]]
    best = torch.argsort(sims, descending=True)[1:k + 1]  # skip the word itself
    return [(vocab.words[i], sims[i].item()) for i in best.tolist()]
```

- `Vocab` counts the words and sorts them, so every word has a fixed index.
- `skipgram_pairs` walks through every sentence and, for each position, emits a (center, context) pair for every other position within `window` steps, as in **Figure 37.1**.
- `SkipGram` holds the two embedding tables of Equation (37.2): `center` for $\mathbf{v}$ and `context` for $\mathbf{u}$. Center vectors start small and random, context vectors at zero, as in the original word2vec code. `forward` computes Equation (37.3) for a whole batch: `(v * u_pos).sum(dim=1)` is one dot product per pair, and `torch.bmm` (batch matrix multiplication) computes the k negative dot products of every pair at once. `logsigmoid` computes $\log\sigma$ in a numerically safe way.

- `train` builds the pairs and the noise distribution of Equation (37.4), then runs Adam over shuffled batches of 256 pairs, drawing fresh negatives for every batch with `torch.multinomial`.
- `normalized` returns the center vectors scaled to length 1, so that a matrix product gives all cosines of Equation (37.5) at once, and `neighbors` returns the k most similar words, skipping the word itself.

37.4.3 Training and inspecting

Listing 37.3 trains for five epochs, saves the normalized vectors, prints the four nearest neighbors of six probe words, and measures how often a word's five nearest neighbors belong to its own category.

Listing 37.3 `train_embeddings.py`: training the embeddings and checking their neighbors.

```
"""Train word embeddings on corpus.txt and inspect them (Chapter 37)."""
import time
import torch
from make_corpus import WORDS
from word2vec import Vocab, neighbors, normalized, read_corpus, train

torch.set_num_threads(1)
sentences = read_corpus()

hits = total = 0
for word, cat in category.items():
    for w, _ in neighbors(E, vocab, word, 5):
        hits += category.get(w) == cat
        total += 1
print(f"top-5 neighbors in the same category: {hits}/{total} = {hits / total:.2f}")
```

37.4.4 The application

Listing 37.4 is a small word explorer. Given words, it lists their nearest neighbors. Given `--odd` and a group of words, it computes the group's average direction and names the word that fits it least.

Listing 37.4 `embed_app.py`: nearest neighbors and the odd one out.

```
"""Word explorer: nearest neighbors and the odd one out (Chapter 37).

usage: python embed_app.py WORD [WORD ...]          nearest neighbors
       python embed_app.py --odd WORD WORD WORD ...  which word does not belong?
"""
import sys
import torch

saved = torch.load("embeddings.pt", weights_only=True)
E, words = saved["E"], saved["words"]
index = {w: i for i, w in enumerate(words)}
args = sys.argv[1:] or ["laundry"]

unknown = [w for w in args if w != "--odd" and w not in index]
if unknown:
    sys.exit(f"not in the vocabulary: {', '.join(unknown)}")
if args[0] == "--odd":
    group = args[1:]
    V = E[[index[w] for w in group]]
    centroid = V.mean(dim=0)
    sims = V @ centroid / centroid.norm()        # cosine with the group mean
    for w, s in zip(group, sims.tolist()):
        print(f"  {w:10s} similarity to the group {s:+.2f}")
    print(f"odd one out: {group[int(sims.argmin())]}")
else:
    for w in args:
        sims = E @ E[index[w]]
        best = torch.argsort(sims, descending=True)[1:6].tolist()
        print(f"{w}: " + ", ".join(f"{words[i]} ({sims[i]:.2f})" for i in best))
```

37.4.5 Tests

Listing 37.5 checks that `skipgram_pairs` produces exactly the pairs within the window, and that the initial loss equals $(k+1)\log 2$, as computed in Section 37.3.3.

Listing 37.5 `test_word2vec.py`: unit tests for the pairs and the loss.

```
"""Unit tests for the skip-gram code (run: python -m unittest)."""
import unittest
import torch
from word2vec import SkipGram, Vocab, skipgram_pairs

class Word2VecTest(unittest.TestCase):
    def test_pairs_within_window(self):
        vocab = Vocab([["a", "b", "c"]])
        pairs = skipgram_pairs([["a", "b", "c"]], vocab, window=1).tolist()
        self.assertEqual(sorted(pairs), [[0, 1], [1, 0], [1, 2], [2, 1]])

    def test_loss_is_log2_times_k_plus_1_at_start(self):
        model = SkipGram(10, dim=4)                 # context vectors start at 0
        c, o = torch.tensor([1, 2]), torch.tensor([3, 4])
        neg = torch.tensor([[5, 6, 7], [7, 8, 9]])
        expected = 4 * torch.log(torch.tensor(2.0))  # (1 + 3 negatives) log 2
        self.assertAlmostEqual(model(c, o, neg).item(), expected.item(), places=5)

if __name__ == "__main__":
    unittest.main()
```

37.5 Running It

```
python train_embeddings.py
```

```
89 words, training time 2.1 s
loss per epoch: 2.456 1.461 1.361 1.345 1.331
kucing    -> anjing 1.00, mengelus 0.77, kesayangan 0.74, ini 0.59
kopi      -> wedang 0.99, teh 0.99, es 0.69, susu 0.68
surabaya  -> bandung 1.00, malang 1.00, jakarta 1.00, medan 0.79
kemeja    -> jaket 1.00, celana 1.00, handuk 0.82, disetrika 0.81
merah     -> biru 0.99, kuning 0.99, putih 0.99, hijau 0.99
ibu       -> kakak 0.99, adik 0.99, ayah 0.99, nenek 0.99
top-5 neighbors in the same category: 170/210 = 0.81
```

The loss falls from its starting value of about 4.16 to 2.46 on average over the first epoch and to 1.33 after five. The neighbors are the interesting part. *Kucing* (cat) is closest to *anjing* (dog), and then to *mengelus* (to stroke) and *kesayangan* (beloved), the words that only pets keep company with; the farm animals follow at about 0.5, after the odd guest *ini* (this) at 0.59, a reminder that small corpora leave some noise. *Kopi* is closest to *wedang* and *teh*, the other hot drinks, at 0.99; the cold drinks *es* and *susu* follow at about 0.68. *Surabaya* is almost identical to *bandung*, *malang* and *jakarta*, the other train cities, and *medan*, reached by plane, is further away at 0.79. *Kemeja* (shirt) sits with *jaket* and *celana* (trousers), then with *handuk* (towel) and the verb *disetrika* (ironed). The model has recovered not only the seven categories but the sub-groups within them, from nothing but word order. Overall, 81% of the five nearest neighbors of our 42 content words are in the same category.

Two of the probes are less exciting: all colors, and all family members, are near-copies of each other (0.99). That is correct for this corpus, where *merah* and *biru* appear in exactly the same templates; with identical company they get identical vectors. A real corpus would separate them.

Figure 37.2 shows the cosine similarity between twelve words as a table. The block structure is striking: hot drinks agree with each other at 1.0 and with cold drinks at 0.7; pets and farm animals agree within their groups at 1.0 and across at 0.5 to 0.6; drinks and animals are nearly unrelated (0.0 to 0.3).

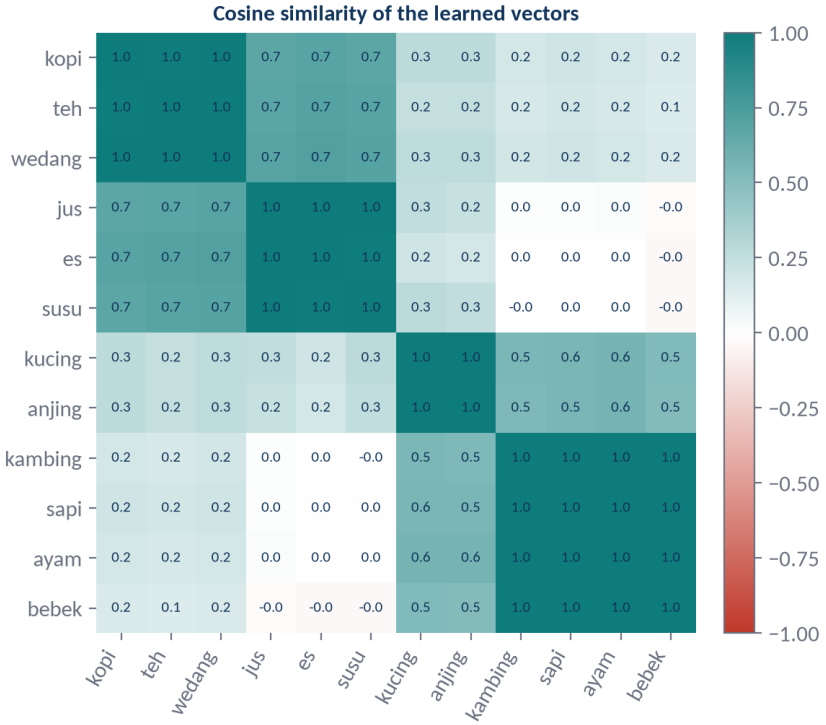

Figure 37.2 Cosine similarity (Equation (37.5)) between the learned vectors of six drinks and six animals. Blocks along the diagonal are sub-groups: hot and cold drinks, pets and farm animals.

To see all words at once we can project the 16-dimensional vectors onto their two main directions, as PCA did in Chapter 34. **Figure 37.3** does that. The categories form separate islands, and the sub-groups are visible within them. A projection loses information, though: the pets land next to the food in two dimensions, although **Figure 37.2** and the neighbor lists show they are not similar in the full 16.

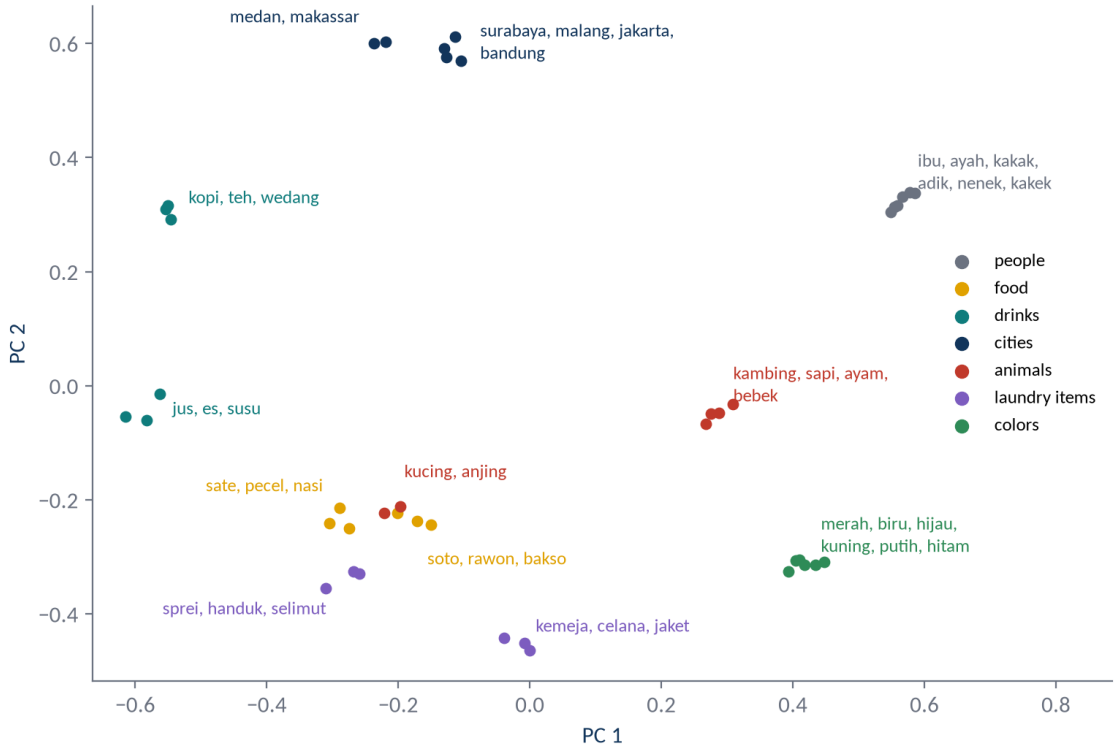

Figure 37.3 The embeddings of the 42 content words projected onto their first two principal components. Each label names the words of one sub-group.

Now the explorer. Neighbors of *laundry*, *kereta* (train) and *dingin* (cold):

```
python embed_app.py laundry kereta dingin
```

```
laundry: membawa (0.86), merah (0.72), hijau (0.72), hitam (0.72), kuning (0.71)
kereta: cuaca (0.73), pesawat (0.72), ke (0.71), naik (0.67), pergi (0.66)
dingin: segar (0.69), siang (0.65), jus (0.61), panas (0.60), susu (0.60)
```

Laundry keeps company with *membawa* (to bring) and with colors, because the templates bring colored items to the laundry; *kereta* with *pesawat* (plane), *naik* (to ride) and *pergi* (to go), the words of travel; *dingin* with *segar* (fresh), *siang* (midday) and the cold drinks. And the odd one out:

```
python embed_app.py --odd kopi teh wedang susu
```

```
  kopi       similarity to the group +0.98
  teh        similarity to the group +0.98
  wedang     similarity to the group +0.98
  susu       similarity to the group +0.82
odd one out: susu
```

```
python embed_app.py --odd sapi kambing ayam kucing
```

```
  sapi       similarity to the group +0.97
  kambing    similarity to the group +0.97
  ayam       similarity to the group +0.98
  kucing     similarity to the group +0.73
odd one out: kucing
```

Susu (milk) is a drink, but the only cold one in the group; *kucing* is an animal, but the only pet. The model's answers reflect exactly how these words were used.

The tests:

```
python -m unittest
```

```
..
----------------------------------------------------------------------
Ran 2 tests in 0.016s

OK
```

37.6 Improving It

Is a neural network needed at all? **Listing 37.6** compares four ways of building word vectors on the same corpus: rows of the raw co-occurrence table, PPMI plus SVD to 16 dimensions (Equation (37.6)), and skip-gram with 2 and 16 dimensions and windows of 2 and 5 words.

Listing 37.6 `improve.py`: count-based vectors against skip-gram, scored by how many of each word's five nearest neighbors share its category.

```
"""Counting versus predicting: PPMI + SVD against skip-gram (Chapter 37)."""
import torch
from make_corpus import GROUPS
from word2vec import Vocab, normalized, read_corpus, train

torch.set_num_threads(1)
sentences = read_corpus()
vocab = Vocab(sentences)
V = len(vocab.words)
category = {w: c for c, g in GROUPS.items() for ws in g.values() for w in ws}

def score(E):
    """Share of the top-5 neighbors that belong to the word's own category."""
    hits = 0
    for w in category:
        sims = E @ E[vocab.index[w]]
        best = torch.argsort(sims, descending=True)[1:6].tolist()
        hits += sum(category.get(vocab.words[i]) == category[w] for i in best)
    return hits / (5 * len(category))

def cooccurrence(window):
    C = torch.zeros(V, V)
    for s in sentences:
        ids = [vocab.index[w] for w in s]
        for i, c in enumerate(ids):
            for j in range(max(0, i - window), min(len(ids), i + window + 1)):
                if j != i:
                    C[c, ids[j]] += 1
    return C

C = cooccurrence(2)
raw = C / C.norm(dim=1, keepdim=True)
P = C / C.sum()
pmi = torch.log(P / (P.sum(1, keepdim=True) * P.sum(0, keepdim=True)) + 1e-12)
ppmi = pmi.clamp(min=0)                              # positive PMI
U, S, _ = torch.linalg.svd(ppmi)
svd = U[:, :16] * S[:16]
svd = svd / svd.norm(dim=1, keepdim=True)
```

Listing 37.6 (Continued) *improve.py: count-based vectors against skip-gram, scored by how many of each word's five nearest neighbors share its category.*

```
rows = [("raw co-occurrence counts", raw), ("PPMI + SVD, 16 dims", svd)]
for dim, window in [(2, 2), (16, 2), (16, 5)]:
    model, _ = train(sentences, vocab, dim=dim, window=window)
    rows.append((f"skip-gram, {dim} dims, window {window}", normalized(model)))
print(f"{'method':32s} {'top-5 in same category':>22s}")
for name, E in rows:
    print(f"{name:32s} {score(E):22.2f}")
```

```
python improve.py
```

```
method                           top-5 in same category
raw co-occurrence counts                           0.73
PPMI + SVD, 16 dims                                0.85
skip-gram, 2 dims, window 2                        0.30
skip-gram, 16 dims, window 2                       0.81
skip-gram, 16 dims, window 5                       0.87
```

Raw counts already get 73% of the neighbors right; distributional similarity is real and visible even without any learning. Turning counts into PPMI and compressing them with SVD raises that to 85%, slightly better than our skip-gram with a window of 2 (81%). Widening the skip-gram

window to 5 words lets each word see a whole template and brings it to 87%, the best score. With only two dimensions, skip-gram collapses to 30%: seven categories and their sub-groups do not fit on a plane.

The honest conclusion matches Levy and Goldberg's: on the same data and with comparable settings, count-based and predictive methods perform similarly [6]. The predictive method wins in practice on *large* corpora, because it streams through the text in small batches and never needs the full $V \times V$ table, which for a vocabulary of a million words would have a trillion cells. Other improvements, which the literature has explored thoroughly:

- **More and real text.** Similarity from 4,000 template sentences is clean but narrow. Real embeddings are trained on hundreds of millions of words.
- **Subword information.** *FastText* builds a word's vector from its character n-grams, so that *menyetrika*, *disetrika* and *setrikaan* share information and unseen words still get vectors [7]. That matters greatly for Indonesian, with its rich prefixes and suffixes.
- **Global statistics.** *GloVe* fits vectors directly to the logarithm of co-occurrence counts, combining the two families [8].
- **Contextual embeddings.** A single vector per word cannot tell *bisa* (can) from *bisa* (venom). The Transformer of Chapter 39 computes a vector for each word *in its sentence*, which solves that.

37.7 Common Mistakes, and How to Avoid Them

Reading too much into a 2-D picture. A projection such as **Figure 37.3** keeps only two directions of sixteen. Judge similarity with cosines in the full space, as the neighbor lists and **Figure 37.2** do.

Using dot products of unnormalized vectors. Frequent words get long vectors and would appear "similar" to everything. Normalize first, or use Equation (37.5).

Too few dimensions or too narrow a window. Two dimensions scored 30% in Section 37.6. The window decides what "company" means: narrow windows capture grammatical role, wider ones topic.

Expecting analogies to always work. Vector arithmetic (Equation (37.7)) works when a relation is expressed consistently in the corpus. Exercise 37.4 shows a success and a failure side by side.

Forgetting that embeddings learn the corpus, including its prejudices. Bolukbasi and colleagues showed that embeddings trained on news text completed "man is to computer programmer as woman is to ?" with "homemaker" [9]. Our templates contain no such associations by construction, but embeddings trained on real text inherit whatever associations the text contains. Check before deploying; Chapter 99 returns to fairness.

Letting the evaluation depend on the training templates. Our category score is meaningful because we *know* the categories from the generator. On real text, evaluate on independent judgments, such as human similarity ratings or a downstream task.

37.8 Chapter Summary

- A word embedding is a row of a learned matrix (Equation (37.1)); words that keep similar company end up with similar rows.

- Skip-gram predicts a word's neighbors (Equation (37.2)); negative sampling makes it cheap by asking "real or fake?" for one true pair and k random ones (Equation (37.3)), drawn from frequency to the power $\frac{3}{4}$ (Equation (37.4)).
- Similarity is measured by the cosine (Equation (37.5)); analogies by vector differences (Equation (37.7)).
- On 4,000 generated Indonesian sentences, 16-dimensional skip-gram vectors recover categories and sub-groups: 81% of top-5 neighbors share the category (87% with a window of 5).
- Count-based PPMI + SVD (Equation (37.6)) does about as well on this small corpus; the predictive method's advantage is scale.

37.9 Exercises

1. Compute the cosine similarity of $\mathbf{a} = (3,0,4)$ and $\mathbf{b} = (4,0,3)$, and of $\mathbf{a}$ and $\mathbf{c} = (-3,0,-4)$.
2. Using Equation (37.3), compute the loss for a real pair with score 0.5 and three negatives with scores 1, -2 and 0. Which term is largest, and what does training do about it?
3. For words with counts 1000, 100 and 10, compute the sampling probabilities with raw frequency and with Equation (37.4).
4. Try four analogies with Equation (37.7) on the trained embeddings: *kopi : panas :: jus : ?*, *surabaya : kereta :: medan : ?*, *kucing : rumah :: sapi : ?* and *kemeja : disetrika :: sprei : ?*. Explain which ones work and why the others do not.
5. Why do *merah* and *biru*, or *ibu* and *ayah*, end up with a cosine of 0.99 in our embeddings? What kind of sentences would have to be in the corpus for them to differ?
6. The skip-gram model learns two vectors per word, $\mathbf{v}$ and $\mathbf{u}$. Why is it helpful to keep them separate during training? (Hint: what would the model have to do to say that a word rarely appears next to *itself*?)

37.10 Solutions to the Exercises

Solution 1. $\mathbf{a} \cdot \mathbf{b} = 12 + 0 + 12 = 24$, and both lengths are $\sqrt{9+16} = 5$, so $\cos(\mathbf{a}, \mathbf{b}) = 24/25 = 0.96$. For $\mathbf{c} = -\mathbf{a}$, $\mathbf{a} \cdot \mathbf{c} = -25$ and $\cos = -1$: exactly opposite directions.

Solution 2. $\sigma(0.5) = 0.622$, so the first term is $-\log 0.622 = 0.474$. The negative terms use $\sigma(-s)$: $\sigma(-1) = 0.269$ gives 1.313; $\sigma(2) = 0.881$ gives 0.127; $\sigma(0) = 0.5$ gives 0.693. The total is $0.474 + 1.313 + 0.127 + 0.693 = 2.607$. The largest term comes from the negative with score $+1$, a random word that currently lines up *with* the center. Its gradient pushes $\mathbf{u}_n$ and $\mathbf{v}_c$ apart, more strongly than for the others, while the real pair is pulled closer.

Solution 3. Raw: the total is 1110, so 0.901, 0.090, 0.009. With the power $\frac{3}{4}$: $1000^{0.75} = 177.8$, $100^{0.75} = 31.6$, $10^{0.75} = 5.62$, total 215.0, so 0.827, 0.147, 0.026. The rarest word is sampled almost three times as often as with raw frequency.

Solution 4. Listing 37.7 applies Equation (37.7) to the saved vectors.

Listing 37.7 `sol_analogy.py`: four analogies by vector arithmetic.

```
"""Exercise 37.4: analogies by vector arithmetic, a : b :: c : ?"""
import torch

saved = torch.load("embeddings.pt", weights_only=True)
E, words = saved["E"], saved["words"]
index = {w: i for i, w in enumerate(words)}
for a, b, c in [("kopi", "panas", "jus"), ("surabaya", "kereta", "medan"),
                ("kucing", "rumah", "sapi"), ("kemeja", "disetrika", "sprei")]:
    target = E[index[b]] - E[index[a]] + E[index[c]]
    sims = E @ (target / target.norm())
    for w in (a, b, c):
        sims[index[w]] = -2.0                    # do not answer with the question
    best = torch.argsort(sims, descending=True)[:3].tolist()
    answer = ", ".join(f"{words[i]} {sims[i]:.2f}" for i in best)
    print(f"{a} : {b} :: {c} : ?   ->  {answer}")
```

```
kopi : panas :: jus : ?   ->  dingin 0.76, siang 0.65, segar 0.62
surabaya : kereta :: medan : ?   ->  makassar 0.68, ke 0.67, cuaca 0.62
kucing : rumah :: sapi : ?   ->  rumput 0.77, kamar 0.69, bebek 0.67
kemeja : disetrika :: sprei : ?   ->  dicuci 0.83, handuk 0.81, selimut 0.80
```

The first and the last work: *jus* is to *dingin* as *kopi* is to *panas*, and *sprei* is *dicuci* (washed) as *kemeja* is *disetrika* (ironed). In both, the corpus expresses the relation consistently with a single word per sub-group: every hot drink appears with *panas*, every cold one with *dingin*; every piece of clothing with *disetrika*, every piece of bedding with *dicuci*. The third gives *rumput* (grass) rather than *kandang*, a reasonable answer, since farm animals appear with both. The second fails: the answer should be *pesawat*, but the difference between *kereta* and *surabaya* is dominated by everything else that separates a vehicle from a city, and *medan* has too little text of its own for the travel relation to stand out. Analogies are a fragile test; they are fun, but not a reliable measure of quality.

Solution 5. In our corpus every color fills the slot `{color}` in exactly the same templates, and every family member fills `{person}` in exactly the same templates, chosen at random. Their contexts have the same distribution, so nothing in the training objective can tell them apart, and their vectors converge. They would differ if the corpus contained sentences where they behave differently, for example *langit biru* (blue sky) and *cabai merah* (red chili), or *ibu memasak* and *ayah menyetir*; real text is full of such differences.

Solution 6. With one shared vector per word, the score of the pair (*es*, *es*) would be $\mathbf{v}_{\text{es}} \cdot \mathbf{v}_{\text{es}} = \|\mathbf{v}_{\text{es}}\|^2$, which is always positive and large for a well-trained word, so the model would be forced to believe that every word is a likely neighbor of itself. Words rarely appear next to themselves, and two separate vectors let the model say so. Separate tables also make each word's role as center and as context independent, which gives the optimizer more freedom. After training, one usually keeps the center vectors, as we do, or averages the two.

Chapter 38

Attention, Visualized

The RNN of Chapter 36 carried everything it had read in one small hidden state, updated letter by letter. By the tenth letter, the first had been squeezed through ten updates. *Attention* takes a different road: whenever the network needs information, it looks back at *all* the positions at once, decides how relevant each one is, and takes a weighted average of what they offer. That single operation is the heart of the Transformer (Chapter 39) and of every large language model in Part 9. This chapter builds it from scratch and, above all, makes it visible. By the end of the chapter you will be able to explain queries, keys and values with an everyday picture, compute scaled dot-product attention by hand for four words, write it as one matrix formula, train a one-layer attention model in PyTorch that learns to reverse, rotate and copy sequences of digits and draw its attention as a heat map, use attention as a soft dictionary that looks up values by their keys, show with a small experiment why the scores are divided by $\sqrt{d}$, and use a *causal mask* to stop a position from looking at the future. Everything trains in seconds.

38.1 Why Attention?

Think of a laundry counter with a wall of numbered cubbyholes, each holding a bag of washed clothes with a tag. A customer walks in and says “the blue bed sheet, under the name Wulan”. The clerk does not walk past the cubbyholes one by one, remembering each; she glances at all the tags at once, sees which ones match the request best, and pulls those bags. If two tags match equally well she might bring both.

That is attention. The request is a *query*. Each tag is a *key*. The contents of the bag are the *value*. The clerk compares the query with every key, turns the comparisons into weights, and returns a weighted combination of the values. Nothing has to be carried along step by step, and the first cubbyhole is exactly as easy to reach as the last.

Attention entered neural networks through machine translation. In 2015, Bahdanau, Cho and Bengio let a translation network, while writing each word of the output sentence, look back at all words of the input sentence with learned weights, instead of relying on a single summary vector [1], [2]. Their network learned, without being told, which source words correspond to which target words. In 2017 Vaswani and colleagues went all the way: their Transformer uses attention *instead* of recurrence, and its title, “Attention is all you need”, turned out to be close to true [3]. Almost every modern language, speech and vision model now contains the operation this chapter builds.

There is one more reason to study attention, which gives the chapter its title: its weights can be drawn. For each output, we can see which inputs it looked at and how strongly. That makes attention one of the few places inside a neural network where we can watch the computation, although, as Section 38.7 warns, we must be careful how much we read into the pictures.

38.2 The Idea in Plain Words

Attention takes three kinds of vectors.

- A **query** says what the current position is looking for.
- Each position of the input offers a **key**, which says what it contains, in a form that queries can be compared with.
- Each position also offers a **value**, which is what it passes on if it is chosen.

The computation has three steps. First, compare the query with every key by a dot product: a large product means a good match. Second, turn the list of scores into weights that are positive and add up to 1, with the softmax you know from Chapter 32. Third, return the weighted average of the values. That is all.

Keys and values are separate on purpose. A cubbyhole's tag ("Wulan, bed sheet, blue") is what you *search by*; the bag is what you *take away*. In a network, keys and values are both computed from the same input positions, but by different learned weight matrices, so the network can learn what to search by and what to pass on independently.

Where do the queries come from? That depends on the model. In this chapter's first model, each output position has its own learned query, a fixed question like "which input should output position 3 copy?". In the dictionary model of Section 38.6, the query is computed from a letter that the user asks about. In the Transformer of Chapter 39, every position computes a query from its own content and attends to the other positions of the same sequence, which is called *self-attention*.

> **KEY INSIGHT.** Attention is a differentiable dictionary lookup. Instead of returning the one value whose key matches exactly, it returns a blend of all values, weighted by how well their keys match the query, and because the blend is smooth, the network can learn what to look for by gradient descent.

38.3 The Mathematics, Gently

38.3.1 One query

Let the query be a vector $\mathbf{q}$ of length d, and let there be n input positions with keys $\mathbf{k}_1, \dots, \mathbf{k}_n$ and values $\mathbf{v}_1, \dots, \mathbf{v}_n$. The *score* of position j is the scaled dot product

$$s_j = \frac{\mathbf{q} \cdot \mathbf{k}_j}{\sqrt{d}} \tag{38.1}$$

The weights are the softmax of the scores,

$$a_j = \frac{e^{s_j}}{\sum_{m=1}^{n} e^{s_m}} \tag{38.2}$$

so every a_j is positive and $a_1 + \cdots + a_n = 1$. The output is the weighted average of the values:

$$\mathbf{o} = \sum_{j=1}^{n} a_j \, \mathbf{v}_j \tag{38.3}$$

Because the weights are positive and sum to one, $\mathbf{o}$ always lies "between" the values: it is a *convex combination* of them. With one weight near 1 and the others near 0, attention picks a single value; with equal weights it averages them all.

38.3.2 A worked example with four words

Take the phrase *ibu minum kopi panas* (mother drinks hot coffee). Give each word a 3-dimensional key and a 2-dimensional value, chosen by hand so that the numbers are easy to follow:

Table 38.1 Hand-made keys and values for the four words of the worked example.

Word	Key	Value
ibu (mother)	(1,0,0)	(1,0)
minum (drink)	(0,1,0)	(0,1)
kopi (coffee)	(0,0.8,0.6)	(0.5,0.5)
panas (hot)	(0,0.2,1)	(0.2,0.9)

Suppose the verb *minum* asks the query $\mathbf{q} = (0,1,0.5)$, "what is being drunk?", which matches keys with a large second and a moderate third coordinate. With $d = 3$, $\sqrt{3} = 1.732$, Equation (38.1) gives

- *ibu*: $(0 + 0 + 0)/1.732 = 0$,
- *minum*: $(0 + 1 + 0)/1.732 = 0.577$,
- *kopi*: $(0 + 0.8 + 0.3)/1.732 = 0.635$,
- *panas*: $(0 + 0.2 + 0.5)/1.732 = 0.404$.

The exponentials are $e^{0} = 1$, $e^{0.577} = 1.781$, $e^{0.635} = 1.887$ and $e^{0.404} = 1.498$, with sum 6.166, so by Equation (38.2) the weights are 0.16, 0.29, 0.31 and 0.24. *Kopi* receives the most attention, as intended, but only a little more than the others: the scores are close, and softmax of close scores is fairly flat. By Equation (38.3) the output is

$$\mathbf{o} = 0.16\,(1,0) + 0.29\,(0,1) + 0.31\,(0.5,0.5) + 0.24\,(0.2,0.9) = (0.36,0.66).$$

Figure 38.1 draws both steps: the scores and weights on the left, and on the right the four values as circles sized by their weights, with the output, a star, inside the region they span.

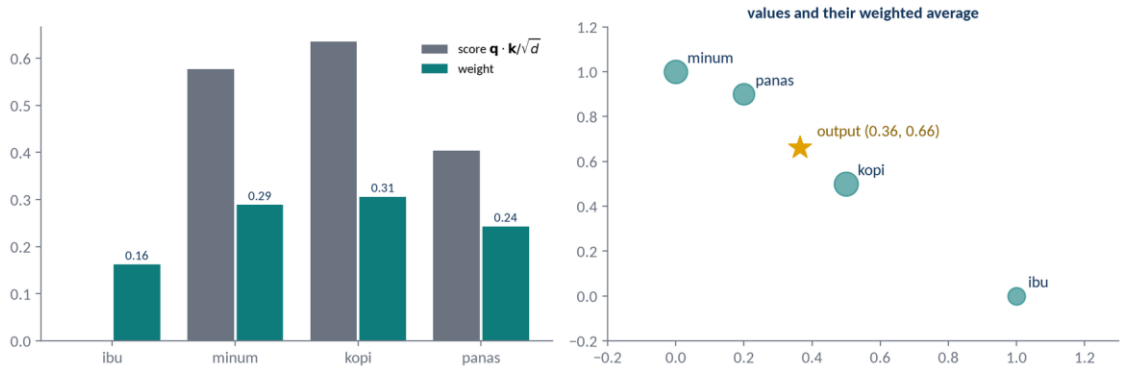

Figure 38.1 The worked example. Left: the scores of Equation (38.1) and the softmax weights of Equation (38.2). Right: the values of **Table 38.1**, sized by weight, and the output of Equation (38.3), their weighted average.

38.3.3 Many queries at once

In practice there are many queries, one per output position. Stack them as the rows of a matrix Q ($n_q \times d$), the keys as rows of K ($n \times d$) and the values as rows of V ($n \times d_v$). Then all scores are the matrix product $QK^{\top}$, and the whole of Equation (38.1), Equation (38.2) and Equation (38.3) becomes one line, the formula of the Transformer paper [3]:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^\top}{\sqrt{d}}\right)V \tag{38.4}$$

where the softmax is applied to each row separately. The matrix of weights, $A = \text{softmax}\left(QK^\top/\sqrt{d}\right)$, has one row per query and one column per input position, and every row sums to 1. That matrix is what we will draw.

The queries, keys and values are not usually given directly; they are computed from the input vectors X by learned matrices:

$$Q = X_q W_Q, \qquad K = XW_K, \qquad V = XW_V \tag{38.5}$$

where X_q holds whatever the queries are computed from. Learning W_Q, W_K and W_V is how the network learns what to look for, what to offer as a key, and what to pass on.

38.3.4 Why divide by $\sqrt{d}$?

Suppose the entries of **q** and **k** are independent random numbers with mean 0 and variance 1, as they roughly are at the start of training. Their dot product $\sum_{i=1}^{d} q_i\, k_i$ is a sum of d independent terms, each with mean 0 and variance $1 \cdot 1 = 1$, and variances of independent terms add:

$$\text{Var}(\mathbf{q} \cdot \mathbf{k}) = \sum_{i=1}^{d} \text{Var}\,(q_i k_i) = d, \qquad \text{so the typical size of } \mathbf{q} \cdot \mathbf{k} \text{ is } \sqrt{d} \tag{38.6}$$

With $d = 256$ the raw scores are typically around ± 16. The softmax of numbers that far apart puts almost all the weight on the largest one: it *saturates*. A saturated softmax has tiny gradients for all the losing positions, so the network cannot easily learn to shift its attention. Dividing by $\sqrt{d}$ brings the scores back to a typical size of 1, whatever the dimension. Section 38.6 measures both effects.

38.3.5 Masks

Sometimes a position must not look at certain others. A language model that predicts the next word must not look at that word; a translation model must not attend to padding. We enforce this by setting the forbidden scores to $-\infty$ before the softmax, because $e^{-\infty} = 0$. The *causal mask* forbids every position i from attending to any later position j:

$$s_{ij} = -\infty \quad \text{whenever } j > i \tag{38.7}$$

After the softmax, row i of the weight matrix has zeros to the right of the diagonal. Exercise 38.4 shows what that does to a task that needs the future.

38.4 Building It Step by Step

The code is in `Chapter038` and uses NumPy 2.4.6 for the worked example and PyTorch 2.14 for the rest.

38.4.1 The worked example in code

Listing 38.1 is Section 38.3.2 in NumPy: the keys and values of **Table 38.1**, the query, and Equation (38.1), Equation (38.2) and Equation (38.3), one line each.

Listing 38.1 `attention_by_hand.py`: scaled dot-product attention for one query and four words.

```
"""Scaled dot-product attention, step by step, on four words (Chapter 38)."""
import numpy as np

np.set_printoptions(precision=2, suppress=True)
words = ["ibu", "minum", "kopi", "panas"]
# keys: what each word offers; values: what each word passes on
K = np.array([[1.0, 0.0, 0.0],      # ibu:   a person
              [0.0, 1.0, 0.0],      # minum: an action
              [0.0, 0.8, 0.6],      # kopi:  a drink, linked to actions
              [0.0, 0.2, 1.0]])     # panas: a property
V = np.array([[1.0, 0.0],
              [0.0, 1.0],
              [0.5, 0.5],
              [0.2, 0.9]])
q = np.array([0.0, 1.0, 0.5])       # "minum" asks: what is being drunk?

d = K.shape[1]
scores = K @ q / np.sqrt(d)                     # one score per word
weights = np.exp(scores) / np.exp(scores).sum() # softmax
output = weights @ V                            # weighted average of values
for w, s, a in zip(words, scores, weights):
    print(f"{w:6s} score {s:5.2f}   weight {a:.2f}")
print("output (weighted average of the values):", output)
```

```
python attention_by_hand.py
```

```
ibu    score  0.00   weight 0.16
minum  score  0.58   weight 0.29
kopi   score  0.64   weight 0.31
panas  score  0.40   weight 0.24
output (weighted average of the values): [0.36 0.66]
```

The numbers match the hand calculation.

38.4.2 A model that learns where to look

To see attention *learned*, we need a task where the right place to look is known, so we can check the picture. **Listing 38.2** defines three tasks on sequences of eight random digits: *reverse* (output position i must show input $7 - i$), *rotate* (output i shows input $i + 3$, wrapping around) and *copy*. A model that solves one of them must learn to look at exactly one input per output.

Listing 38.2 `attn_model.py`: three rearrangement tasks and a one-layer attention model with learned queries.

```
"""One attention layer that learns to rearrange a sequence (Chapter 38)."""
import math
import torch
from torch import nn

LENGTH, DIGITS = 8, 10
TASKS = {
    "reverse": lambda x: x.flip(1),                  # out[i] = in[7 - i]
    "rotate": lambda x: x.roll(-3, dims=1),          # out[i] = in[i + 3]
    "copy": lambda x: x,                             # out[i] = in[i]
}

def make_data(n, task, generator):
    x = torch.randint(0, DIGITS, (n, LENGTH), generator=generator)
    return x, TASKS[task](x)

class AttentionRearranger(nn.Module):
    """Output position i asks a learned query; input positions answer."""

    def __init__(self, d=32, scale=True):
        super().__init__()
        self.tok = nn.Embedding(DIGITS, d)
        self.pos = nn.Embedding(LENGTH, d)
        self.query = nn.Parameter(torch.randn(LENGTH, d) * 0.1)  # one per output
        self.W_k = nn.Linear(d, d, bias=False)
        self.W_v = nn.Linear(d, d, bias=False)
        self.out = nn.Linear(d, DIGITS)
        self.scale = 1 / math.sqrt(d) if scale else 1.0

    def forward(self, x):
        h = self.tok(x) + self.pos(torch.arange(LENGTH))   # (B, L, d)
        K, V = self.W_k(h), self.W_v(h)
        scores = self.query @ K.transpose(1, 2) * self.scale  # (B, L, L)
        A = torch.softmax(scores, dim=-1)                # each row sums to 1
        return self.out(A @ V), A                        # logits, attention
```

Listing 38.2 (Continued) *attn_model.py: three rearrangement tasks and a one-layer attention model with learned queries.*

```
def train(task, steps=1500, d=32, scale=True, lr=0.01, seed=0):
    torch.manual_seed(seed)
    gen = torch.Generator().manual_seed(seed)
    model = AttentionRearranger(d, scale)
    opt = torch.optim.Adam(model.parameters(), lr=lr)
    history = []
    for step in range(steps):
        x, y = make_data(64, task, gen)
        logits, _ = model(x)
        loss = nn.functional.cross_entropy(logits.reshape(-1, DIGITS),
                                           y.reshape(-1))
        opt.zero_grad()
        loss.backward()
        opt.step()
        history.append(loss.item())
    return model, history

def accuracy(model, task, n=1000, seed=123):
    x, y = make_data(n, task, torch.Generator().manual_seed(seed))
    with torch.no_grad():
        pred = model(x)[0].argmax(-1)
    right = pred == y
    return right.float().mean().item(), right.all(1).float().mean().item()
```

- `TASKS` defines each task as a function from input tensor to target tensor. `flip(1)` reverses along the sequence; `roll(-3, dims=1)` shifts every element three places to the left, wrapping around.
- `make_data` draws random digit sequences with a given generator, so data is unlimited and never repeats: the model cannot memorize, it must learn the rule.
- In `AttentionRearranger`, every input position is described by the sum of its digit's embedding and its position's embedding, `h`. Keys and values are linear maps of `h`, as in Equation (38.5). The queries are a learned parameter, one vector per output position: output position 3 asks the same question for every sequence, "where is my digit?". The scores are $QK^\top$ times the scale factor, the softmax gives the weight matrix `A` of Equation (38.4), and `A @ V` is the attended output, which a final linear layer turns into 10 digit scores. The model returns the weights too, so we can draw them. With `scale=False` the division by $\sqrt{d}$ is switched off, for the experiment of Section 38.6.
- `train` runs 1,500 Adam steps on fresh batches of 64 sequences; `accuracy` measures, on 1,000 new sequences, the fraction of correct digits and of completely correct sequences.

Listing 38.3 trains one model per task and saves it.

Listing 38.3 `train_attention.py`: training the attention model on the three tasks.

```
"""Train the attention layer on three rearrangement tasks (Chapter 38)."""
import time
import torch
from attn_model import accuracy, train

torch.set_num_threads(1)
for task in ("reverse", "rotate", "copy"):
    start = time.perf_counter()
    model, history = train(task)
    per_digit, per_seq = accuracy(model, task)
    print(f"{task:8s} loss {history[0]:.2f} -> {history[-1]:.4f}  "
          f"digits right {per_digit:.3f}  sequences right {per_seq:.3f}  "
          f"({time.perf_counter() - start:.1f} s)")
    torch.save(model.state_dict(), f"attn_{task}.pt")
```

38.4.3 The application

Listing 38.4 lets you type eight digits and see what a trained model does with them. It prints the result and then the attention matrix as text: one row per output position, one column per input digit, with darker characters for larger weights, and, at the end of each row, which input received the most attention.

Listing 38.4 `attn_app.py`: rearranging digits and drawing the attention weights.

```
"""See where attention looks: rearrange 8 digits and draw the weights.

usage: python attn_app.py TASK DIGITS    e.g.  python attn_app.py reverse 20250917
       TASK is reverse, rotate or copy   (run train_attention.py first)
"""
import sys
import torch
from attn_model import LENGTH, AttentionRearranger

SHADES = " .:-=+*#%@"
task = sys.argv[1] if len(sys.argv) > 1 else "reverse"
digits = sys.argv[2] if len(sys.argv) > 2 else "31415926"
if len(digits) != LENGTH or not digits.isdigit():
    sys.exit(f"please give exactly {LENGTH} digits")

model = AttentionRearranger()
model.load_state_dict(torch.load(f"attn_{task}.pt", weights_only=True))
x = torch.tensor([[int(c) for c in digits]])
with torch.no_grad():
    logits, A = model(x)
answer = "".join(str(d) for d in logits.argmax(-1)[0].tolist())
print(f"task {task}: {digits} -> {answer}")
print("attention (rows: output positions, columns: input digits)")
print("        " + "  ".join(digits))
for i, row in enumerate(A[0]):
    cells = "  ".join(SHADES[min(int(w * 10), 9)] for w in row.tolist())
    best = int(row.argmax())
    print(f"  out {i}  {cells}   <- input {best} ('{digits[best]}') "
          f"weight {row[best]:.2f}")
```

38.4.4 Tests

Listing 38.5 checks that each row of the attention matrix is a probability distribution (non-negative, summing to 1), that the task functions do what their names say, and, for the dictionary task of Section 38.6, that the answer really is the value stored under the query's key.

Listing 38.5 `test_attention.py`: unit tests for the attention models and the tasks.

```
"""Unit tests for the attention models (run: python -m unittest)."""
import unittest
import torch
from attn_model import LENGTH, AttentionRearranger, TASKS
from lookup import LookupAttention, make_lookup

class AttentionTest(unittest.TestCase):
    def test_weights_are_a_distribution(self):
        x = torch.randint(0, 10, (3, LENGTH))
        _, A = AttentionRearranger()(x)
        self.assertEqual(tuple(A.shape), (3, LENGTH, LENGTH))
        self.assertTrue(torch.allclose(A.sum(-1), torch.ones(3, LENGTH)))
        self.assertTrue((A >= 0).all())

    def test_tasks(self):
        x = torch.tensor([[0, 1, 2, 3, 4, 5, 6, 7]])
        self.assertEqual(TASKS["reverse"](x)[0].tolist(), [7, 6, 5, 4, 3, 2, 1, 0])
        self.assertEqual(TASKS["rotate"](x)[0].tolist(), [3, 4, 5, 6, 7, 0, 1, 2])

    def test_lookup_answer_is_stored_under_query(self):
        k, v, q, a = make_lookup(50, torch.Generator().manual_seed(0))
        for i in range(50):
            j = k[i].tolist().index(q[i].item())
            self.assertEqual(v[i, j].item(), a[i].item())
        logits, A = LookupAttention()(k, v, q)
        self.assertEqual(tuple(logits.shape), (50, 10))

if __name__ == "__main__":
    unittest.main()
```

38.5 Running It

```
python train_attention.py
```

```
reverse  loss 2.34 -> 0.0000  digits right 1.000  sequences right 1.000  (5.2 s)
rotate   loss 2.34 -> 0.0000  digits right 1.000  sequences right 1.000  (5.1 s)
copy     loss 2.34 -> 0.0000  digits right 1.000  sequences right 1.000  (4.2 s)
```

All three tasks are learned perfectly in a few seconds: the loss starts at 2.34, close to $\log 10 = 2.30$ for guessing among ten digits, and falls to zero, and all 1,000 test sequences come out exactly right. Now let us look inside, with the date 17 September 2025 written as eight digits:

```
python attn_app.py reverse 20250917
```

```
task reverse: 20250917 -> 71905202
attention (rows: output positions, columns: input digits)
        2  0  2  5  0  9  1  7
  out 0                     @   <- input 7 ('7') weight 0.97
  out 1                  @      <- input 6 ('1') weight 0.97
  out 2               @         <- input 5 ('9') weight 0.99
  out 3            @            <- input 4 ('0') weight 0.98
  out 4         @               <- input 3 ('5') weight 0.95
  out 5      @                  <- input 2 ('2') weight 0.99
  out 6   @                     <- input 1 ('0') weight 0.96
  out 7 @                       <- input 0 ('2') weight 0.96
```

Output position 0 puts 97% of its attention on input position 7, output 1 on input 6, and so on: the attention matrix is the anti-diagonal, exactly the reversal. The rotation model on the same digits:

```
python attn_app.py rotate 20250917
```

```
task rotate: 20250917 -> 50917202
attention (rows: output positions, columns: input digits)
        2  0  2  5  0  9  1  7
  out 0           @              <- input 3 ('5') weight 0.94
  out 1              @           <- input 4 ('0') weight 0.98
  out 2                 @        <- input 5 ('9') weight 0.99
  out 3                    @     <- input 6 ('1') weight 0.98
  out 4                       @  <- input 7 ('7') weight 0.97
  out 5  @                       <- input 0 ('2') weight 0.91
  out 6     @                    <- input 1 ('0') weight 0.95
  out 7        @                 <- input 2 ('2') weight 0.99
```

Output 0 looks at input 3, output 1 at input 4, and outputs 5, 6, 7 wrap around to inputs 0, 1, 2. **Figure 38.2** draws the three learned attention matrices side by side. Each is a clean permutation pattern, the rule of its task made visible: nobody told the model to attend this way, it discovered that attending this way minimizes the loss.

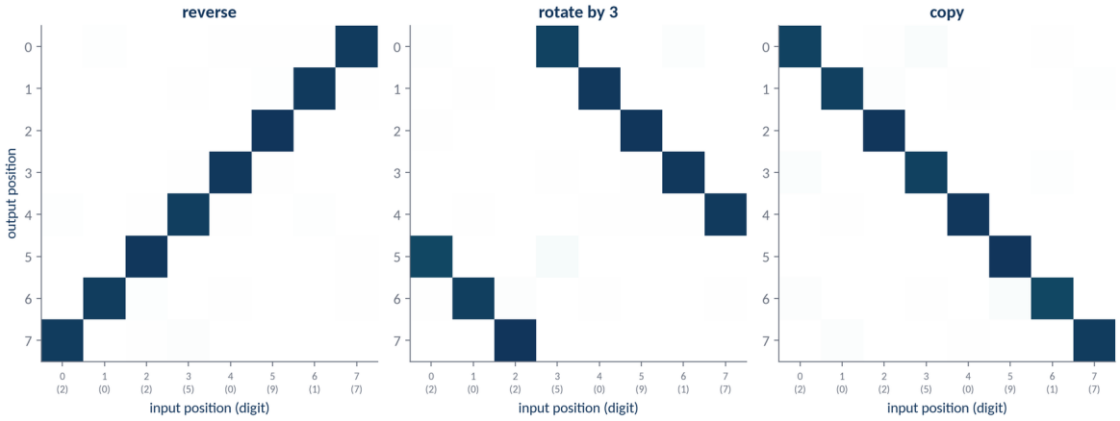

Figure 38.2 The attention weights of the three trained models for the input 20250917. Rows are output positions, columns input positions (with their digits); darker means more attention.

Notice that the pictures would look the same for any input digits, because in these tasks *where* to look depends only on position, never on content. The queries are fixed per output position, and the keys that matter come from the position embeddings. The next section gives the model a task where content matters.

The tests:

```
python -m unittest
```

```
...
----------------------------------------------------------------------
Ran 3 tests in 0.059s

OK
```

38.6 Improving It: Looking Up by Content, and Scaling

38.6.1 Attention as a soft dictionary

In **Listing 38.6**, each example is a small dictionary of six records, each a (key letter, value digit) pair such as *j: 9*, plus a query letter that is one of the six keys. The answer is the digit stored under the query. Here the query is computed from the query letter, and the keys and values from the records, as in Equation (38.5); the model must learn to match letters by *content*.

Listing 38.6 `lookup.py`: the dictionary-lookup task and an attention model that solves it.

```
"""Attention as a soft dictionary: find the value stored under a key (Ch. 38).

A sample holds 6 records (key letter, value digit) and one query letter;
the answer is the digit stored under the query's key.
"""
import math
import torch
from torch import nn

KEYS, VALUES, RECORDS = 26, 10, 6

def make_lookup(n, generator):
    keys = torch.stack([torch.randperm(KEYS, generator=generator)[:RECORDS]
                        for _ in range(n)])                  # distinct keys
    values = torch.randint(0, VALUES, (n, RECORDS), generator=generator)
    pick = torch.randint(0, RECORDS, (n,), generator=generator)
    query = keys[torch.arange(n), pick]
    answer = values[torch.arange(n), pick]
    return keys, values, query, answer

class LookupAttention(nn.Module):
    def __init__(self, d=64, scale=True):
        super().__init__()
        self.key_emb = nn.Embedding(KEYS, d)
        self.val_emb = nn.Embedding(VALUES, d)
        self.W_q = nn.Linear(d, d, bias=False)
        self.W_k = nn.Linear(d, d, bias=False)
        self.W_v = nn.Linear(d, d, bias=False)
        self.out = nn.Linear(d, VALUES)
        self.scale = 1 / math.sqrt(d) if scale else 1.0

    def forward(self, keys, values, query):
        records = self.key_emb(keys) + self.val_emb(values)   # (B, R, d)
        q = self.W_q(self.key_emb(query)).unsqueeze(1)        # (B, 1, d)
        scores = q @ self.W_k(records).transpose(1, 2) * self.scale
        A = torch.softmax(scores, dim=-1)                     # (B, 1, R)
        return self.out((A @ self.W_v(records)).squeeze(1)), A.squeeze(1)
```

Listing 38.6 (Continued) *lookup.py: the dictionary-lookup task and an attention model that solves it.*

```
def train_lookup(d=64, scale=True, steps=600, lr=0.003, seed=0):
    torch.manual_seed(seed)
    gen = torch.Generator().manual_seed(seed)
    model = LookupAttention(d, scale)
    opt = torch.optim.Adam(model.parameters(), lr=lr)
    history = []
    for step in range(steps):
        k, v, q, a = make_lookup(128, gen)
        loss = nn.functional.cross_entropy(model(k, v, q)[0], a)
        opt.zero_grad()
        loss.backward()
        opt.step()
        history.append(loss.item())
    return model, history

def lookup_accuracy(model, n=2000, seed=123):
    k, v, q, a = make_lookup(n, torch.Generator().manual_seed(seed))
    with torch.no_grad():
        return (model(k, v, q)[0].argmax(1) == a).float().mean().item()
```

Each record is embedded as the sum of its key letter's and its value digit's embeddings. `W_q` turns the query letter into a query vector, `W_k` and `W_v` turn records into keys and values, and one attention step retrieves a blend of values, from which the output layer reads the digit. **Figure 38.3** shows the attention weights of a trained model (dimension 64, 600 training steps) on one new example: the query *j* puts essentially all of its weight on the record *j: 9*, and the prediction is 9. The dictionary lookup has been learned end to end, from examples, without any rule saying "compare letters".

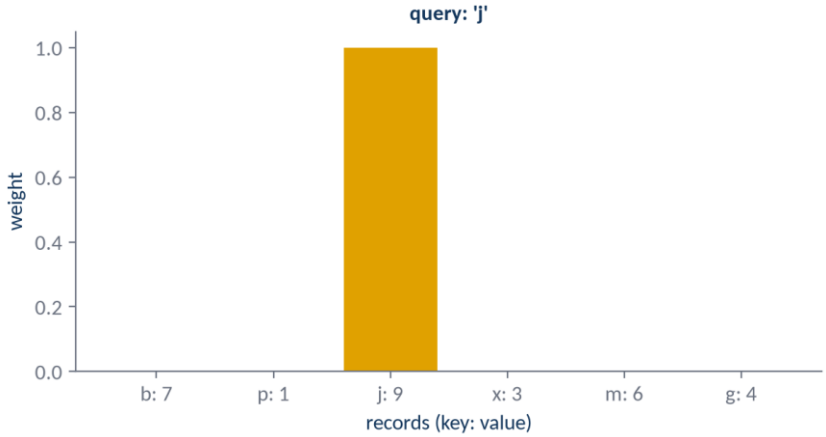

Figure 38.3 Attention weights of the trained lookup model for one example. The query letter *j* attends to the record whose key is *j* (amber) and retrieves its value, 9.

38.6.2 Measuring the $\sqrt{d}$ effect

Listing 38.7 first checks Equation (38.6) with random vectors, then trains the lookup model with dimension 256 with and without the scaling.

Listing 38.7 `improve.py`: softmax saturation with and without the $\sqrt{d}$ scaling, and its effect on training.

```
"""Why divide by sqrt(d)? Softmax saturation, then the lookup task (Ch. 38)."""
import math
import torch
from lookup import lookup_accuracy, train_lookup

torch.set_num_threads(1)
gen = torch.Generator().manual_seed(0)
print("random query and 6 random keys, entries ~ N(0, 1):")
for d in (4, 64, 256):
    q = torch.randn(1000, 1, d, generator=gen)
    K = torch.randn(1000, 6, d, generator=gen)
    raw = (q @ K.transpose(1, 2)).squeeze(1)
    for label, s in [("raw", raw), ("/sqrt(d)", raw / math.sqrt(d))]:
        top = torch.softmax(s, dim=-1).max(dim=-1).values.mean().item()
        print(f"  d={d:3d} {label:9s} score std {s.std():6.2f}   "
              f"average largest weight {top:.2f}")

print("lookup task, d = 256, 600 steps:")
for scale in (True, False):
    model, h = train_lookup(d=256, scale=scale)
    tail = torch.tensor(h[-100:])
    print(f"  {'scaled' if scale else 'unscaled':8s}  last-100 loss mean "
          f"{tail.mean():.3f}, max {tail.max():.3f}   "
          f"accuracy {lookup_accuracy(model):.3f}")
```

```
python improve.py
```

```
random query and 6 random keys, entries ~ N(0, 1):
  d=  4 raw       score std   1.99   average largest weight 0.57
  d=  4 /sqrt(d)  score std   1.00   average largest weight 0.39
  d= 64 raw       score std   7.89   average largest weight 0.88
  d= 64 /sqrt(d)  score std   0.99   average largest weight 0.41
  d=256 raw       score std  16.15   average largest weight 0.94
  d=256 /sqrt(d)  score std   1.01   average largest weight 0.42
lookup task, d = 256, 600 steps:
  scaled    last-100 loss mean 0.000, max 0.001   accuracy 1.000
  unscaled  last-100 loss mean 0.238, max 0.517   accuracy 0.979
```

The first table confirms Equation (38.6): raw scores have standard deviation about $2 = \sqrt{4}$, $8 = \sqrt{64}$ and $16 = \sqrt{256}$, and after dividing by $\sqrt{d}$ they are about 1 in every case. With raw scores, the average largest of six weights climbs from 0.57 to 0.94 as d grows, even though the vectors are random and no position deserves special attention; scaled, it stays near 0.4. The left panel of **Figure 38.4** plots this for eight dimensions.

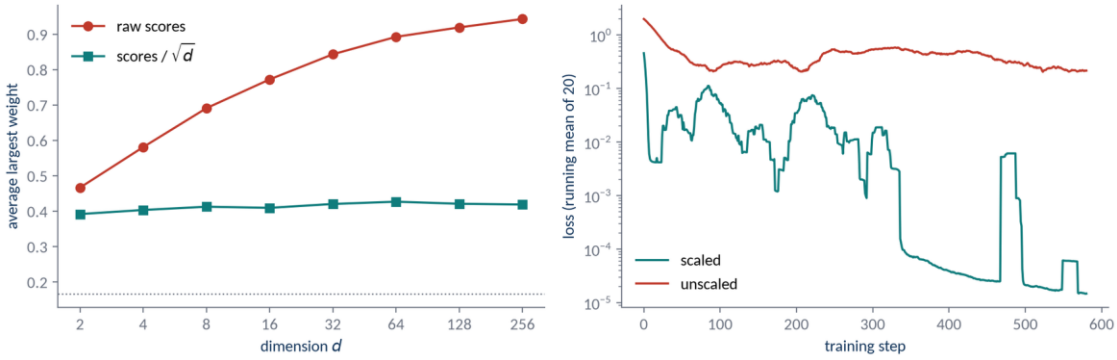

Figure 38.4 Left: the average largest attention weight among six random keys, with raw and scaled scores, as the dimension grows; the dotted line is the uniform 1/6. Right: training loss of the lookup model with $d = 256$, with and without scaling (running mean over 20 steps, logarithmic axis).

The training runs show why it matters. With scaling, the model with $d = 256$ solves the lookup task perfectly: its loss over the last 100 steps averages 0.000 and its test accuracy is 100%. Without scaling, the same model trains erratically: the loss wanders between about 0.2 and 0.5 (right panel of **Figure 38.4**), and the accuracy stays at 97.9%. The saturated softmax sends almost no gradient to positions that are currently losing, so a wrong early preference is hard to correct. At $d = 32$ or 64 the difference is small, which is why the rearrangement tasks did not need it; at the dimensions of real models, 64 to 128 per attention head and more, it is essential.

38.6.3 Beyond one head

Real models improve on this chapter's layer in two ways that Chapter 39 implements. *Multi-head attention* runs several attention operations in parallel, each with its own W_Q, W_K, W_V of a smaller dimension, and concatenates their outputs, so that one head can track position while another tracks content. And *self-attention* computes queries, keys and values from the same sequence, so that every position can gather information from every other; stacking such layers builds up context step by step.

38.7 Common Mistakes, and How to Avoid Them

Softmax over the wrong axis. The weights must sum to 1 over the *input positions* for each query, which is the last axis of $QK^\top$. Normalizing over the queries instead produces weights that look plausible and are meaningless. The test in **Listing 38.5** checks the row sums.

Forgetting the scale. Without $1/\sqrt{d}$, attention saturates at large dimensions, as Section 38.6 showed. PyTorch's built-in `scaled_dot_product_attention` applies it for you [4].

Masking with zero instead of $-\infty$. Setting a forbidden score to 0 does not forbid anything: $e^0 = 1$. Masks must be applied to the scores *before* the softmax, with $-\infty$ (or a very large negative number), as in Equation (38.7).

Reading attention maps as explanations. Our heat maps are exact because the tasks are simple and single-layer. In deep models, a large weight does not necessarily mean that an input was *important* for the decision: values can be small, later layers can mix everything again, and different weight patterns can give the same output. Jain and Wallace showed that attention weights often do not line up with other measures of importance [5], and Wiegreffe and Pinter showed when they can still be informative [6]. Treat attention maps as a view of the mechanism, not as a verdict on why the model decided something.

Quadratic cost. The weight matrix has one entry per (query, key) pair: for a sequence of n tokens attending to itself, n^2 entries. For $n = 8$ that is 64; for a document of 100,000 tokens it is ten billion. Long-context models use special techniques to avoid storing it all.

38.8 Chapter Summary

- Attention compares a query with every key (Equation (38.1)), turns the scores into weights with a softmax (Equation (38.2)), and returns the weighted average of the values (Equation (38.3)); in matrix form, $\text{softmax}\left(QK^\top/\sqrt{d}\right)V$ (Equation (38.4)), with learned projections (Equation (38.5)).
- The weights can be drawn: a one-layer model with learned queries learns reversal, rotation and copying perfectly, and its attention matrices show the permutations.
- With queries computed from content, attention works as a soft dictionary, retrieving the value stored under a matching key.
- Dot products of d-dimensional random vectors have size about $\sqrt{d}$ (Equation (38.6)); dividing by it prevents saturation, and at $d = 256$ it is the difference between perfect and erratic training.
- A causal mask (Equation (38.7)) stops positions from seeing the future; attention maps are views of the mechanism, not explanations.

38.9 Exercises

1. Two positions have keys $\mathbf{k}_1 = (2,0)$ and $\mathbf{k}_2 = (0,2)$ and values $\mathbf{v}_1 = (10)$ and $\mathbf{v}_2 = (20)$. Compute the attention output for the queries (1,0), (1,1) and (0,3), with $d = 2$.
2. In the worked example of Section 38.3.2, what query would make *panas* receive the largest weight? Give one and verify it with Equation (38.1).
3. Show that if all keys are equal, every query gives equal weights, whatever it is. What is the output then?
4. Add a causal mask (Equation (38.7)) to the rearrangement model and train it on *copy* and on *reverse*. Report the accuracy per output position and explain the pattern.
5. For a sequence of n positions attending to itself with dimension d, how many multiplications does computing $QK^\top$ take? Evaluate for $n = 8, d = 32$ and for $n = 4096, d = 128$.

6. Why does the lookup model need the value digit to be part of each *record's* embedding, and not only of the value vectors? (Hint: which vectors are computed from what?)

38.10 Solutions to the Exercises

Solution 1. With $\sqrt{2} = 1.414$: for (1,0) the scores are $2/1.414 = 1.414$ and 0, the weights $e^{1.414}/(e^{1.414}+1) = 4.11/5.11 = 0.80$ and 0.20, and the output $0.80 \cdot 10 + 0.20 \cdot 20 = 12$. For (1,1) both scores are 1.414, the weights are 0.5 each, and the output is 15, the plain average. For (0,3) the scores are 0 and $6/1.414 = 4.24$, the weights $1/(1+69.6) = 0.014$ and 0.986, and the output $0.014 \cdot 10 + 0.986 \cdot 20 = 19.86$, almost exactly $\mathbf{v}_2$. The query's direction chooses, and its length sets how decisively.

Solution 2. *Panas* has key (0,0.2,1), with most of its weight on the third coordinate, which *kopi* shares only partly. The query (0,0,1) gives scores 0, 0, $0.6/1.732 = 0.346$ and $1/1.732 = 0.577$ for *ibu*, *minum*, *kopi*, *panas*: *panas* wins. Its weight is $e^{0.577}/(1+1+1.414+1.781) = 1.781/5.195 = 0.34$.

Solution 3. If $\mathbf{k}_j = \mathbf{k}$ for every j, every score is the same number $\mathbf{q} \cdot \mathbf{k}/\sqrt{d}$, and the softmax of n equal numbers is $1/n$ each. The output is the plain average of the values, $\frac{1}{n}\sum_j \mathbf{v}_j$. Attention can only discriminate between positions whose keys differ, which is why the rearrangement model adds position embeddings to the digit embeddings: without them, two positions holding the same digit would be indistinguishable.

Solution 4. **Listing 38.8** subclasses the model, sets the scores above the diagonal to $-\infty$, and trains both tasks.

Listing 38.8 `sol_causal.py`: the rearrangement model with a causal mask.

```python
"""Exercise 38.4: a causal mask forbids looking ahead (Chapter 38)."""
import torch
from torch import nn
from attn_model import DIGITS, LENGTH, AttentionRearranger, make_data

torch.set_num_threads(1)
MASK = torch.triu(torch.ones(LENGTH, LENGTH, dtype=torch.bool), diagonal=1)

class CausalRearranger(AttentionRearranger):
    def forward(self, x):
        h = self.tok(x) + self.pos(torch.arange(LENGTH))
        K, V = self.W_k(h), self.W_v(h)
        scores = self.query @ K.transpose(1, 2) * self.scale
        scores = scores.masked_fill(MASK, float("-inf"))   # no peeking ahead
        A = torch.softmax(scores, dim=-1)
        return self.out(A @ V), A

for task in ("copy", "reverse"):
    torch.manual_seed(0)
    gen = torch.Generator().manual_seed(0)
    model = CausalRearranger()
    opt = torch.optim.Adam(model.parameters(), lr=0.01)
    for step in range(1500):
        x, y = make_data(64, task, gen)
        loss = nn.functional.cross_entropy(model(x)[0].reshape(-1, DIGITS),
                                           y.reshape(-1))
        opt.zero_grad()
        loss.backward()
        opt.step()
    x, y = make_data(1000, task, torch.Generator().manual_seed(123))
    with torch.no_grad():
        right = (model(x)[0].argmax(-1) == y).float().mean(0)
    print(f"{task:8s} accuracy per output position: "
          + " ".join(f"{a:.2f}" for a in right.tolist()))
```

```
copy     accuracy per output position: 1.00 1.00 1.00 1.00 1.00 1.00 1.00 1.00
reverse  accuracy per output position: 0.09 0.10 0.09 0.11 1.00 1.00 1.00 1.00
```

Copy is still perfect, because output i needs input i, which the mask allows. *Reverse* is perfect for output positions 4 to 7 and at chance level (about 0.1) for positions 0 to 3. Output 0 needs input 7, which lies in its future; the mask hides it, so the model can only guess. Outputs 4 to 7 need inputs 3 to 0, all in the past. This is exactly the situation of a language model generating text: it may use everything already written, never what comes next, and Chapter 39 builds its Transformer with this mask.

Solution 5. $QK^\top$ is an $n \times n$ matrix, each entry a dot product of length d, so $n^2 d$ multiplications. For $n = 8, d = 32$: $64 \cdot 32 = 2048$. For $n = 4096, d = 128$: $16{,}777{,}216 \cdot 128 \approx 2.1 \times 10^9$ per head and per layer, and the product with V costs the same again. The n^2 factor is why long contexts are expensive.

Solution 6. The keys and values are both computed from the *same* record vector by different matrices, W_K and W_V. If the value digit were not in the record vector, W_V would have nothing to pass on but the key letter, and the model could find the right record but not read its digit. Putting both the key letter and the value digit into the record lets W_K learn to extract the letter (to be matched) and W_V to extract the digit (to be returned), the same division of labor as the tag and the bag in Section 38.1.

Chapter 39

A Tiny Transformer Language Model

The large language models of Part 9, the ones that answer questions, summarize documents and write code, are Transformers trained to do one thing: predict the next piece of text. This chapter builds one, small enough to read in a page and to train in half a minute on a laptop, from the parts of the last three chapters: embeddings (Chapter 37), attention (Chapter 38) and the character-level language modeling of Chapter 36. It reads and writes one character at a time and learns from a 9,000-character Indonesian story about a laundry, written for this book. By the end of the chapter you will be able to explain every part of a GPT-style Transformer block, namely token and position embeddings, multi-head causal self-attention, layer normalization, the feed-forward network and residual connections, write each as an equation, implement the whole model in about a hundred lines of PyTorch, count its 106,780 parameters by hand, train it with early stopping, generate text with temperature and top-k sampling, look at what its eight attention heads attend to, measure how much context and depth help compared with a bigram model, and see exactly why the causal mask is indispensable. The model is tiny, and its Indonesian is shaky, but its architecture is the architecture of the models you will use in Part 9.

39.1 Why Build a Transformer?

In Chapter 36 the RNN read a message one letter at a time and carried everything in a hidden state of 128 numbers. That design has two weaknesses. Information from far back must survive many updates, and the updates must happen one after another, so the computation cannot be spread over the thousands of cores of a modern graphics card. The Transformer of Vaswani and colleagues removed the recurrence altogether [1]. Every position looks directly at every earlier position through attention, and all positions of a sequence are computed at the same time. Radford and colleagues at OpenAI then showed that a stack of Transformer blocks trained only to predict the next token, the *GPT* recipe, learns a remarkable amount about language [2], [3]. Scaled up by factors of millions, the same recipe produces today's large language models.

Nothing in that recipe requires a data center to *understand*. Andrej Karpathy's *nanoGPT* showed that the whole architecture fits in a few hundred lines [4], and this chapter's model is smaller still: two blocks, four attention heads, 64 numbers per position. Building it yourself turns "large language model" from a mysterious service into a program whose every line you have read. When Chapter 81 connects to a local model with billions of parameters, you will know what is inside.

Our training text is `cerita.txt`: 132 short lines, about 9,000 characters, of plain Indonesian about Bu Wulan's laundry in Surabaya, her helper Adi and her granddaughter Sari, washing, ironing, coffee stains and a fifty-year-old kebaya. That is roughly a million times less text than a real language model reads, so we must not expect fluent Indonesian. We can expect, and will get, recognizable words, spaces and full stops in the right places, and names from the story.

39.2 The Idea in Plain Words

Picture the text as a row of characters. The model's job at every position is to guess the next character, using only the characters up to that position.

First, every character becomes a vector: an embedding for *which* character it is plus an embedding for *where* it is. The position embedding matters because attention by itself has no sense of order; Solution 38.3 showed that positions with identical keys cannot be told apart.

Then the vectors pass through a stack of identical *blocks*. Each block does two things.

- **Gather.** Every position asks a question (a query) and all earlier positions answer (keys and values): causal self-attention, from Chapter 38. It does this with several *heads* at once, each with its own small queries, keys and values, so that one head can, say, look at the previous character while another looks back to the start of the current word.
- **Think.** Every position then passes its gathered vector through a small two-layer network, the same network at every position, which can combine and transform what was gathered.

Each of the two steps *adds* its result to the vector it received rather than replacing it, a *residual connection*, and each starts by normalizing its input, *layer normalization*. Both are there to make deep stacks train smoothly.

Finally, the vector at each position is turned into 28 scores, one per character of the vocabulary, and softmax turns them into probabilities for the next character. Training is Chapter 36 again: cross-entropy against the actual next characters. Generating is Chapter 36 again too: draw a character, append it, repeat. **Figure 39.1** shows the whole model.

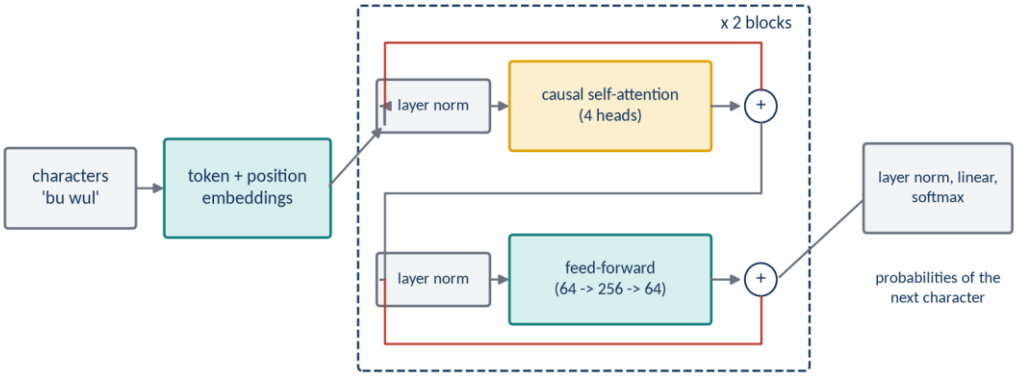

Figure 39.1 The tiny Transformer. Characters become token-plus-position vectors, pass through two identical blocks of causal self-attention and feed-forward layers, each wrapped in a layer norm and a residual connection (red lines), and end as probabilities for the next character.

> **KEY INSIGHT.** A GPT-style model is a stack of "gather from the past, then think" blocks, trained on nothing but next-token prediction. Everything it knows about the text it learned in order to make that single prediction better.

39.3 The Mathematics, Gently

Let the text be characters $c_1, c_2, \ldots$, each an index into a vocabulary of $V = 28$ symbols: the 23 letters that occur in the story (there is no *q*, *x* or *z*), plus space, comma, hyphen, full stop and newline. The model works on windows of at most $T = 48$ characters, the *context length*, with $d = 64$ numbers per position.

39.3.1 Embeddings

Position t of the window starts as the sum of two learned vectors:

$$\mathbf{x}_t = E_{\text{tok}}[c_t] + E_{\text{pos}}[t] \tag{39.1}$$

where E_{tok} is a $V \times d$ table (Chapter 37's lookup) and E_{pos} a $T \times d$ table, one learned vector per position. Stacking the $\mathbf{x}_t$ as rows gives a $T \times d$ matrix X.

39.3.2 Multi-head causal self-attention

With $h = 4$ heads, each head i has its own projections $W_Q^{(i)}, W_K^{(i)}, W_V^{(i)}$ of size $d \times d_k$, with $d_k = d/h = 16$. Each head computes the attention of Chapter 38 from X itself, with the causal mask of Equation (38.7) in Chapter 38:

$$\begin{aligned} \text{head}_i &= \text{softmax}\left(\frac{(XW_Q^{(i)})(XW_K^{(i)})^\top}{\sqrt{d_k}} + M\right) XW_V^{(i)}, \qquad \text{MHA}(X) \\ &= [\text{head}_1, \ldots, \text{head}_h]\, W_O \end{aligned} \tag{39.2}$$

Here M is the mask matrix, 0 on and below the diagonal and $-\infty$ above it, so position t attends only to positions $1, \ldots, t$. The square brackets mean placing the four $T \times 16$ results side by side into one $T \times 64$ matrix, and W_O ($d \times d$) mixes them. Four heads of size 16 cost the same as one head of size 64, but can attend to four different places.

39.3.3 Layer normalization

Before each sub-layer, every position's vector is normalized to mean 0 and variance 1 across its d entries, then scaled and shifted by learned vectors $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ [5]:

$$\text{LN}(\mathbf{x}) = \boldsymbol{\gamma} \odot \frac{\mathbf{x} - \mu}{\sqrt{\sigma^2 + \epsilon}} + \boldsymbol{\beta}, \qquad \mu = \frac{1}{d}\sum_i x_i\,, \quad \sigma^2 = \frac{1}{d}\sum_i (x_i - \mu)^2 \tag{39.3}$$

A worked example with $d = 4$: $\mathbf{x} = (1,2,3,6)$ has $\mu = 3$ and $\sigma^2 = (4 + 1 + 0 + 9)/4 = 3.5$, so with $\boldsymbol{\gamma} = \mathbf{1}$, $\boldsymbol{\beta} = \mathbf{0}$ and tiny ϵ, $\text{LN}(\mathbf{x}) = (-2, -1, 0, 3)/1.871 = (-1.07, -0.53, 0, 1.60)$. Whatever the scale of the input, the sub-layer sees numbers of a standard size, which keeps training stable.

39.3.4 The feed-forward network

The "think" step is a two-layer network applied to each position separately, widening to $4d = 256$ units and narrowing back:

$$\text{FFN}(\mathbf{x}) = W_2\, \text{GELU}(W_1\mathbf{x} + \mathbf{b}_1) + \mathbf{b}_2 \tag{39.4}$$

GELU is a smooth relative of ReLU, $\text{GELU}(a) = a\,\Phi(a)$ with Φ the standard normal distribution function, used in GPT models [6].

39.3.5 The block and residual connections

A block applies the two sub-layers, each with a residual connection:

$$X \leftarrow X + \text{MHA}(\text{LN}_1(X)), \qquad X \leftarrow X + \text{FFN}(\text{LN}_2(X)) \tag{39.5}$$

The "$X+$" is the residual connection of He and colleagues [7]. Each sub-layer only has to learn a *correction* to its input, and the gradient has a direct path through the additions from the loss back

to the embeddings, which is what lets deep stacks of blocks train at all. After the last block, a final layer norm and a linear layer produce the scores $\mathbf{o}_t = W_{\text{out}}\,\text{LN}(\mathbf{x}_t) + \mathbf{b}_{\text{out}}$ for each position.

39.3.6 Training objective and sampling

As in Chapter 36, the model is trained to minimize the average negative log-probability of the actual next character at every position of the window:

$$L = -\frac{1}{T}\sum_{t=1}^{T} \log \text{softmax}(\mathbf{o}_t)_{c_{t+1}} \tag{39.6}$$

Every window gives T training examples at once, one per position, and the causal mask guarantees that the prediction at position t never saw c_{t+1}. To generate, we use temperature (Chapter 36) and *top-k sampling*: keep only the k largest scores, set the rest to $-\infty$, and sample from the renormalized softmax,

$$p_j = \begin{cases} \frac{e^{o_j/\tau}}{\sum_{m \in \text{top}_k} e^{o_m/\tau}} & \text{if } j \in \text{top}_k \\ 0 & \text{otherwise} \end{cases} \tag{39.7}$$

which removes the long tail of unlikely characters that high temperatures would otherwise let through [8].

39.3.7 Counting the parameters

Every weight can be counted from the equations. Embeddings: $Vd + Td = 28 \cdot 64 + 48 \cdot 64 = 1792 + 3072 = 4864$. One block: two layer norms, $2 \cdot 2d = 256$; attention, $d \cdot 3d + 3d = 12{,}480$ for W_Q, W_K, W_V with biases and $d^2 + d = 4160$ for W_O; feed-forward, $d \cdot 4d + 4d = 16{,}640$ and $4d \cdot d + d = 16{,}448$. That is 49,984 per block, 99,968 for two. The final layer norm adds 128 and the output layer $dV + V = 1820$. In total

$$N = 4864 + 2 \cdot 49{,}984 + 128 + 1820 = 106{,}780 \tag{39.8}$$

exactly the number the program prints. GPT-2's smallest version has about 124 million parameters with the same kind of blocks [3], about a thousand times more.

39.4 Building It Step by Step

The code is in `Chapter039` and needs only PyTorch 2.14. The training text `cerita.txt` ships with it.

39.4.1 The model

Listing 39.1 is the whole model, the data helper and an evaluation function.

Listing 39.1 `tiny_gpt.py`: causal self-attention, the Transformer block, the model with generation, the character data, and loss estimation.

```

- `CausalSelfAttention` computes the queries, keys and values of all heads with one linear layer `qkv` and splits the result three ways. The `view` and `transpose` reshape (B, T, d) into (B, h, T, d_k), so that one matrix multiplication computes the scores of all heads, Equation (39.2). The mask is a lower-triangular matrix stored with `register_buffer`, which makes it part of the module (it moves with the model and is saved with it) without being a trainable parameter. `masked_fill` writes $-\infty$ above the diagonal. The weights are kept in `last_attention` so we can draw them. Finally the heads are put back side by side and mixed by `proj`, the W_O.
- `Block` is Equation (39.5), with Equation (39.3) as `nn.LayerNorm` and Equation (39.4) as the `mlp`. Dropout randomly zeroes some of each sub-layer's output during training, as in Chapter 33.
- `TinyGPT` adds the token and position embeddings, Equation (39.1), runs the blocks, applies the last layer norm and the output layer, and, if targets are given, computes Equation (39.6). `generate` implements Equation (39.7): it feeds at most the last `block` characters, divides the last scores by the temperature, masks everything below the k-th largest score, samples, and appends.
- `CharData` turns the text into indexes, keeps the first 90% for training and the last 10% for validation, and cuts random windows. The target window `y` is the input window `x` shifted by one character, so each position's target is the next character.
- `estimate` averages the loss over 20 fixed batches from each part, so that successive measurements are comparable.

39.4.2 Training

Listing 39.2 trains for 1,200 steps with AdamW, Adam with decoupled weight decay [9], checks the validation loss every 100 steps, saves the model whenever it improves, and finally generates 160 characters after the prompt “bu wulan”.

Listing 39.2 `train_gpt.py`: training with a checkpoint at the best validation loss, then a sample.

```
"""Train the tiny Transformer on cerita.txt and let it write (Chapter 39)."""
import textwrap
import time
import torch

                     args.temperature, args.top_k,
                     torch.Generator().manual_seed(args.seed))
text = data.decode(out[0].tolist())
print("\n".join(textwrap.fill(line, 78) for line in text.split("\n")))
```

39.4.4 Tests

Listing 39.4 checks the shapes, the causal property directly (changing characters 8 to 11 must not change the model's outputs at positions 0 to 7, but must change them at 8 to 11), and that the stored attention weights are zero above the diagonal and sum to 1 in each row.

Listing 39.4 `test_tiny_gpt.py`: unit tests, including a direct check that the future cannot influence the past.

```
"""Unit tests for the tiny Transformer (run: python -m unittest)."""
import unittest
import torch
from tiny_gpt import TinyGPT

class TinyGPTTest(unittest.TestCase):
    def setUp(self):
        torch.manual_seed(0)
        self.model = TinyGPT(vocab=20, d=32, heads=4, layers=2, block=16).eval()

    def test_shapes(self):
        logits, loss = self.model(torch.zeros(3, 10, dtype=torch.long),
                                  torch.zeros(3, 10, dtype=torch.long))
        self.assertEqual(tuple(logits.shape), (3, 10, 20))
        self.assertEqual(loss.dim(), 0)

    def test_future_cannot_change_the_past(self):
        a = torch.randint(0, 20, (1, 12))
        b = a.clone()
        b[0, 8:] = (b[0, 8:] + 5) % 20                  # change positions 8..11
        la, _ = self.model(a)
        lb, _ = self.model(b)
        self.assertTrue(torch.allclose(la[0, :8], lb[0, :8], atol=1e-6))
        self.assertFalse(torch.allclose(la[0, 8:], lb[0, 8:]))

    def test_attention_rows_are_causal(self):
        self.model(torch.randint(0, 20, (1, 6)))
        A = self.model.blocks[0].attn.last_attention[0, 0]
        self.assertTrue(torch.all(A.triu(diagonal=1) == 0))
        self.assertTrue(torch.allclose(A.sum(-1), torch.ones(6)))

if __name__ == "__main__":
    unittest.main()
```

39.5 Running It

```
python train_gpt.py
```

```
characters: 8130 training, 904 validation, vocabulary 28
parameters: 106780
step  100  train 2.078  val 2.151  (saved)

step  900  train 0.950  val 1.640
step 1000  train 0.863  val 1.650
step 1100  train 0.802  val 1.711
step 1200  train 0.722  val 1.736
training time: 39 s
sample:
bu wulan mengan pertaya sarun mengolol telok datangkop cucian dengan membaik
dengan menurikan tangga tempat kecil.
ia mil menjawaknya menjawa.
kecibaya itu putu dan besa
```

The model has exactly the 106,780 parameters of Equation (39.8). Its loss starts near $\log 28 = 3.33$ and falls quickly; the validation loss reaches its minimum, 1.610 nats per character, at step 700, and rises afterward while the training loss keeps falling, the familiar sign of overfitting on a

small text, visible in **Figure 39.2**. The checkpoint at step 700 is kept. A validation loss of 1.61 is a perplexity of $e^{1.61} = 5.0$: at each step the model is about as uncertain as a choice among five characters, instead of 28.

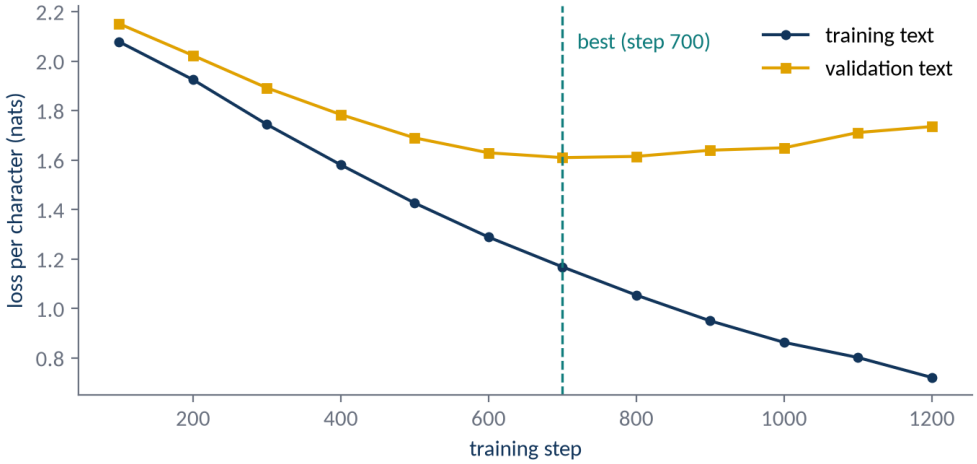

Figure 39.2 Training and validation loss every 100 steps during the run of **Listing 39.2**; the checkpoint with the lowest validation loss (step 700) is kept.

The sample is not Indonesian, but it is clearly Indonesian-*shaped*. Real words appear: *bu wulan*, *cucian*, *dengan*, *tempat kecil*, *pelanggan*, *sore hari*, *selimut*, *di bawah*. Sentences begin with characters from the story, *sari*, *bu wulan*, *pelanggan itu*, and end with full stops followed by a new line. Invented words such as *menurikan* and *menceringkap* follow Indonesian patterns: the prefix *me-* with a nasal, the suffix *-kan*. All of that was learned from 8,130 characters in 30 seconds.

Now the application:

```
python gpt_app.py "sari bertanya, "
```

```
sari bertanya, sari bertawa halu.
bu wulan menjang dengan cucian ail dengan mengak pelanggan.
sore hari sadi mangil cucian menceringkap
```

At a low temperature the model sticks to its most familiar paths:

```
python gpt_app.py "pelanggan itu " --temperature 0.5
```

```
pelanggan itu di berwarna selimut pelanggan kelop telop delong dengan dan
semua kemua di bawah anang dengan ini selum di dengan sepela
```

At a high temperature with no top-k limit ($k = 26$ keeps nearly everything), it wanders:

```
python gpt_app.py "pelanggan itu " --temperature 1.3 --top-k 26
```

```
pelanggan itu dian berya.
sari itu mulihiangkannya cucian di berkaya-huar.
bu wuke di bolak. wula. berjagi mini ydan cucian delang
kep
```

What are the heads doing? **Figure 39.3** draws the attention of all eight heads, two layers of four, for the phrase *bu wulan mencuci kemeja* (Bu Wulan washes a shirt), with spaces shown as underscores. The matrices are lower triangular, as the mask demands. Head 4 of layer 1 is the clearest: almost every position attends to the character just before it, with an average top weight of 0.81, a *previous-character head*. With that information in hand, the next layer can look for patterns spanning two characters. Heads in layer 2 look further back, several of them to the space or first letter of the current or previous word. Such previous-token heads are a well-known

building block that also appears in large models, where researchers have found them working together with later heads to copy patterns seen earlier in the text [10].

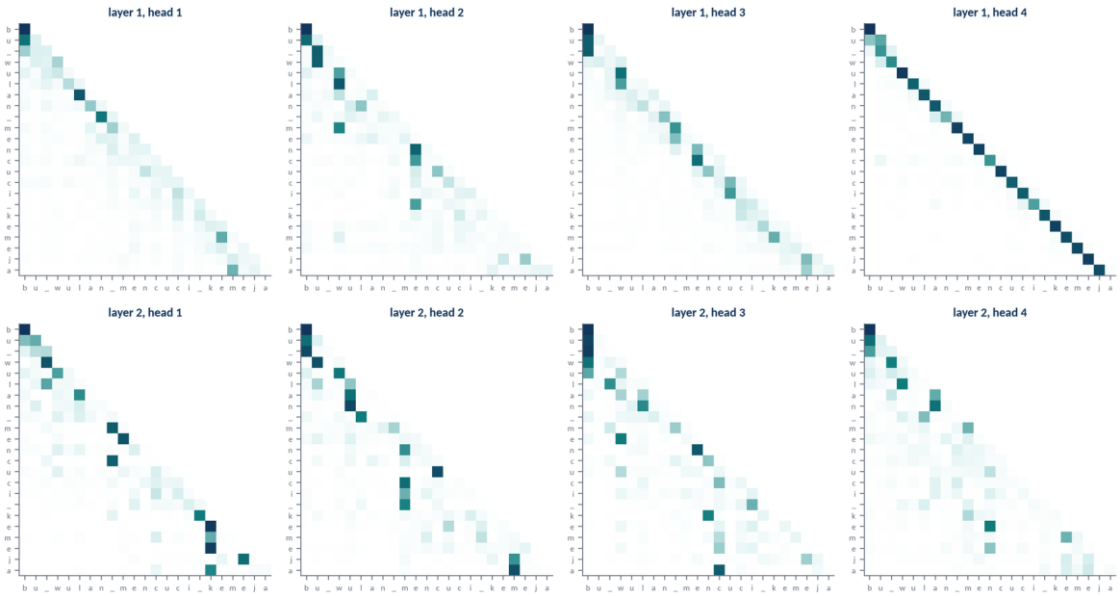

Figure 39.3 The attention weights of the eight heads for the input *bu wulan mencuci kemeja* (spaces shown as underscores). Rows are the positions that look, columns the positions looked at; head 4 of layer 1 looks at the previous character.

The tests:

```
python -m unittest
```

```
...
----------------------------------------------------------------------
Ran 3 tests in 0.167s

OK
```

39.6 Improving It

What does each ingredient contribute? **Listing 39.5** compares a bigram count model with Transformers of one and two layers and contexts of 8 and 48 characters, each trained for 1,200 steps and judged by its best validation loss.

Listing 39.5 `improve.py`: a bigram baseline and three Transformer variants on the same text.

```
"""How much do context and depth help? Bigram vs three Transformers (Ch. 39)."""
import math
import torch
from tiny_gpt import CharData, TinyGPT, estimate

torch.set_num_threads(1)
data = CharData(open("cerita.txt", encoding="utf-8").read())
V = len(data.chars)

counts = torch.ones(V, V)                           # add-one smoothing
for a, b in zip(data.train[:-1].tolist(), data.train[1:].tolist()):
    counts[a, b] += 1
logp = torch.log(counts / counts.sum(1, keepdim=True))
val = data.val.tolist()
bigram = -sum(logp[a, b].item() for a, b in zip(val, val[1:])) / (len(val) - 1)
rows = [("bigram counts", "-", bigram)]

for layers, block in [(1, 8), (2, 8), (2, 48)]:
    torch.manual_seed(0)
    model = TinyGPT(V, layers=layers, block=block)
    opt = torch.optim.AdamW(model.parameters(), lr=2e-3, weight_decay=0.1)
    gen = torch.Generator().manual_seed(0)
    best = float("inf")
    for step in range(1, 1201):
        x, y = data.batch("train", 32, block, gen)
        _, loss = model(x, y)
        opt.zero_grad()
        loss.backward()
        opt.step()
        if step % 100 == 0:
            best = min(best, estimate(model, data, block)["val"])
    rows.append((f"Transformer, {layers} layer(s)", block, best))

print(f"{'model':26s} {'context':>7s} {'val loss':>9s} {'perplexity':>11s}")
for name, block, loss in rows:
    print(f"{name:26s} {block:>7} {loss:9.3f} {math.exp(loss):11.2f}")
```

```
python improve.py
```

```
model                      context  val loss  perplexity
bigram counts                    -     2.172        8.78
Transformer, 1 layer(s)          8     1.713        5.55
Transformer, 2 layer(s)          8     1.657        5.25
Transformer, 2 layer(s)         48     1.610        5.00
```

The bigram table, which sees one character back, reaches a perplexity of 8.8. A one-layer Transformer that sees 8 characters back cuts that to 5.6, a second layer to 5.3, and a 48-character context to 5.0. Every ingredient helps, and the largest single step is from counting pairs to attention over a short context: most of what can be learned from 8,000 characters lies within a few letters. The gains from depth and context are real but small here, because the text is too short to contain many long-range patterns worth learning.

The honest verdict is the one Chapters 36 and 37 also reached: with this little data, the model is limited by the data, not by the architecture. The path to fluent text is the path the large models took:

- **Much more text.** Real models read hundreds of billions of tokens. Even a few megabytes of Indonesian would improve this model dramatically.
- **Subword tokens.** Instead of characters, modern models use tokens of a few characters each, learned by *byte-pair encoding*, so that a context of 48 tokens covers a paragraph rather than a sentence.

- **More and wider blocks, trained longer, on a GPU.** The architecture scales without change: GPT-2 small is this model with 12 blocks, 12 heads and $d = 768$ [3].
- **Instruction tuning and feedback.** Turning a next-token predictor into an assistant that answers questions takes further training on dialogues, which Part 9 discusses when it uses such models.

39.7 Common Mistakes, and How to Avoid Them

Forgetting or breaking the causal mask. Without the mask, the model can simply read the next character from the input. Exercise 39.4 shows the result: a training loss near zero and generated text that is gibberish. Always test the causal property, as **Listing 39.4** does.

Exceeding the context length. The position table has only T rows. Generation must crop the input to the last T characters, as `generate` does with `idx[:, -self.block:]`; otherwise it crashes.

Reshaping heads wrongly. Splitting d into heads with `view(B, T, h, d_k)` and then `transpose(1, 2)` is correct; `view(B, h, T, d_k)` directly produces the right shape with scrambled contents and no error. The causal test catches many such mistakes.

Judging by training loss. Our training loss reaches 0.72 while the validation loss rises: the model is memorizing the story. Keep the checkpoint with the best validation loss.

Expecting knowledge from a small model. A model trained on 9,000 characters knows only those 9,000 characters. The fluency of large models comes from their data as much as from their architecture.

Believing generated text. Even large models generate fluent sentences that are false. Our model makes that obvious; with large ones it is easy to forget. Part 9 returns to checking model output.

39.8 Chapter Summary

- Each position starts as a token plus a position embedding (Equation (39.1)); blocks of multi-head causal self-attention (Equation (39.2)) and a feed-forward network (Equation (39.4)), each preceded by layer normalization (Equation (39.3)) and wrapped in a residual connection (Equation (39.5)), transform it; a linear layer gives next-character scores.
- Training minimizes next-character cross-entropy at every position (Equation (39.6)); the causal mask makes that honest. Generation samples with temperature and top-k (Equation (39.7)).
- Our model has 106,780 parameters (Equation (39.8)), trains in about 30 seconds, and reaches a validation perplexity of 5.0 on a 9,000-character story, against 8.8 for bigram counts.
- Its heads specialize: one looks at the previous character, others back to word boundaries.
- Small data, not the architecture, limits the result; the same architecture, scaled up and fed far more text, is a modern language model.

39.9 Exercises

1. Verify the per-block parameter count 49,984 of Section 39.3.7 term by term, and compute the total for a model with $d = 128$, 4 heads and 4 blocks, keeping $V = 28$ and $T = 48$.
2. Apply Equation (39.3) to $\mathbf{x} = (2,2,2,10)$ with $\boldsymbol{\gamma} = \mathbf{1}$ and $\boldsymbol{\beta} = \mathbf{0}$. What happens to a vector whose entries are all equal?

3. For scores (3,2,1,0) at temperature 1, compute the sampling probabilities with $k = 2$ and with $k = 4$ using Equation (39.7).
4. Train the model for 300 steps with the causal mask switched off (fill the mask with `True`) and compare its training and validation loss and a generated sample with a normally masked model. Explain.
5. Why does the model need position embeddings? What would a Transformer without them compute for the inputs "abc" and "cba" at the last position?
6. The residual connection Equation (39.5) adds each sub-layer's output to its input. Explain in two sentences why this helps the gradient reach the embeddings in a deep stack.

39.10 Solutions to the Exercises

Solution 1. Two layer norms: $2 \times (64 + 64) = 256$. W_Q, W_K, W_V in one linear layer: $64 \times 192 + 192 = 12{,}480$. W_O: $64 \times 64 + 64 = 4160$. Feed-forward: $64 \times 256 + 256 = 16{,}640$ and $256 \times 64 + 64 = 16{,}448$. Sum: $256 + 12{,}480 + 4160 + 16{,}640 + 16{,}448 = 49{,}984$. For $d = 128$: a block has $2 \cdot 256 + (128 \cdot 384 + 384) + (128^2 + 128) + (128 \cdot 512 + 512) + (512 \cdot 128 + 128) = 512 + 49{,}536 + 16{,}512 + 66{,}048 + 65{,}664 = 198{,}272$; four blocks 793,088; embeddings $28 \cdot 128 + 48 \cdot 128 = 9728$; final layer norm 256; output $128 \cdot 28 + 28 = 3612$; total 806,684. Doubling d roughly quadruples a block, because most weights sit in $d \times d$ matrices. The number of heads does not change the count.

Solution 2. $\mu = 16/4 = 4$, $\sigma^2 = (4 + 4 + 4 + 36)/4 = 12$, $\sigma = 3.464$, so $\mathrm{LN}(\mathbf{x}) = (-2, -2, -2, 6)/3.464 = (-0.58, -0.58, -0.58, 1.73)$. If all entries are equal, every $x_i - \mu$ is 0 and the result is $\boldsymbol{\beta}$: the normalized part carries no information, and the small ϵ prevents a division by zero.

Solution 3. The exponentials are $e^3 = 20.09$, $e^2 = 7.39$, $e^1 = 2.72$, $e^0 = 1$. With $k = 2$ only the first two remain: $20.09/27.48 = 0.731$ and $7.39/27.48 = 0.269$, and the others have probability 0. With $k = 4$ nothing is removed: the sum is 31.20 and the probabilities are 0.644, 0.237, 0.087, 0.032. Top-k takes the 12% of probability that sat on the two unlikely choices and gives it to the likely ones.

Solution 4. **Listing 39.6** trains both versions from the same start.

Listing 39.6 `sol_no_mask.py`: training with and without the causal mask.

```
"""Exercise 39.4: what happens without the causal mask (Chapter 39)."""
import torch
from tiny_gpt import CharData, TinyGPT, estimate

torch.set_num_threads(1)
data = CharData(open("cerita.txt", encoding="utf-8").read())
for masked in (True, False):
    torch.manual_seed(0)
    model = TinyGPT(len(data.chars))
    if not masked:
        for blk in model.blocks:
            blk.attn.mask.fill_(True)            # every position sees everything
    opt = torch.optim.AdamW(model.parameters(), lr=2e-3, weight_decay=0.1)
    gen = torch.Generator().manual_seed(0)
    for step in range(300):
        x, y = data.batch("train", 32, 48, gen)
        loss = model(x, y)[1]
        opt.zero_grad()
        loss.backward()
        opt.step()
    est = estimate(model, data, 48)
    out = model.generate(torch.tensor([data.encode("bu wulan ")]), 50,
                         0.8, 10, torch.Generator().manual_seed(1))
    print(f"mask {'on ' if masked else 'off'}: train {est['train']:.3f}  "
          f"val {est['val']:.3f}")
    print(f"   sample: {data.decode(out[0].tolist())!r}")
```

```
mask on : train 1.744  val 1.892
   sample: 'bu wulan menanya, dasan sorut lunya lesembukan cucuci pernd'
mask off: train 0.051  val 0.052
   sample: 'bu wulan wuuw   wulu ulu wu wu w uuu  du wuuu u uulu du uu '
```

Without the mask, both losses fall to about 0.05 within 300 steps, far below anything the honest model reaches. The model has learned to *copy*: the target at position t is the input at position $t+1$, which it can now see. The validation loss is equally low because copying works on any text. But generation feeds the model only the text written so far, where there is no future to copy, and the model has learned nothing useful for that situation: it produces *wuuw wulu ulu wu*, fragments of the prompt. A leaking mask produces a model that looks brilliant in training and fails completely in use, which is why the causal test belongs in every Transformer project.

Solution 5. Attention combines values with weights that depend only on query-key scores, and without position embeddings the keys and values of a character are the same wherever it stands. The last position of "abc" (the character *c*) and the last position of "cba" (the character *a*) have different queries, but for a fixed query character, any rearrangement of the earlier characters gives the same set of keys and values and therefore the same output: the model would see "abc" and "bac" as identical at the last position. Language depends on order ("ibu" is not "ubi"), so position must be added, here by a learned table, in other models by fixed sine waves or by rotating the query and key vectors.

Solution 6. With $X \leftarrow X + F(X)$, the derivative of the output with respect to the input is the identity plus the derivative of F, so even if F's gradients are small, the identity part passes the gradient from the loss back to the embeddings unchanged through every block. Without the "$X+$", the gradient would be multiplied by one sub-layer's derivative after another, and could vanish in a deep stack, as in the RNN of Chapter 36.

Chapter 40

Privacy-Preserving Synthetic Data with a GAN

Profitina Laundry would like a student team to build a better demand forecast, and a vendor to test a new cashier app, and neither needs to know that Bu Nabila, 47, brings two bed covers to the Rungkut outlet every other Saturday. What they need is data that *behaves* like the real bills: the same mix of services, the same prices per kilo, the same busy hours. This chapter builds a generator of such data, a **generative adversarial network** (GAN) for tables, and then asks the question that decides whether it may be shared: how much does the synthetic table still reveal about the real customers? By the end of it you will be able to turn a table of mixed numbers and categories into vectors a network can generate; train a GAN in which a generator and a critic compete, with the Wasserstein loss and a gradient penalty; measure the *utility* of a synthetic table by its column distributions, its correlations and a model trained on it; measure its *privacy risk* by copies, distances to the closest record and a membership-inference attack; and relate the result to Indonesia's Personal Data Protection Law.

40.1 Who Uses Synthetic Data Today

Banks, hospitals and statistics offices, above all. The United Kingdom's Financial Conduct Authority convened an expert group of banks, insurers, vendors and consumer representatives, whose first report of 2024 described synthetic data as "one of many privacy enhancing technologies that can expand and support data sharing", used to test systems, to reduce bias and to share fraud patterns between institutions [1]. Its second report, of August 2025, is about governance: how to generate and validate synthetic data for models, and how to keep it from leaking the real records it was made from [2]. That second point is the heart of this chapter, and it is not a formality: in 2025, researchers showed that synthetic data sets which passed the popular distance-based privacy tests were still highly vulnerable to membership-inference attacks [3].

For an Indonesian business the question is concrete. The Personal Data Protection Law (UU No. 27 Tahun 2022) has been fully enforceable since 17 October 2024, with administrative fines of up to 2% of annual revenue and criminal penalties of up to four years' imprisonment or Rp4 billion for unlawful disclosure of personal data [4], [5]. A laundry's bills, linked to customers' ages, genders and habits, are personal data. Handing them to a student team or a software vendor "as is" is disclosure. A good synthetic copy can be shared much more freely, but only if we can show it is not the real data in disguise.

Chapter 34 turned an autoencoder into a generator of new images. Here a GAN generates new *rows*, and the measuring matters as much as the generating.

40.2 The Idea in Plain Words

Imagine two people. A forger writes fake laundry bills; an inspector is shown a pile of real bills and a pile of forged ones and gives each bill a "realness" score. At first the forger writes nonsense (a 300-kilo shoe cleaning paid by QRIS at 3 a.m.), and the inspector easily scores it low. The forger

learns from the inspector's scores which features give him away and improves; the inspector, facing better forgeries, looks at subtler features. After thousands of rounds, the forged bills have the same mix of services, the same price per kilo and the same busy hours as the real ones. **Figure 40.1** shows the two networks that play these roles, the **generator** and the **critic**.

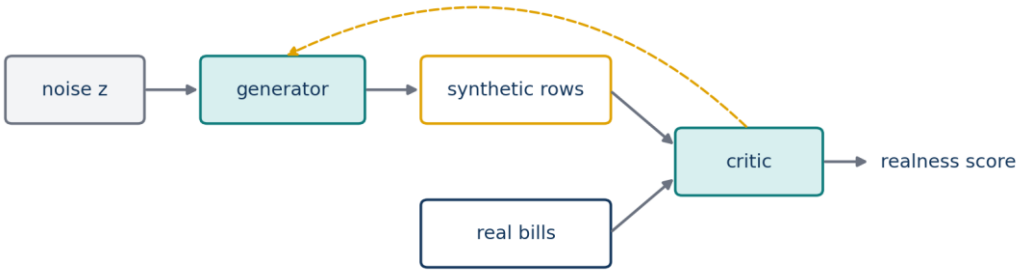

Figure 40.1 A GAN for tables. The generator turns random noise into synthetic rows; the critic scores real and synthetic rows; the generator is trained through the critic's score (dashed) to make its rows score like real ones.

Two things make tables harder than pictures. Columns have different types: *age* and *amount* are numbers, *service* and *payment method* are categories. And the relations between columns are the whole point: the amount of a wash-and-fold bill is Rp8,000 times the kilos. A generator that gets every column's distribution right but pairs 1 kilo with Rp120,000 is useless for forecasting.

And then the privacy question. The forger never sees a real bill directly; he learns only from the inspector's scores. But if he trains long enough on few bills, he may learn to reproduce individual real bills almost exactly, because those are, after all, the most "real" bills there are. So we will compare the GAN with two extremes, the real rows with a little noise and a table whose columns are drawn independently, and measure both how useful and how revealing each is.

40.3 The Mathematics, Gently

40.3.1 The contest

Write a real row as $\mathbf{x}$, drawn from the unknown distribution p_{data} of real bills, and a noise vector as $\mathbf{z}$, drawn from a standard normal distribution p_z. The generator G maps $\mathbf{z}$ to a synthetic row $G(\mathbf{z})$. In the original GAN of Goodfellow et al. [6], the second network D outputs a probability that its input is real, and the two play the game

$$\min_G \max_D \; \mathbb{E}_{\mathbf{x}\sim p_{\text{data}}}[\log D(\mathbf{x})] + \mathbb{E}_{\mathbf{z}\sim p_z}[\log(1 - D(G(\mathbf{z})))] \tag{40.1}$$

$\mathbb{E}$ means "the average over"; D wants the expression large (real rows scored near 1, fakes near 0), G wants it small. When D is the best possible judge, the game measures how far apart the two distributions are, and it is won by G exactly when G's rows have the same distribution as the real ones.

40.3.2 The Wasserstein critic and the gradient penalty

In practice the game of Equation (40.1) is unstable: when D becomes too good, its gradients vanish and G stops learning. The **Wasserstein GAN** replaces the probability by an unbounded

score, the *critic* D, and trains it to make the average score of real rows exceed that of synthetic rows [7]:

$$L_D = \mathbb{E}_{\mathbf{z}}[D(G(\mathbf{z}))] - \mathbb{E}_{\mathbf{x}}[D(\mathbf{x})] + \lambda\, \mathbb{E}_{\hat{\mathbf{x}}}[(\| \nabla_{\hat{\mathbf{x}}} D(\hat{\mathbf{x}}) \| - 1)^2], \qquad L_G = -\mathbb{E}_{\mathbf{z}}[D(G(\mathbf{z}))] \tag{40.2}$$

The last term of L_D is the **gradient penalty** of Gulrajani et al. [8]. The points $\hat{\mathbf{x}}$ lie at random places on straight lines between a real and a synthetic row, and the penalty pushes the length of the critic's gradient there towards 1. This keeps the critic *smooth*: its score cannot jump, so it cannot become a perfect but useless judge. With such a critic, the gap between the average real and average synthetic score estimates the **Wasserstein distance** (also called earth mover's distance): the least total "work" of moving the synthetic distribution's probability onto the real one's. It falls as the generator improves, which makes it a useful training curve. We use $\lambda = 10$ and train the critic five times for every generator step, as [8] recommends.

40.3.3 Turning a bill into numbers, and back

The networks work with vectors. Each numeric column is standardized; the skewed ones (units, amount, turnaround time) are first replaced by $\ln(1 + x)$, so that one 20-kilo bill does not dominate:

$$\tilde{x} = \frac{\ln(1 + x) - \mu}{\sigma} \tag{40.3}$$
